The following candid announcement appears in *The Texas Health Journal*. "*To the Medical Profession of Texas.*—I have devoted many years to the exclusive treatment of diseases of the eye, ear, nose, and throat. That I might feel doubly assured of my ability to treat these diseases with the best possible skill known to the profession, I spent the last winter, spring, and summer in New York and Europe, where I received the special clinical instructions under the most distinguished specialists in the world. My many months of clinical work at the greatest hospitals and clinics in the world, together with the new instruments and apparatus I purchased in Europe, regardless of price, cost me nearly two thousand dollars. I now respectfully ask that the general practitioners of Texas who have not the time and instruments to successfully treat such cases, kindly consider my recent advantages and complete armamentarium, and intrust to me the responsibility of treating such cases. If this courtesy is extended to me, I will be true to the trust confided. Besides, I will make it especially advantageous to every physician who kindly refers cases to me for treatment; try and see if I do not; a hint to the wise is sufficient. Furthermore, I will take pleasure in treating any member of a physician's family, absolutely free. I will also treat any charity case free referred to me by a physician. My present large paying practice

enables me to do this without loss to myself; besides, the pleasure of curing those unable to pay is sufficient renumeration to me. I have opened an elegant new office in the North Texas Bank building; rooms 316, 317, and 318. Call and see me while in the city.

"Fraternally submitted."

A letter of this kind is in our opinion a legitimate result of the approval given by the American Medical Association to the plan of sending out cards with the words "practice limited to" eye diseases, gynecology, etc. Instead of distributing cards to the profession, the specialist puts it in a medical journal, and naturally adds to it a modest account of his unusual experience and skill. The next step would be for the general practitioner to put in an announcement of his special skill in the common run of diseases, and request the specialists and incidentally the public to send him their patients. Very soon, as the examples of these announcements increase, their language must become stronger. For example, there are in Texas a good many physicians who have had a larger experience in eye diseases even than the writer of the above quoted letter. If his conduct is approved, what will be left to them but to imitate him, or rather surpass him, in an attractive presentation of their accomplishments. The results must be disastrous to professional dignity, personal veracity, and mutual confidence.

Medical men cannot afford to enter the field of the advertising agent. The old way is often criticised, and it is not perfect. The man must become known through his works. The profession is not so dull but that it can recognize merit, and it estimates a man's abilities fairly well by his writings and by contact with him in scientific and social meetings. The recognition thus gained comes slowly, but special skill also is acquired slowly, and matters adjust themselves with a good degree of equity in the end.

We hope that the profession of Texas will not endorse the methods adopted by the enterprising young oculist of their State.

News of the Week.

County Medical Society Election.—The Medical Society of the County of New York held their eighty-ninth annual election October 22d. Dr. Egbert H. Grandin was elected *President*; Dr. Richard Van Santvoord, Dr. Wendell C. Phillips, and Dr. S. Henry Dessau were elected *Vice-Presidents*; Dr. Charles H. Avery, *Secretary*; Dr. William E. Bullard, *Assistant Secretary*; and Dr. John S. Warren, *Treasurer*. The *Censors* elected were: Drs. Seneca D. Powell, Edward D. Fisher, George T. Jackson, Charles H. Knight, and Charles L. Gibson.

Conference of Hospitals for Insane in New York.—The Eighth Joint Meeting of the Managers and Medical Superintendents of the Hospitals of the State of New York was held, under the auspices of Honorable Austin Lathrop, at the Matteawan State Hospital, at Fishkill Landing, Thursday, October 18, 1894. Delegates from the different asylums were present. After an inspection of this model institution and congratulatory remarks by the gentlemen present, Dr. H. E. Allison, the medical superintendent, read a paper on the "Care and Treatment of the Criminal Insane." Remarks were made by Judge Graham, of Utica; Professor Stephen Smith, of New York; Dr. Carlos F. Macdonald, President of Lunacy Commission; Dr. S. H. Talcott, of Middletown, N. Y.; Senator Amasa J. Parker, of Albany; C. W. Pilgrim, of Poughkeepsie; C. G. Wagner, of Binghamton; G. Alder Blumer, of Utica; and Dr. George F. Shrady, of New York.

The Monument to Villemin.—On September 30th the monument erected to the memory of Villemin, the discoverer of the infectivity of tuberculosis, was unveiled at Bruyère-en-Vosges, in the presence of a distinguished assembly. Dr. Viger, the Minister of Agriculture, who is a member of the medical profession, represented the Government, and delivered an oration.

The Late Professor Billroth.—The letters of the late Professor Billroth, of Vienna, are about to be published, with the sanction of his widow, under the editorship of Dr. Georg Fischer, surgeon to the Hanover City Hospital. Dr. Fischer asks any English correspondents who may have preserved letters of Billroth's to send them to him at 22, Warmbuchenstrasse, Hanover. Any letters forwarded in response to this request will be copied and returned without delay.

Antidote for Fungi Poisoning.—Dr. Thomas Taylor, chief of the Division of Microscopy of the Department of Agriculture, speaking of recent deaths in this city from eating poisonous fungi, says: "The mushrooms eaten in this case were undoubtedly the *Amanita verna*, which, and *Amanita muscaria*, are the most poisonous mushrooms known. There is but one antidote known for amanitine or muscarine poison, and that is sulphate of atropine. The use of atropine, as has been fully demonstrated, will quickly neutralize the effects of muscarine and amanitine on the nerve-centres of the human system, as well as those of the lower animals. The dose may be administered either by means of hypodermic injection or by the mouth in the usual way."

Anti-toxin and Diphtheria.—The Deputies of the Lower House of Hungary proposed to vote 50,000 florins to be used in treating diphtheria with Behring's serum. At the Government's request the vote was postponed pending the reports of medical inspectors sent to France and Germany. In Buda-Pesth the use of the serum has given excellent results.

The anti-toxin treatment of diphtheria is the topic of the day in Berlin. The Children's Hospital (Kaiser u. Kaiserin Friedrich-Kinder-Krankenhaus is its short and euphonious name) has published in the daily papers an appeal for subscriptions—signed, among others, by Rudolph Virchow, Skrzecska, and Siegmund—in which it is stated that of 169 diphtheria patients treated in the hospital with antitoxin, all recovered, except those that came under treatment at an advanced stage of the disease; that, in fact, the percentage of deaths had been reduced from 42 to 17, and that the results of protective inoculation performed on the sisters and brothers of the diphtheria patients had also been most satisfactory. It must be said, however, that here and there voices are heard warning against too enthusiastic hopes. It is said that a much longer period of observation must elapse before a final judgment on the treatment can be given,

and that possibly the present cases of diphtheria are none of them of the severest type, and that it remains to be seen whether antitoxin will stand the test of one of the severe epidemics—the *foudroyant* cases, that carry off their victims in a few days.—*British Medical Journal.*

Cholera Decreasing in Europe.—The latest advices received by the Marine Hospital service show that cholera is on the decrease everywhere, amounting in the case of Austro Hungary to nearly fifty per cent. The decrease in Russia is remarkable, and it is hoped that the advent of cold weather will put an end to this epidemic entirely. There are still many cases reported in Holland, Belgium, and France, but they seem mostly of a sporadic nature, and nowhere assume an epidemic form. The health of Marseilles is now so satisfactory that the medical inspection of all vessels sailing thence has been discontinued.

A New German Hospital.—The corner-stone of the new German hospital, at Stanhope Street and St. Nicholas Avenue, Williamsburg, was laid October 22d, by Mayor Schieren, in the presence of nearly one hundred societies and several thousand people. A parade of all the societies preceded the laying of the stone. Twenty-seven lots, bounded by St. Nicholas Avenue and Stockholm and Stanhope Streets, were purchased, and a few months ago ground was broken. The cost of the hospital when completed will be about $250,000.

American Academy of Railway Surgeons.—The first meeting of the American Academy of Railway Surgeons will be held in the parlors of the Grand Pacific Hotel, Chicago, November 9 and 10, 1894.

Status and Pay of Japanese Army Surgeons.—The Surgeon-General of the Imperial Army has the rank of major-general and the same amount of salary, 300 yen per month, the yen being equivalent to about 75 cents of our money. Surgeon-inspectors, whose position is analogous to that of colonel and assistant surgeon-general in the United States Army, have the rank of colonel and a salary of 193 yen per month, or 3 yen more than a colonel of cavalry receives, and 15 more than a colonel of infantry. Surgeons of the first class rank as lieutenant-colonel, and their pay, 143 yen, bears the same relation to that of a regimental lieutenant-colonel that the pay of an inspector does to that of regimental commanders. Surgeons of the second class, with the rank of major, draw 93 yen monthly. Assistant surgeons of the first class, and pharmacists of the same grade, have 52 yen, or the pay of a captain. Assistants and pharmacists of the second class rank as first lieutenants and have the pay of that grade, 32 yen. Assistants and pharmacists of the third class have the rank and pay, 26 yen, of the second lieutenant. These medical, like other officers of the army, have increased pay when assigned to special duty; those on duty in the War Department, for instance, having an increase amounting to about one third of the regular salary of their grade.

Vermont State Medical Society.—The annual meeting was held in Montpelier, October 11th and 12th. The following officers were elected: *President*, Dr. J. H. Linsley, of Burlington; *Vice-President*, Dr. F. F. Chaffee, of Stratford; *Secretary*, Dr. D. C. Hawley, of Burlington; *Executive Committee:* Drs. J. H. Linsley, D. C. Hawley, and F. R. Stoddard, (of Shelburne). *Publication Committee:* Drs. D. C. Hawley, J. B. Wheeler, and H. C. Tinkham. *License Censors:* Drs. E. S. Albee, C. M. Ferrin, and H. S. Brown. The attendance was the largest in the history of the Society. Dr. Frederick C. Shattuck, of Boston, read a valuable paper on "The Modern Treatment of Typhoid Fever," and Dr. John C. Irish, of Lowell, Mass., presented one on the "Surgical Treatment of Uterine Neoplasms." The annual banquet was spread at the Pavilion Hotel at 10 P.M. Thursday, and was enjoyed by about a hundred and fifty, including the members of the Society, the Governor of the State, V. A. Woodbury, of Burlington, also the Speaker of the House of Representatives and other officers of the Legislature. The Anniversary Chairman was Dr. A. P. Grinnell, of Burlington. The next annual meeting will be held in Burlington.

New Ruling by the Illinois State Board of Health.—The Illinois State Board of Health will not recognize Dental, Pharmacy, or Veterinary Colleges as entitled to recognition for any part of a medical college course.

Some Recollections of Holmes.—Mr. Ernest Hart gives entertainingly some recollections of a visit which he paid to the late Dr. Holmes a year ago. "We fell," says Mr. Hart, "to talking of his visit to London in 1886, and of our meetings together and our mutual friends. He recalled a brilliant dinner party at the Reform Club on the night of his arrival, and spoke sympathetically of his host, Sir Morell Mackenzie, and some others of the party who were now no more, and of his daughter who had charge of him, whom also he had lost. Laughingly he reminded me of the 'lesson in English' he had received in the hall. During dinner the talk had turned on provincial and American slang. Speaking of one of his latest poems, of which he recited a passage, he had said in banter that he did not think it his worst, adding: 'I tried it on a dog, and the dog didn't die.' He confessed that the 'American language,' about which there was some discussion, was not always identical with the English, but 'it was none the worse for that.' At any rate, he prided himself on talking pure English. As we came away and were taking leave, he said to me, *apropos* of an engagement for the next day when he was coming to lunch with me: 'But you must give me your ticket.' In handing it to him I could not help saying: 'We English call it a card.' He answered: 'I don't know that it is a better word.' 'I did not quite relish then,' he said to me, 'being taught English by a cockney on the first day of my arrival, and I have not forgotten it; but you see I bear no malice.' Speaking of his student life in Paris Dr. Holmes said: 'It was in the days of Louis Philippe, in 1833–35, that I followed the classes of Louis, who was the loadstone of all the young American students, and there I first met Gairdner, of Glasgow, with whom I still sometimes correspond.' 'Bigelow,' he said, 'used to go over once a week to London to hear a lecture, but that was uniquely enterprising.' He claimed for Bigelow, afterward a medical professor in Boston, that he was one of the greatest of modern physicians, and that 'a single lecture which he had published on "Self limited Disease" made "a revolution in medicine." It anticipated Gull's doctrine of "Expectant Medicine," and laid bare the secret of the temporary success but the self-evident folly and

failure of homœopathy.' When a practioner boasted to him that he had 'cured a disease,' he would say: 'Young man, take care; are you sure that you cured? If so, perhaps to morrow you may kill, but then you will only say that the patient died.'"

Dr. Holmes on Walshe, Watson, and Paget.—Dr. Oliver Wendell Holmes thought Dr. Walshe, of University College, an early contemporary, "the most philosophic of the physicians of our day;" Watson, "the most eloquent;" but Paget, "the most persuasive. Persuasive, but not always convincing. He is truly the Gladstone of Medicine, and left often in my mind a doubt whether his reservations and distinctions might not to-morrow lead him to a variation from the conviction to which almost he persuaded you to-day. . . . But that is the infirmity, perhaps, of my dim perception rather than of his circumspect intellect."

A Cyclone Struck the Insane Asylum at Little Rock, Ark., on October 2d, demolishing three stories of a wing containing two hundred and sixty patients. Dr. Ingate, one of the medical staff, and formerly of Mobile, Ala., was killed. Two of the patients were killed also.

Castration for Masturbation.—Dr. Pilcher, Superintendent of the Institution for Imbeciles and Weak-minded Children, at Winfield, Kan., has been bitterly denounced by newspapers in Winfield and Topeka for castrating several boys—inmates—who were confirmed masturbators. His predecessor, Dr. Wile, had treated these boys five years without benefit, and Dr. Pilcher, taking a rational view of the subject, performed the operation for the same reason he would perform any other surgical operation—for its curative effect. There is a strong probability that he will be ndicted for mayhem, to the everlasting disgrace of the civilization of the nineteenth century.—*Texas Medical Journal.*

A Pathetic Appeal.—October is the month of cotton, calves, colds, and collections. We are not interested in any of these "forces" (four c's) except the latter, and we do earnestly hope and expect that our good friends will not forget our patience and long suffering (nor their patients and their long suffering) when they go out in quest of cash.—*The Texas Medical Journal.*

Anti-Handshaking Society.—We hear that a society for the suppression of hand-shaking has been established at Baku, in Russia.

The Golf "Cure" for Insomnia.—A writer in the *Scotsman*, commenting upon the Marquis of Salisbury's recent address to the members of the British Association at Oxford, expressed regret that his lordship should be a victim to the modern and very prevalent disorder of insomnia. He went on to appeal to the medical profession for some prompt and effective remedy for that distressing ill. "Would that the noble leader of the Conservative party would take a three months' course of golf" was the inward exclamation of one who had himself suffered from insomnia, and was at the time rejoicing in a succession of nights of profound and refreshing sleep. Golf is the game for the exhausted brainworker at any stage of his life. No junior is too young, no senior is too old to learn it; to learn it and to enjoy it. The proof of the pudding is in the eating. On the golf links of St. Andrews the man of seventy looks fifty, and the man of fifty has the appearance of thirty-five. Sleeplessness, so far as the writer was able to discover, in a three weeks' sojourn at St. Andrews, is absolutely unknown to the regular golf-player. One may almost say it is impossible. Living, as he does, in the open air, and taking several hours of daily exercise without unpleasant fatigue, and with a mind constantly, but not laboriously, interested, he eats well and so the brain is adequately nourished. The only trouble with the remedy is that a man must be a person of leisure in order to take it.

A Bureau of Autopsy.—In the year 1881 there was founded at Milan a unique and curious institution, which has been at work ever since. This was the Loria Bureau of Autopsy. It was founded, and placed under the direction of Professor A. Verga, for the use of the inhabitants of Milan. That is to say, either courts of law or the family of a deceased person can have a complete examination and report in cases where a death has occurred under suspicious or strange circumstances. All autopsies are recorded, and may be consulted for purposes of study. The Bureau is intended to serve two purposes—the advancement of knowledge, and to remove one objection to cremation raised on the grounds that crime may be less easy of detection when the deceased is effectually placed beyond the reach of examination.

The River Seine "Catch" of 1893.—The following figures are published as a result of the attempt to keep the River Seine clear of cadavera for the year of 1893. There were withdrawn from the river 5,652 dogs, 3,307 cats, 9,108 rats, 1,720 fowls and 3,942 other birds, 4,209 rabbits, 789 pigs, 7 calves, 4 hedgehogs, 33 horses, 15 sheep, 2 colts, and 13 monkeys.

Death of Dr. Virginius A. Turpin.—Dr. Virginius A. Turpin died at his residence in New York, October 11th, at the age of seventy-five years. He was a Virginian by birth. For many years he was regarded as a high authority on the subject of cholera, and during the epidemic of the disease in the year 1866, he was called by the Board of Health of St. Louis to assume the direction of the cholera hospitals of that city. A considerable portion of his life was passed in Chicago, where he enjoyed a high reputation and had an extensive practice. About two years ago he removed to New York, and since that time his health has been gradually failing.

An Appeal to the Pity and Better Natures of the Editors and Publishers of the British Medical Journal and the Lancet.—You know, gentlemen, that the paper upon which is printed the "foreign edition" of your otherwise splendid journals, is simply inexpressibly vile. It is at once thicker, and yet more mushy and rotten than tissue-paper, and is, therefore, properly fit for no purpose whatsoever—absolutely none—of civilized or unregenerate man. We can only explain its use on the ground of a contempt of us, the reason of which dates back to Revolutionary times, or perhaps to Simian ages. You certainly would not, and could not, treat residents of the British Islands thus. We beg of you to remember that however remote the relationship we are at least your Teutonic brethren, and that it is your duty to help on the cause of Anglo-Saxon civilization. Please do not forget that even an American can sometimes grumble, and even revolt, after prolonged indignity and injustice.—*Medical News.*

UNVEILING OF THE SIMS STATUE.

The ceremonies attending the unveiling of the statue of Dr. J. Marion Sims and its presentation to the city of New York were held in Bryant Park on Saturday last, October 20th, at 3 P.M.

A number of representative medical men, with female members of their families, occupied places upon the elevated platform, which was decorated with flags and which faced the statue, also draped in the American flag. The fine October weather enabled the large audience in the Park to comfortably compose itself upon benches provided for the purpose.

On the stand were: Dr. H. Marion Sims and Master Marion Sims Wyeth, the little grandson of the original of the statue. Others present were Dr. D. B. St. John Roosa, President of the Academy of Medicine; Dr. Abraham Jacobi, Dr. Lewis A. Sayre, Dr. E. L. Keyes, Dr. J. A. Wyeth, Civil Justice Stiner, Mr. and Mrs. Edwin Gould, Dr. A. R. Robinson, Dr. and Mrs. William M. Polk, Drs. Robert W. Taylor, O. D. Pomeroy, Y. R. Goffe, W. G. Wylie, Mrs. G. F. Shrady; Drs. O. D. Pomeroy, D. H. Goodwillie, Robert C. Myles, S. Waterman, A. G. Gerster; Dr. and Mrs. T. R. Price, and Dr. W. H. Pancoast, of Philadelphia; Mrs. P. F. Mundé and Miss Bertha Mundé, Medical Director E. S. Bogert, U. S. N., and Hon. A. B. Tappan, who, as a member of the Board of Park Commissioners, accepted the statue for the city. Among the spectators in the Park there were also delegations from the New York Academy of Medicine, the New York Pathological Society, the American Gynecological Association, the Medical Society of the County of New York, the New York Polyclinic, and the New York Post-Graduate Medical School and Hospital.

The Jefferson Medical College of Philadelphia, from which Dr. Sims was graduated in 1835, sent Dr. W. W. Keen and Dr. Theophilus Parvin to represent the Faculty.

Letters of sympathy with regrets of inability to be present at the ceremonies were received from Professor J. M. Da Costa and Dr. Richard J. Dunglison, of Philadelphia; Dr. George J. Englemann, of St. Louis; Professor A. P. Grinnell, of University of Vermont, Burlington, Vt.; Dr. J. C. Reeve, of Dayton, O.; Dr. B. Bernard Browne, of Baltimore; Dr. M. C. Baldridge, of Huntsville, Ala.; Dr. R. Stansbury Sutton, of Allegheny, Pa.; Dr. A. Webb, of Collierville, Tenn.; and Dr. Henry Dickson Burns, of New Orleans, La.

There were not only a goodly number of ladies occupying seats on the platform and in the general audience, but many were seated in carriages which lined the adjoining streets.

The committee in charge of the ceremonies consisted of Dr. George F. Shrady, Dr. William T. Lusk, Dr. William M. Polk, Dr. Thomas Addis Emmet, and Mr. William H. S. Wood.

General Addresses.—Dr. George F. Shrady made the opening address, in which he sketched the character of Dr. Sims as a surgeon and philanthropist (see p. 513).

Professor Paul F. Mundé, M.D., followed with an address on Dr. Sims as the gynecologist, the founder of the New American School (see p. 514).

Presentation of Statue to the City of New York.—On the conclusion of Professor Mundé's address Dr. Shrady, as chairman of the committee, made the following presentation:

"Commissioner Tappan: I have the great honor, on behalf of the many friends and admirers of Dr. J. Marion Sims, and in the name of the medical profession of this and other countries, to present this beautiful statue to the city of New York, with the assurance that it will compare favorably with others of its kind in our parks and squares, and in the hope that in this Park, which is hereafter to be devoted to the meritorious recognition of distinguished services in literature, art, and science, it may take its worthy place."

During these remarks the string was pulled by Master Marion Sims Wyeth, the five-year-old son of Dr. J. A. Wyeth, and the covering fell from the figure, amid the cheering applause of the multitude assembled.

The Acceptance for the City by Hon. A. B. Tappan.—Park Commissioner Tappan, on behalf of the city, made the following speech of acceptance:

"'Whether on scaffold high or in the battle's van,
The noblest place for man to die is where he dies for man!'

"These words of the poet apply, with slight change, to Dr. Marion Sims. His life exemplified the saying that the 'noblest life a man can live is where he lives for man.' A citizen of high repute, a benefactor of the human race, a man who reached the most exalted place in his profession, it is due to his memory that all who knew him professionally, and all who knew him by reputation, should stop by the wayside of the busy field of our daily life and shed a tear to the memory of his many virtues and his most distinguished services.

"Dr. Sims had, indeed, a most exalted career as a citizen and as a professor of the art of preservation of the human race and of the laws of life and health. No eulogy can do justice to his merits, and in erecting this heroic statue to his memory those who knew him, and by whom this work was created and is erected, are doing themselves high honor.

"The city of New York feels most proud of the citizenship of its distinguished men in every department of active life. The profession of which Dr. Sims was a most prominent member has a just pride in the deed of to-day in erecting this statue. I repeat that it is an honor, not merely to one who has filled and finished an exalted career and has gone to his reward, but to those who participate in the ceremonies of this occasion.

"Mr. Chairman, I might add much, very much, to these brief remarks, deputed as I am by the public authorities of our city to speak on this occasion; but that task has been better performed by others. The work and all that it is intended to perpetuate are now a part of the history of our metropolis, and is accepted with all the high honor accorded to contributors that so justly belongs to them. One word more and my agreeable duty is finished:

"'Count that day lost whose low, descending sun
Sees no good deed or worthy action done.'

"Gentlemen, this day has not been lost. The deed in which we are all participating will mark it in our calendar as a day well spent and always to be remembered. We thank you for your public spirit in offering a statue of high excellence in its workmanship, and claim it now as an additional ornament to the city at large, and especially to Bryant Park, the scene of these ceremonies.'

The statue is the work of Müller, of Munich. It is of bronze, in full length, and of heroic proportions. It stands upon a pedestal of brown granite. On one side is the inscription:

J. Marion Sims, M.D., LL.D.
Born in South Carolina, 1813.
Died in New York City, 1883.
Surgeon and Philanthropist.
Founder of the Woman's Hospital, State of New York.
His brilliant achievements carried the fame of
American Surgery
Throughout the civilized world.
In recognition of his services in the cause of
Science and Mankind
He received the highest honor in the city of his countrymen,
And decorations from the Governments of
France, Portugal, Spain, Belgium, and Italy.

On the opposite side the inscription recites that the statue was "Presented to the city of New York by his professional friends, loving patients, and many admirers throughout the world."

Clinical Department.

TWO COMMON FORMS OF ALOPECIA, WITH THEIR TREATMENT.

By ELLICE M. ALGER, M.D.,

NEW YORK.

CLINICAL ASSISTANT IN DERMATOLOGY NEW YORK POST GRADUATE SCHOOL.

The premature falling out of the hair is a trouble that causes a great deal of mental disquietude in young people and not infrequently leads to certain more serious ills. It is exceedingly common, and yet comparatively few cases are brought to the physician's notice, for it is generally understood that the family doctor knows little and cares less about such a trifling matter.

It should not be so, for a little study in this direction will be more profitable, both for him and his patients, than a profound research into "thyroid feeding" or leprosy.

In a certain number of cases of alopecia no sufficient cause for the hair-fall can be found, even on careful examination. These idiopathic cases begin, generally, in individuals between twenty and thirty, with a very gradual loss of hair from the vertex or sides of the forehead. At the same time a progressive decrease in the size and vigor of the hairs can be plainly seen, till after a certain length of time the vitality of the hair follicle is exhausted and complete baldness ensues. The time required for this process to be completed varies from two to ten years, and is usually much shorter in patients who lead sedentary lives.

In looking for predisposing causes it is often found that early baldness has been a family trait for one or more generations, and this influence in many cases seems to be transmitted along sexual lines; the daughters of a bald father do not on that account suffer as much as though the mother were prematurely bald. Another undoubted factor is the wearing of hot or tight-fitting headgear, since it is argued that a hat tight or heavy enough to compress blood-vessels must interfere with pilary growth and nutrition. The frequent soaking of the head which many people seem to think necessary, is undoubtedly injurious.

Just how nerve-strain should cause early loss of hair cannot be satisfactorily explained, but it is beyond question a factor in many cases.

Women are apparently much less subject to alopecia than men, probably because they wear different head-gear and are naturally provided with a more abundant layer of subcutaneous tissue. Also they pay much more attention to the condition of the scalp, and are more skilful in concealing their losses by artificial means.

The prognosis in these idiopathic cases is bad, the gravity increasing as the layer of subcutaneous fat becomes less, and as age increases. The rate of progress is best indicated by the size of the individual hairs and their clipped ends in men, and their length in women; these indicating whether they have matured and fallen naturally, or come out while immature. A constant fall of lanugo hairs would indicate an advanced and grave state of the trouble. The indications for treatment are first prophylactic. The general health has a direct bearing on the case; the scalp should be frequently brushed with a moderately stiff brush and any deficiency in the oily secretions should be artificially supplied. If the trouble seems caused by a lack of the hair-forming elements in the body, a generous diet must be insisted on and supplemented by tonics, iron, hypophosphites, etc. Locally, stimulants are called for and remedies which shall cause an unusual supply of blood in the scalp. Tr. cantharides, Tr. nucis vom., Tr. capsic., and quinine all have more or less value. They can be used in oily excipients if the scalp be very dry, or in alcohol if the sebaceous secretion is sufficient.

The following will give some idea of the local treatment:

℞. Tr. cantharides,
Tr. capsic.,
Tr. nucis vom.,
Ol. ricini.....āā ʒ ij.
Alcohol ..... ʒ ij.
Spts. rosmarini ..... ʒ j.
M. Sig.: Apply to scalp night and morning.

Another very good thing which should be carefully used is muriate of pilocarpin, either hypodermically or according to Lassar's formula as follows:

℞. Pilocarp. muriat. ..... gr. xv.
Vaseline ..... ʒss.
Lanolin ..... ʒss.
M. Sig.: Rub in carefully twice daily.

But in another and much larger class of cases an unmistakable cause appears in the presence of a larger or smaller amount of "dandruff," which gives the name alopecia furfuracea. Clinically this dandruff takes on two forms, which are probably due to the same cause. The common variety consists in the constant shedding of dry scales. European writers would have us believe that this is parasitic in origin; that the irritation of parasites results in the shedding of epithelial scales while yet imperfectly formed, and that the falling out of hairs and the succeeding atrophy of the follicles occur because they form only parts of the epithelial covering and are eventually subject to the same processes.

In another form, the so-called seborrhœal eczema of Unna, the scalp is covered with adherent crust and scales, frequently taking the form of circular patches and showing a marked tendency to spread over the face and body if undisturbed. These patches are inflammatory in character, especially on their margins, and are very greasy. This seborrhœal eczema is most common from puberty to about thirty, that being the time when the sebaceous glands are most active, and it has been demonstrated by the experiments of Lassar and Bishop that the cause is a parasite, but whether the crusts are the result of sebaceous or sudoriferous hypertrophy is still a matter of dispute.

At any rate, owing to parasitic irritation, one of two things takes place. Either the cells formed in the glands and hair follicles are shed while yet imperfect, taking the hair with them, or from the constant production of sebum a hypertrophy of the glands results, followed by atrophy of the hair from pressure.

In this variety of alopecia the prognosis is better than in the idiopathic form, but the treatment is quite different. To begin with a stimulating treatment would aggravate instead of alleviate the difficulty, and this is the mistake commonly made. The first thing to do is to remove the crusts, and this is first accomplished by soaking the scalp thoroughly with some bland oil at nighttime, and cleaning it thoroughly in the morning. A nice way of accomplishing this is to shampoo the head with a mixture made of egg-yolks beaten up in limewater, washing the scalp thoroughly afterward. When the crusts are pretty well gone we can apply anti-parasitic treatment. This requires patience, and application must be made long after the trouble is apparently gone. The remedies at command are numerous. Perhaps the most universally serviceable is sulphur in one form or another, for it is a parasiticide and a good stimulant to the hair growth, supplying elements which contribute directly to its growth. It can best be used in ointment form. One of the nicest preparations is that devised by Dr. Jackson, called sulphur cream. The formula is:

℞. Cera alb. ..... ʒ viij.
Ol. petrolat. ..... ʒiv.
Aq. rosæ ..... ʒijss.
Sod. biborat. ..... gr. xxxvj.
Sulphur ..... ʒ vij.
M. Sig.: Apply night and morning.

Resorcin is another valuable remedy. It can be used in ointment in strengths of from five to ten per cent., but a more agreeable preparation is the following:

℞. Hydrarg. bichlor ..... gr. j.
Resorcin..... ʒij.
Alcohol,
Aq.....āā ʒjss.
M. Sig.: Apply night and morning.

Ichthyol and naphthol, thymol and many other remedies have their advocates and values. The treatment must be persisted in as long as any traces of seborrhœa remain, the frequency of applications being gradually diminished. Afterward the hair thickens up, its growth being assisted, if necessary, by the stimulating remedies advised under alopecia idiopathica.

325 East Nineteenth Street.

SEWER-GAS A CAUSE OF PNEUMONIA.

By THEODORE ZANGGER, M.D.,

late assistant physician, university hospital, zurich, switzerland.

In his interesting paper on "Sewer-gas a Cause of Throat Disease," in the Medical Record of September 1, 1894, Dr. Robinson has written on a subject of no small import. Perhaps the following two cases, which I had under my care at a health-resort in the Bernese Oberland, may help to throw some further light on the subject.

Case I.—Miss O. T——, aged fifteen, of healthy parents, pale, anæmic, who had undergone an operation for adenoids six weeks before, sickened with acute pharyngitis and tonsillitis without any formation of membrane. Fever remittent, normal or rather subnormal in the morning, and rising to 102° F. and 102.5° F. in the evening; no lung symptoms except slight bronchial catarrh. After three days the patient developed a circumscribed pneumonia of the lower lobe of the left lung. Recovery in three weeks. The drainage of the châlet was in a very bad state, nauseous odors spreading all over the house; the drains were immediately seen to, and no other member of the household (five adults, four children) showed any illness.

Case II.—Miss Z——, fifteen years of age, weak and anæmic, still suffering from albuminuria subsequent to scarlatina, four months previous. Three weeks later than Case No. 1, she was attacked with acute tonsillitis and subsequent pneumonia of a portion of the lower lobe of the right lung. Temperature remittent, the fever never exceeded 102° F.; great prostration. Recovery took place in a fortnight. No other cases among the one hundred and twenty guests of the hotel. Drainage very defective, nauseous odors rising at night up to the windows of the patient's bedroom.

At the same time, but at another hotel, there was one case of severe erythematous tonsillitis, and one of follicular tonsillitis simulating diphtheria in all its symptoms. Both recovered in from three to five days. There were no other infectious diseases at the time among the three hundred visitors and the sixteen hundred inhabitants of the village.

These cases, occurring at an Alpine resort four thousand six hundred feet above the level of the sea, among patients of the better classes who were accustomed to pay every attention to hygiene of the body, point to the possibility, or rather, I would say, the probability, of sewer-gas as causation. The form of pneumonia, localized as it was and limited to a small portion of the lobe of one lung, the remittent type of the fever, and perhaps the undue amount of prostration in both cases, are striking. I can explain this only by considering the "causa agens" to be the same in both cases: micro-organisms contained in and disseminated by the sewer-air and affecting just these patients as being in a low state of general health. The similarity of the cases may even point to the similarity of species and similarity of virulence of these bacteria, just as we see patients suffering from typhoid fever or diphtheria due to the same source of infection, offer curious analogies as to the severity and the complications of the disease.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, October 8, 1894.

B. Farquhar Curtis, M.D., Chairman.

Election of Chairman.—The resignation as Chairman of Dr. Charles A. Powers, he having removed to Denver, was accepted with regret, and Dr. B. Farquhar Curtis was elected to fill the vacancy.

Hernia Treated by the Wire Mattress Method.—Dr. A. M. Phelps presented a young man to illustrate the treatment of hernia by the method which he had described some months ago, one of the chief features of which consisted in weaving silver wire in the form of a mattress into the layers of muscle when closing the wound, with a view to offering a stronger barrier against recurrence. While there had been no recurrence in the several patients treated in this manner, yet it was too early to speak of a permanent cure, and he showed this patient simply to prove that the presence of the wire in the tissues caused no inconvenience after having been worn seven months. In one or two cases there had been a little superficial suppuration, but not of consequence; the cases which he had treated had been severe ones, the opening large.

Hernia Afflicted.—The Chairman, Dr. Curtis, presented a man who had had double inguinal hernia, the McBurney operation having been done on one side, the Czerny on the other. Both had given way, the McBurney first, after which it had been followed by Macewen's operation, which still held. Four weeks ago Dr. Curtis performed Basini's operation on the other side.

Bending of Neck of the Femur.—The Chairman presented another patient, a young man, who had been admitted to St. Luke's with the diagnosis of tubercular arthritis at the hip of fifteen months' duration; but when Dr. Curtis came to operate he found, on reaching the neck of the femur, that it was healthy in appearance, but bent, bringing the head down on a level with the trochanter. The neck appeared also to be somewhat shortened. He at once closed the wound, and it healed by primary intention. The case belonged among a class of which Hoffmeister had collected about forty, of softening of the neck of the femur, resulting in bending and consequent shortening of the limb, and more or less mechanical limitation of motion and pain on use. The trochanter projected more than on the sound side.

Dr. Royal Whitman presented two patients, a young man and a boy, with the same trouble. In the first there was bending of the neck of the femur in both limbs, producing the deformity known as scissors legs, the two limbs crossing each other at the knee. In this case the diagnosis of softening of the neck was made before there was scarcely any deformity, but his advice was not taken, the patient continued at his work, saw various physicians who made the usual diagnosis of hip-joint disease, and finally of paralysis, because of his awkwardness. Dr. Whitman intended soon to divide the femora and overcome the crossed position of the legs. Flexion and extension were almost free, but power of abduction was very limited; rotation was also limited. In the second case there was bending of the neck of the femur only on one side, and the symptoms were like those in other forms of knock-knee. There was only limitation of abduction in this case, and the shortening amounted to half an inch. No case yet reported had occurred after the twentieth year.

Fracture of Ulna and Radius.—Dr. Jacob Teschner presented a boy who had fractured the ulna and radius from a fall in July, and when seen soon afterward was found to have the end of the lower fragment of the radius in contact with the end of the upper fragment of

the ulna. Four short splints, one on each of the four aspects of the forearm, were applied, and over these a longer splint with a webbing, extending two inches beyond the fingers, to give sufficient extension to prevent the fractured ends from slipping past one another. The result had been perfect.

Enormous Sarcoma of Ilium Treated Successfully by Inoculations.—Dr. W. B. Coley presented the young man whom he had first shown to the section last spring, through the kindness of Drs. George F. Shrady and F. Kammerer, when there was an enormous sarcoma of the ilium on the right side. The patient's health was declining rapidly, an operation was entirely impractical, and under these circumstances he had, with the consent of the gentlemen named, undertaken treatment by injections of the combined virus of erysipelas and the bacterium prodigiosus. The injections were kept up over a month, during a part of which time, and for some weeks after cessation of treatment, the tumor sloughed and discharged in great masses. While the sloughing was going on, the patient's condition became critical, but afterward he regained flesh and strength. At present there was only a slight discharge from one of the sinuses, around which there was moderate inflammatory thickening. The ilium had resumed nearly its normal size. In a paper which he had read at Washington last spring, he had reported five other cases which could be pronounced cured by this method, the total number so treated by him having been twenty-five at that time. Since then he had had two other cases. The percentage of successes had been about one in five.

Dr. George F. Shrady remarked that he had watched this case and the treatment with great interest from the time it first entered his wards, and had been perfectly astonished at the result. It was clearly an inoperable case, as an operation would have involved resection of the ilium and division of the man into two parts. He had very little faith that anything could be done by way of toxin treatment, but knowing that this was an age of progress he asked Dr. Coley to kindly come into the wards and try that method. The result seemed to be that the patient was cured. He could not recognize any of the original growth, and there was reason to hope there would be no recurrence. He believed now that there was a great future for this toxin, and should never be discouraged in inoperable cases until it had been tried. It gave one reason to hope that something might yet be found equally efficient in cancer.

The Chairman referred to a case in St. Luke's Hospital, of very large secondary sarcoma of the clavicle, the growth of which had ceased after using the injections two weeks, but the treatment had to be discontinued on account of deposits in the lungs, and hæmoptysis. The effect of the injections had also been shown in the regular rise of the temperature every day or two, just as had occurred in Dr. Coley's case.

Resection of Knee for Charcot's Disease.—The Secretary showed, in behalf of Dr. Willy Meyer, a man with locomotor ataxia with so-called Charcot's disease of the left knee, which had been resected by Dr. Willy Meyer in 1887. Although the spinal disease had progressed, there had been no further trouble with the affected knee. Bony union had not taken place. There was slight motion, nature having formed a sort of condyle and socket.

Dr. Syms was not convinced that this patient was better off than he would have been without an operation. At the same time that Dr. Meyer was about to operate, he had himself a patient on whom he wished to excise the knee for Charcot's disease, but the patient refused, and afterward partial bony anchylosis formed and left a better joint than probably would have resulted from any effort to bring about artificial anchylosis.

Improved Osteoclast.—Dr. W. M. Phelps presented a Grattin osteoclast which he had modified in a way to obviate breaking of the skin and producing compound fracture. The new instrument was also stronger and easier to operate.

Multiple Neuro-fibromata. Dr. C. N. Dowd read a brief paper in which he described two cases of this affection. The first was in a man aged thirty-three, who during the past two years had had probably as many as two hundred tumors on the surface of the body, most of them freely movable on the underlying tissue but attached to the skin, the surface having a red angiomatous appearance. On removing one it was found to be a fibroma of the variety known as neuro-fibroma. Such tumors were ordinarily benign, and caused trouble only by their mechanical irritation and disfiguration.

The second case was in a man aged thirty-five, who first noticed a tumor over the olecranon of one arm, and afterward others over various parts of the body, varying in size from a pea to a horse chestnut. They had the appearance of the tumors in the other case, except that in some there was a tendency to necrosis. There was no history of syphilis, yet mercurial inunctions caused the tumors to disappear, proving their syphilitic origin. Replying to a question, he said there was no neurotic history.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 26, 1894.

George C. Freeborn, M.D., President, in the Chair.

Report of the Microscopical Committee.—Dr. E. K. Dunham, on behalf of the Microscopical Committee, reported the results of the examination of the specimen presented to the Society on February 20, 1894—supposed gumma of the heart. Because of the presence of certain bodies closely resembling giant cells, this specimen had been referred to the Committee. The special object was to make a differential diagnosis between a possible tubercular or syphilitic causation of the growth. At that meeting the opinion was advanced by one of the members of the Society, that the bodies resembling giant-cells were derived from the muscular fibres of the heart. Further microscopical examinations had confirmed that view, as it had been found possible to select a series of transitional forms explaining the changes. In order to distinguish between tuberculosis and syphilis, a large number of sections were examined for tubercle bacilli, but none were found. The sections also failed to show any reason for regarding the growth as of tubercular origin. In support of the opinion that the growth was of syphilitic origin, were certain appearances in the blood-vessels which seemed to indicate a beginning thickening of the vascular wall. The results of the microscopical examinations were therefore confirmatory of the original diagnosis.

Giant-Cells in Epitheliomata.—Dr. George P. Biggs referred to a specimen of epithelioma, which he had presented to the Society last November, in which there were giant cells. The tumor had been removed from a man sixty years of age, who had given a history of having received a compound fracture of the inferior maxilla five years before. Following this, a tumor developed in the floor of the mouth, which proved to be an epithelioma. A small nodule was said to have recurred in the scar left after the operation for the removal of the growth. Later, a growth appeared in the submaxillary region on the same side, and this had grown steadily for four months previous to his coming under observation. The specimen referred to, which was a typical epithelioma, contained large numbers of giant-cells of peculiar character, some of them very large, and containing a great many nuclei grouped near the centre rather than at the periphery. The specimen had been submitted to the Microscopical Committee, and Dr. Dunham, after examining a number of sections stained in various ways, was able to demonstrate that these giant-cells had been formed from epithelial cells.

He desired at the present meeting to present a similar specimen, which had been removed at the New

York Hospital by Dr. Stimson, from a man fifty years of age who gave a history of progressive loss of voice, and of some pain on swallowing, for four years. For five or six months previous to the operation, he had suffered from dyspnœa, which had become so severe that an operation was undertaken. The family history was tubercular, but there was no personal history or symptoms of tuberculosis. The operation consisted in opening the larynx and removing from its interior a large part of the mucous membrane and a new-growth. Examination of the latter showed it to be a typical epithelioma. In this specimen also were giant-cells apparently of the same nature as those found in the first specimen referred to. Some of these cells were large, others had only three or four nuclei, sometimes grouped in the epithelial structure and sometimes by themselves. Some of them were round, while others were irregular in shape. Tubercle bacilli were searched for, but not found. Since then, in two other cases he had seen similar cells, but not as distinct as in the microscopical specimen just presented. They seemed more prone to form in epitheliomata of slow growth. The literature of this subject was very meagre.

Dr. Thomas H. Manley asked the clinical significance of these cells—in other words, whether their presence was to be considered an element in the prognosis. We know that, as a rule, cancerous growths, particularly on the tongue, were rapidly fatal, and that sarcomata in this region often did not recur for a considerable time after their removal. He recalled one or two illustrative cases which had occurred in his own practice.

Dr. Biggs replied that he had not seen a sufficient number of cases to admit of his stating definitely in regard to their possible clinical significance,-but in those cases he had reported the growth had been quite slow.

The Society then adjourned.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 15, 1894.

Samuel B. W. McLeod, M.D., President, in the Chair.

1, Posture in Anæsthetic Accidents; 2, The Use of Sedatives in Heart Disease; 3, The Efficacy of Ichthyol on Inflamed Tissues.—Dr. Hobart A. Hare, of Philadelphia, read a paper containing brief remarks upon these three subjects. Under the title Posture in Anæsthetic Accidents, he spoke of the position of the head, neck, and tongue, and their influence on opening or closing the glottis. Artificial respiration was often rendered nugatory by placing the head or tongue in a position which closed the glottis and obstructed entrance of air to the lungs. If the tongue were pulled out and over the lower incisors by the tip it would not raise the epiglottis; it must be pulled outward and upward toward the upper incisors. Regarding control of the glottis by Howard's method of extension of the head and depression of the neck, Dr. Hare showed by experiment on the cadaver, and could give clinical evidence, that the neck must not be depressed, but lifted, else the velum and tongue would obstruct the passage of air through the mouth, which would prove very serious if the nostrils should also happen to be obstructed. Regarding the comparative efficacy of Sylvester's and Marshall Hall's methods of artificial respiration, he had made some experiments which proved that Sylvester's was much more efficacious in inflating the lungs. It was important that the feet should be held while the movements were being made with the arms—that the body should be stretched.

Cause of Death in Chloroform Anæsthesia. — Dr. Hare referred to his studies in connection with the Hyderabad Commission, and said he was convinced that the chief factor in causing death in chloroform anæsthesia was cessation of respiration through paralysis of the respiratory centre in the medulla, although he knew also of the influence exerted on the vaso-motor system, and through it upon the heart, and did not doubt that the heart might first give out in certain cases where this organ was diseased, just as death might take place from cardiac shock brought on by various causes provided the heart was already unsound. The death from chloroform in such a case was due more to sudden vascular distention than to direct influence on the heart. He had found that atropine allowed more chloroform to be used without depression.

Cause of Death in Traumatic Shock.—The author had observed in many cases of death supposed to be due to circulatory failure in traumatic shock that respiration was first to give out. He had, therefore, made use of Sylvester's method of artificial respiration in similar cases, and had seen the breathing and pulse improve from the increased quantity of air made to enter the chest.

Sedatives in Heart Disease.—The next part of the paper dealt with the treatment of heart disease. Digitalis had been much abused. It was very useful in certain cases, but was contra-indicated in others, while agents of an opposite nature, sedatives, not stimulants, were called for. These agents were aconite, atropine, gelsemium. In practice he found that he prescribed the sedatives oftenest. Digitalis was beneficial in those cases where the heart was failing and unable to do its work. The sedative agents did best where the heart was beating with sufficient force or too much force, but spasmodically, irregularly, and ineffectually. In cases of compensatory hypertrophy among laborers or gymnasts the heart was likely to cause trouble when they ceased their usual degree of exertion. Digitalis, under such circumstances, would increase the palpitation and cardiac symptoms, while aconite would act as a sedative and give relief. Next to aconite in value as a cardiac sedative came gelsemium, then veratrum viride. The form of cardiac palpitation and oppression complained of by medical students on climbing stairs at the commencement of a term was usually best relieved by one of these agents.

The Efficacy of Ichthyol on Inflamed Tissues.—Dr. Hare concluded his paper by citing some experiments made on rabbits at his suggestion in the laboratory, with a view to explain the influence of ichthyol over inflammatory action. Under certain precautions the skin of the rabbits was bruised in a way to produce subcutaneous injection and inflammation. The rabbits were divided into nine series: in one the affected area not receiving treatment; in another it was simply rubbed; in a third, ichthyol was applied; in a fourth, the ichthyol was applied with rubbing; in a fifth, it was applied along with lanolin; in a sixth, the latter was applied alone, and so on, the object being to determine whether the benefit was due to the rubbing, the ichthyol, the lanolin, or to any combination in the use of these agents. Sections of the skin were examined microscopically. The conclusions drawn from the experiments were, that the inflammatory exudate disappeared more quickly under rubbing than without; that it disappeared most quickly with the combined use of rubbing and ichthyol, and that lanolin had no effect. The rubbing made the oil-globules penetrate more deeply.

Dr. E. K. Dunham was requested to open the discussion. He showed some cultures of micro-organism which he had made with a view to determining whether ichthyol had any antiseptic value. Its action on the growth of disease germs was found to be only slightly inhibitory.

Prolonged Lincoln's Life.—Dr. C. A. Leale said that in drowning and anæsthetic accidents, he put the finger far back in the mouth and drew the tongue forward, thus accomplishing what Professor Hare did by pulling the end of the tongue forward and upward. He had been much indebted to Dr. Flint for knowledge

acquired in his laboratory regarding artificial respiration as it had led him, when he found President Lincoln sitting in a chair after the shooting, the head dropped forward, breathing stopped, pulse absent at the wrist, to immediately lay him on his back upon the floor and to lift the chin and thereby restore respiration. The coaguli were then removed from the skull, relieving cerebral pressure, whereupon he had the happiness to see restoration of lung and heart action. Miss Keen, the actress, came in while in stage costume, and seeing the President lying upon the floor, sympathetically begged permission to hold his head. Dr. Leale replied, "No, the head must not be raised an inch, or else it may interfere with respiration and cause death."

Dr. Leale also referred to a case of suicidal attempt with two ounces of chloroform, which he had reported in 1873, and in which he practised artificial respiration and irritated the great sympathetic ganglia by introducing his hand a distance of sixteen inches up the colon.

Much of the further discussion was directed to the comparative safety of ether and chloroform as anæsthetics.

Dr. Manley felt that ordinarily to give chloroform instead of ether was to needlessly imperil the patient's life. He inquired the author's opinion of the new French method of rhythmical traction on the tongue where breathing had ceased; also of Dr. Fell's method of artificial respiration.

Dr. Rupp said Dr. A. C. Post had years ago taught and practised pulling the jaw and tongue forward, the finger being applied to the back of the tongue.

Dr. J. Mount Bleyer said with reference to the method of artificial respiration credited to Dr. Fell, that he had himself first described it, in a paper read in 1886, one tube being used for the introduction of air into the lungs, the other for its escape. Further remarks were made by Drs. Collyer, McKeeby, Brothers, and others. Chloroform had its advocates.

Dr. Hare in some concluding remarks said that a person's susceptibility to chloroform or ether, like to some other drugs, seemed to depend to some extent upon the climate. In the South and in Europe chloroform appeared to be less dangerous than in this section of the United States. Here, judging by immediate results, ether was much safer, but it was a question whether as much could be said of it if the after-accidents as nephritis, bronchitis, etc., attributable to its use, were taken into consideration. The observations of those who had discussed the question this evening were in harmony with those of all others who had made it a point of special investigation that in chloroform accidents the respiration ceased before the heart-beat, although a contrary view had generally been held at first.

Chart Illustrating Mortality Tables Used by Life Assurance Companies.—Dr. N. S. Westcott explained such a chart. On it vertical lines were drawn to the number of 100, every fifth one heavier than the others; they were crossed by horizontal lines up to any required number. The horizontal lines beginning at the bottom of the left were numbered from 1 up, which stood for thousands, the number living; the perpendicular lines beginning at the left and bottom were numbered from 1 to 100, the age; at the top the same lines contained the number still living for the respective years, the number decreasing from left to right until zero was reached at the age of one hundred. A red line was drawn from the left upper corner of the chart, sloping gradually to the right lower corner, dropping as it proceeded to each horizontal line representing the number of living at any given year. There was a rapid fall in this oblique line the first five years, another increased declination after the fiftieth year, and a third, corresponding in degree to the first, beginning at old age. By this chart one could quickly estimate the probability of life at given ages. Without the age being given, mortality rate per thousand in any community was of little value.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE WINTER SESSION—THE MEDICAL SOCIETIES—EPIDEMICS — DIPHTHERIA — ANTITOXIN — EPIDEMIC SKIN DISEASE—EPIDEMIC MUSCULAR RHEUMATISM—BERI-BERI—THE CHELSEA HOSPITAL SCANDAL—HONORARY MEDICAL OFFICERS TO PAY WARDS.

London, October 6, 1894.

We are already settling down to the work of the winter session. The schools having opened on the traditional October 1st, and a number of them having celebrated the occasion with a dinner, are now quietly engaged in their usual work. The societies, too, are all awakening, and next week we shall be in the full tide of their proceedings. The Obstetrical Society has already met; on Monday the Medical Society of London will begin its session with an address by the President, Sir W. Dalby; on Wednesday the Hunterian Society will be addressed by Mr. Bryant; on Thursday the Gynecological Society will meet; on Friday, the Clinical Society.

I have not yet heard when the Epidemiological Society will hold the first of its few meetings, but an early date would seem to be appropriate, for much of our attention has lately been demanded by epidemics, and we seem to be threatened with an outbreak of epidemiological conversation and literature. I do not refer in this to cholera or the more distant Eastern plague, but to diseases in our midst with a more or less epidemic character. First of these is diphtheria, which has for some years been present in London, but seems to have rather increased. Last week there were sixty-seven deaths, and the numbers admitted to the hospitals of the Asylums Board show that the disease has been more prevalent in the last quarter than in previous Michaelmas quarters. The same may be said of the numbers of notifications. A most interesting point in reference to diphtheria is the success that has attended the treatment by antitoxin. Stimulated by the success reported from the Continent, quite a number of practitioners have been using the new treatment, and successful cases are being rapidly accumulated. Like all other remedies, it must be employed in the early stage if it is to be effectual, and there is some evidence that it is even preventive. The Pasteur Institute prepares the remedy on a large scale, but not enough for French demand. It is not easy to obtain a supply here, but soon perhaps may be. It is to be hoped that no spurious or imperfect preparations will come into the market. A considerable time is required for preparing the remedy, and no little skill. Now is the time for the British Institute of Preventive Medicine to show its capacity and establish its position. Some are calling out for the State to provide a supply. That is not likely to be done in a hurry, and the British Institute ought to be able to meet the demand.

The second epidemic that forces itself on our notice is exfoliative dermatitis. Your readers will remember my report on this three years ago, when Dr. Savill first described it as "a contagious malady in which the main lesion is a dermatitis, sometimes attended by vesicles, always resulting in desquamation of the cuticle, usually accompanied by a certain amount of constitutional disturbance, and running a more or less definite course of seven or eight weeks." This disease was epidemic in some of our workhouse infirmaries in 1891, and in them studied by Dr. Savill. It has since recurred each summer and autumn, but this year to a much greater extent. It chiefly affects the old and feeble, and the temperature is generally subnormal. The mortality in 1891 was 12.8 per cent.; this year, so far, it has been 11.6. A diplococcus was discovered by Dr. Savill, but he has not been able to find it in later cases. Milk and other articles of food have been suspected of conveying the contagium, but there is not much evidence on the point. . .

Another disease alleged to be epidemic in several localities, is muscular rheumatism. I am informed that some of the so-called epidemics resembled influenza, but in others this was not the case. At all events the outbreaks were not very serious. The attacks lasted some two or three days, and consisted in sudden pain in the head or chest, with a rise in pulse and temperature. Some observers mention pleurodynia and neuralgia as being similar, others notice sweating of the odor common in acute rheumatism. No one that I know of has met with cardiac complication.

Yet another epidemic is reported. In a lunatic asylum in Dublin there has been an outbreak of beri-beri. The origin of the disease has not been traced, and it is not a little singular that it should appear in our climate as an epidemic limited to an institution in Dublin. Odd cases have at times been brought to our ports, but as a rule do not spread.

The Chelsea hospital is not yet "out of the wood." The Home Secretary has declined the request of the vestry to appoint an official inquiry, as he has full reliance on the impartiality of the independent inquiry that has been held. This he reads as a condemnation of the management and of the staff. You will remember that I foresaw the medical staff would be made the scapegoat, as usual in all hospital scandals. The cool assurance of the managing committee in proceeding to elect a new staff when the old resigned, is just what might be expected from an ordinary hospital committee. But this one was involved in the same condemnation—only, as an Irishman says, "more so"—as the staff. The ladies' committee seem to be able to show the others the proper course of conduct, for most of these ladies have sent in their resignations. The managers should do likewise, and the governors would do well to make a clean sweep of all the lay committeemen, and start afresh with new management by new men. If any of the staff are still to be scapegoats, let them all go too into the wilderness of unrecognized medical service. Then, if the profession were worthy of its position, no one should succeed them as unpaid officers. Let the public pay their doctors, and they would then appreciate their value. Unpaid medical service is the bane of the profession. A further development of this has lately occurred. The Great Northern Central Hospital is starting pay wards. Patients are to be admitted at two guineas per week. The honorary staff is to attend the pay wards on the same terms as the other parts of the hospital. Delightful, is it not? A department to be run at a profit, and the doctors to do everything for nothing. This is the notion of managers of our charitable institutions. Ah! "Charity, what crimes are committed in thy name."

DANGER FROM INDISCRIMINATE HOT INTRA-UTERINE IRRIGATIONS.

To the Editor of the Medical Record.

Sir: In the Medical Record of October 6th is an excellent article on the management of abortion. In the closing paragraph, however, the recommendation is made that "in septic cases large, *hot*, antiseptic intra-uterine injections should follow the cleansing of the uterus." The italics are mine. In justice to the author I would say that I have repeatedly seen the same recommendation by good authorities, and have witnessed the procedure carried out by eminent men. Yet it is this very recommendation and practice which I must enter a vigorous protest against as illogical and dangerous.

Of the value of curetting or otherwise clearing the uterine cavity, with, in suitable cases, gauze-packing and intra-uterine irrigation, in cases of septic metritis following abortion, miscarriage, or childbirth, there can be no doubt. As to the value of antiseptic douches there is no question. That *hot* intra-uterine irrigations are invaluable in their proper place I am ready to concede. But is this the place for a hot douche?

I may state here that I have repeatedly observed cases of acute septic metritis which were curetted, the curetting being followed by the hot douche, and the douche almost as uniformly followed by a severe chill (often before the operator had left the room), the chill being in turn followed by fever, sweating, and other evidences of acute septicæmia. I have seen this occur repeatedly in the same patient every time the procedure was gone through with until the patient and her friends begged the doctor not to interfere and "bring on those dreadful chills," while the doctor assured her that the douches were essential to her recovery. I have seen this occur in private practice under expert gynecologists; I have seen it occur in the routine of hospital work; I have seen it occur in the practice of the country doctor; I have seen it altogether too frequently.

Cases of septic trouble following abortion are common—much too common. A woman has a miscarriage, perhaps a criminal miscarriage, at the fourth month let us say. The fœtus is expelled. Shreds of placental tissue and decidual membrane come away, but some remain. The patient has a temperature of 100° or 101° F. The pulse is good. There is mild septicæmia. The lochia is dark, bloody, profuse, has a gangrenous odor. If left to nature she will keep on in this state for some time. Eventually pelvic peritonitis, cellulitis, or general septicæmia will result, or more fortunately a gradual separation of the decidua occurs and a protracted convalescence follows, complicated perhaps by prolonged metrorrhagia and chronic metritis or other sequelæ.

But the doctor is called. He is *fin de siècle*. He is acquainted with bacteria,

> "And various animalculæ
> Of middle, high, and low degree."

He uses antiseptic vaginal washes. Good! He sterilizes his hands and instruments. Better! He clears out the uterus thoroughly. Best yet! Then he uses a hot intra uterine irrigation. Error in judgment! He kills a few more putrid or septic germs, but he checks drainage.

Why?

What have we to deal with in the septic cases referred to? A uterus, the cavity of which has just been cleared of decomposing *débris*; but a uterus, the structure and substance of which is infiltrated with septic germs; a uterus with its blood-vessels and lymphatics filled with morbific products; a uterus which under rational treatment, now that the focus of infection is removed, will pour out offensive discharges for days and drain itself of the poisonous products as nature intended, by a free lochial discharge. That is the object at which we all aim—elimination.

Now use a hot injection into the uterine cavity. The most constant and powerful action of a hot douche is to check hemorrhage. It contracts the blood vessels. It contracts the uterus. It does it rapidly, thoroughly; watch the result. The blood-stained malodorous discharge is checked; drainage is thus interfered with; the distended vessels filled with poisonous products, cut off from their natural sewerage into the uterine cavity, and compressed by the sharp contraction of the uterus under the stimulus of a hot injection, empty themselves into the general circulation, and a chill, with general septicæmia takes the place of what had been prior to this time a more localized septic process. This occurs more frequently in the septic states following childbirth than in those following early abortions, simply because the uterus being larger contains more septic material to be forced into the general circulation. As well apply an Esmarch bandage from the hand up to the shoulder in a cellulitis of the arm as a hot injection into the cavity of a uterus swarming with bacteria and infiltrated with septic poison.

This argues nothing against intra-uterine irrigation properly performed and used with good judgment. But the use of hot injections immediately following the curet-

ting of a septic uterus is far too common. That their use is dangerous is reasonable and logical in theory, and any careful observer will find that the theory is borne out by clinical experience.

Why use a hot intra uterine irrigation, when a warm one would be more comfortable to the patient, would be far safer, and would fulfil every indication?

W. N. MacArtney.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 20, 1894.

	Cases.	Deaths.
Tuberculosis	61	102
Typhoid fever	30	8
Scarlet fever	40	2
Cerebro-spinal meningitis	1	2
Measles	30	0
Diphtheria	141	42
Small-pox	2	0

Apomorphine and Hysterical Attacks.—Rosser recommends one tenth of a grain of apomorphine, hypodermically, to break up and prevent the recurrence of hysterical attacks.

Breakfast for Chlorotic Girls.—Dr. Carl Von Noorden, in the *International Medical Magazine*, May, 1894, speaking of the dietetic treatment of chlorosis says: "Most chlorotic girls feel weakest and worn out during the hours of the forenoon, and incapable of any proper kind of work. This condition is uncomfortable, and directly harmful from the educational point of view. The best remedy is the English fashion of a good hearty meal at the beginning of the day. Chlorotic girls are advised to drink half a litre of milk of the best quality, while still in bed, and to do it very slowly, taking fifteen minutes to drink the quantity prescribed. Half an hour later they should rise and be rubbed with a dry, rough, woollen towel. Then comes the breakfast, consisting of a small cup of tea, one or two slices of buttered toast, and plenty of meat. Two hours and a half later some bread and butter is to be eaten, together with two eggs, this to be followed by a quarter of a litre of milk. A glass of sherry is now permissable, if special reasons warrant it. This morning regulation of diet makes the forenoon hours quite comfortable. Fixed rules for other meals are of less importance."

Death-rates and Race.—I will not weary you with further details of figures, which those of you who are specially interested in the subject will find in the reports of the Vital Statistics of the Eleventh United States Census, but will merely say that the corresponding data from Boston, Philadelphia, Baltimore, Washington, and from the New England States as a whole, taken with those from New York State and New York City, and with those derived from a special investigation of over 10,000 Jewish families, including over 50,000 persons, lead to the following conclusions as being probable for the United States: 1. The colored race is shorter lived than the white, and has a very high infantile death rate; it is specially liable to tuberculosis and pneumonia, and less liable than the white race to malaria, yellow fever, and cancer. 2. The Irish race has a rather low death-rate among its young children, but a very high one among adults, due to a considerable extent to the effects of tuberculosis, pneumonia, and alcoholism. 3. The Germans appear to be particularly liable to disorders of the digestive organs and to cancer. 4. The Jews have a low death rate and a more than average longevity; they are less affected than other races by consumption, pneumonia, and alcoholism, but are especially liable to diabetes, locomotor ataxy, and certain other diseases of the nervous system.—Dr. J. S. Billings.

Morphinomania in the Medical Profession.—Dr. Jules Rochard, in the *Union Médicale*, draws a gloomy picture of the increase of the morphine habit in France and elsewhere. The habit, he finds, becomes incurable at the end of six months of indulgence. The fair sex and the doctors are, in his opinion, the most deeply addicted to morphine. He draws an unpleasant comparison between the behavior of each kind of delinquent. Women, he says, delight in declaring how they indulge in this vice, and show ornamental hypodermic syringes to their friends. Dr. Notet states that a lady having broken the needle of her syringe in a remote country village, wounded her skin with scissors and thrust the stump of the needle into the wound, injecting herself in this manner till a new syringe arrived from Paris. Men, Dr. Rochard declares, and especially medical men, the bulk of male morphine injectors, take the greatest pains to hide their vice. Hence the precise number cannot be estimated. He believes, however, that doctors and persons associated with them form nearly half the total of men addicted to morphine.

Medical Sculpture.—Dr. Paul Richer, the director of the Salpêtrière laboratory, has been recently engaged in enriching that renowned neurological school with a series of heads and busts reproducing certain types of pathological deformities. In the last number of the *Iconographie de la Salpêtrière* there appears the photograph of one of these busts, representing a subject affected with primary progressive myopathy. This patient was frequently shown by the late regretted Professor Charcot at his cliniques as a perfect example of the myopathic physiognomy of the Landouzy-Déjerine type.

Catharsis by Means of Hypodermatic Injections Impossible.—The editor of *The Medical Age* believes it to be absolutely proved that catharsis cannot be induced by the introduction beneath the skin of purgative elements. He relates some of his own experiences. A number of tablets of both sulphate of magnesium and sulphite of soda were prepared, embodying the utmost quantity available for hypodermatic use. These were employed in some thirty instances, and a quantity distributed among a half-dozen other physicians, who used them in from fifteen to fifty cases each. In no instance was any cathartic effect observed, except now and again when a patient was informed of a probable purgative action—here the results were only such as would accrue to "suggestion." In one instance the physician experimented upon himself, making use of two tablets of magnesium sulphate of one and one half grain each, injecting into the upper and external aspect of the thigh at 8 P.M.; at 10 P.M. he retired to stool, but felt no assistance had been given to defecation—was rather constipated than otherwise. Being very easily influenced by laxatives, and the hour of defecation being that of daily habit, he is quite positive that no better test could have been given of the utter inefficiency of the drug. Further, says *The Age*, the evidence *per se* is conclusive that neither magnesium sulphate nor soda sulphite can be employed hypodermatically as a purgative, even were one sure of a cathartic effect, since the dose available for the sub-cellular method is entirely too small and the method itself, so far as purgative drugs are concerned, too unsatisfactory for adoption. The hypodermic holds the keys that bind, but not those that loose.

Trichinosis.—At a recent meeting of the Pathological Section of the Buffalo Academy of Medicine, Dr. Frank J. Thornbury made a preliminary report on 500 cases of trichinosis observed in his work as Inspector in the Bureau of Animal Industry of the United States Department of Agriculture, at Buffalo, N. Y. Special attention was given to conditions in the pathology not previously spoken of, comprising peculiarities of encapsulation of

the trichinæ, degenerations, calcifications, pigmentations, etc. A large number of photographs and drawings were presented which showed these conditions, and an extensive exhibit of rare and interesting slides under microscopes was given. Reference was made to the relative frequency of location in the hog and extent of infection of the different parts examined according to the Government system of inspection. The parts examined comprise the diaphragm, neck, and loin respectively. The entire number of cases in which trichinæ were found in the diaphragm was 399, in the loin, 291, in the neck, 171. The average number of trichinæ found in the diaphragm in the entire number of cases was 8, in the loin 5, and in the neck 3. In the 500 cases studied all of the three parts were infected in 200 instances, two parts were involved in 136, and one part only was infected in 164 cases. The part of predilection for the trichinæ therefore appears to be the diaphragm. This is explained by its close proximity to the digestive tract, from which the trichinæ primarily migrate. It would appear also that the tenderloin is not to be preferred as an article of diet. This comprises the psoas muscles. Where the hogs are extensively affected the trichinæ are also usually found in the hams, shoulders, sides, and, in fact, in almost any part of the body. Dr. Thornbury has also studied the subject of trichinosis in man with the following results: Of 21 subjects examined in the dissecting-room of the University of Buffalo, trichinæ were found in the muscles in three cases. The muscles principally affected were those of the extremities (one slide from the biceps of the arm containing fifty of the parasites), the diaphragm, intercostals, abdominal muscles, the psoas, etc. Many of the trichinæ were old and calcified, others were still alive. One of the cases of infection was not very extensive, the trichinæ being scattered in limited numbers through the muscles of the thorax and abdomen. This observer contends that many cases of chronic muscular rheumatism are disguised under this head. This is corroborated by the continued observation of cases of trichinosis in the acute stage and seeing the patient suffer from muscular pains which under ordinary circumstances would be regarded as simply rheumatism.

Bicycling.—The Paris Academy of Medicine recently discussed the question of bicycling, and came to the conclusion that this form of exercise might be attended with great danger to the heart in those who suffered from any affection of this organ. One speaker referred to the recent death of three persons from heart disease while riding bicycles, and asserted that not less than one thousand wheelmen in Paris were suffering from cardiac affections, and were in danger of the same fate.

Suicide.—The number of suicides in England has increased so much in recent years, that the question has been raised whether the elimination from insurance policies of the clause dealing with that subject has not tended to encourage self-destruction. One of the leading insurance journals has taken the matter up, and concludes that the cause must be sought elsewhere; and that it is only very rarely that a man puts an end to his life from a desire to benefit his family, although it is possible that, having already made up his mind to kill himself, he may take out extra insurance for the sake of his wife and children. Such deliberate suicide is, however, among the most seldom of occurrences. Some German statistics recently published show that Saxony heads all the other states of the empire in the matter of suicides, the percentage being almost double that of Prussia. One per cent. of the suicides are children under twelve.

Dr. Sacharjin, the Czar's regular medical attendant, is a most eccentric person. When called to see a patient, he insists upon the removal of all female attendants during the time of his visit, and allows no one to utter a word in his presence except in reply to his questions, and in many other ways he is noted for his blunt frankness, often rudeness, toward his patients, including those of the highest rank. When the Czar's illness became so alarming that it was thought best to have his physician constantly within call, Dr. Sacharjin could with difficulty be persuaded to come, and when he did finally consent to take up his residence temporarily in the palace, he positively refused to occupy the suite on the third floor which had been provided for him, because he was accustomed to the ground floor, and he required apartments to be provided for him there. When the Czarina asked him to lunch at the imperial table he declined, on the ground that he was not in the habit of taking his meals with women. He was allowed to eat in his own rooms. In spite of his eccentricity he is in great demand among the aristocracy of Moscow and St. Petersburg. He is reported to be worth 7,000,000 rubles, made in the practice of his profession.

Wouldn't Trade with Him.—The following story is told by the *Medical Herald*, at the expense of Dr. F. C. Hoyt, superintendent of the insane hospital at Clarinda, Iowa. One of the chief attractions for him in the Midway was Hagenbach's "trained animal" show. He is noted for his sympathetic nature and, after witnessing the performance, sought an opportunity to converse with the lion-tamer. After a few preliminary inquiries as to the disposition of the animals, the doctor proceeded to sympathize with the king of the den concerning his lot, isolated as he was from civilization, and compelled to associate entirely with the wild beasts. Doctor Hoyt digressed eloquently upon the uncertainty of life, and expressed his great satisfaction at not having to play with the monster lion, who was nervously pacing his cage and growling. The keeper listened attentively, only remarking that he was "used to it." When the doctor turned to depart, the "king" courteously asked for his card. It read: "Iowa Hospital for the Insane." "Great guns!" gasped the tamer, "I wouldn't trade jobs with you for a million dollars."

Data on Keeleyism.—Rev. Dr. J. M. Buckley, editor of the *Christian Advocate*, of New York (150 Fifth Avenue, New York City), solicits specific data in reference to "Keeley Institutes." He asks only for information from physicians and ministers, and desires to make a thorough and impartial investigation of the Keeley business. He will not, we think, be able to find anything very new or instructive, unless he is able to collect the facts regarding relapses. The Keeley cure is atropine, strychnine, simple bitters, good resolutions, and a certain amount of hypnotism.

State Board of Medical Examiners.—An autumn examination will be held by the Pennsylvania Board. Its influence is already clearly felt in the solicitude shown by some of the medical schools concerning the fitness of students to pursue the study of medicine. It was rare in former years to hear the dean of a medical school advise a pupil not to enter or continue in the course unless indeed the student had paid all the fees that the college could exact. We hear now, however, occasionally of students being advised that they are not sufficiently prepared to enter upon the medical course. It is to be hoped that the Pennsylvania Board will maintain the position that was assumed in the first examination.—*Medical News.*

Anatomical Material.—The Association of American Anatomists has issued the following circular: "*Dear Sir*—At the last meeting of the Association of American Anatomists, the undersigned committee was appointed to 'consider the question of the collection and preservation of anatomical material, and to report, at the next meeting, what in their opinion are the best means of accomplishing these objects.' In order to make the work of the committee as comprehensive as possible, and to obtain information which will be of service in arriving at definite conclusions as to the best methods of accomplishing the purposes indicated in the resolution, the committee has deemed it desirable to send to the teach-

ers of anatomy, not only in this country, but abroad, this circular letter, with the questions appended, and respectfully to request answers thereto, as fully as they can be made.

"1. Is anatomical material obtained in accordance with a legal enactment, wholly or in part?

"2. If there is an anatomical law in your country or State, please send a copy of it to the chairman of this committee, Dr. J. Ewing Mears, 1429 Walnut Street, Philadelphia, Pa. Please state whether the law is satisfactory, whether it is readily obeyed by those upon whom duties are imposed by it, and mention any improvements you would suggest, as to its requirements.

"3. Is the material received in good condition?

"4. What disposal is ultimately made of the remains?

"5. Please state what means are employed to preserve anatomic material for the purposes of dissection or operative surgery. If injections of preservative fluids are used, state their composition and the methods of use, at what point injections are made, whether at the heart or in the large arteries, and their effect in accomplishing the preservation, with any changes in the color or the character of the tissues. What length of time can material be used in dissection by the methods employed by you? If preservation by means of 'cold storage' is employed, please state the cost of the machinery which it was necessary to construct for this purpose, and what means are taken to prevent decomposition after the subject is placed upon the table for dissection.

"6. Please state the cost, by the method employed by you, for each subject: *a*, for receiving it; *b*, for injecting and preserving it.

"7. Do you obtain an adequate supply of material for the purposes of anatomic instruction? How many students are assigned to each subject, and what is the method of allotment?

"8. Please give any information which you may deem of importance. As the report will be general in character the name of the informant or institution will not be mentioned by the committee unless requested.

"Your compliance with the request of the committee, at an early date, will be fully appreciated as rendering assistance to it in accomplishing its work, and it desires to thank you for the same in advance.

J. Ewing Mears, M.D.,
Joseph D. Bryant, M.D.,
Thomas Dwight, M.D."

A Medical School for Women is to be established in St. Petersburg through the initiative of Prince Wolkowski, the educational representative of Russia at the World's Fair in Chicago.

Medical Etiquette Among the Ancients.—In an old Latin poem, the manuscript of which has been found in the National Library at Paris, occur some interesting pages in which the author, whose name is unknown, explains the proper conduct of a physician. (*Boston Medical and Surgical Journal.*)

"On approaching the patient, you should assume a calm expression and avoid any gesture of greed or vanity; greet those who salute you with an humble voice and sit down when they do. Then, turning to the sick person, ask him how he is, and examine his pulse and his urine. To the patient you promise cure, but immediately on leaving the room you say to the relatives that the disease is grave. The result will be that, if you cure him, your merit is greater and you will receive the greater praise and fee; while, if he dies, they will say that you had no hope from the first."

This counsel has been well followed by some physicians to the present day. The directions for table manners are equally amusing:

"When those who preside over the house ask you to the table, conduct yourself in a seemly manner. Each time that a new dish is brought on, do not fail to ask for the condition of the patient. This will give him great confidence in you, as he sees that in the midst of the variety of the repast you do not forget him. On leaving the table, return to the patient, and tell him that you have dined most excellently, and that everything was served to perfection. The sick person who was anxious about these points will rejoice at your words."

Professor Amoyama, of Tokio, who accompanied Dr. Kitazato to Hong-Kong to study the plague, contracted the disease and nearly lost his life. Happily, however, he finally recovered, and has not returned to Tokio.

TREATMENT OF DIPHTHERIA.[1]

By A. CAMPBELL WHITE, M.D.,
NEW YORK.
RESIDENT PHYSICIAN OF THE WILLARD PARKER HOSPITAL.

THE cases of diphtheria included in this investigation were subjected to three different modes of treatment.

In the first series, the nasal and throat cavities were thoroughly irrigated, every one to three hours, with warm salt solution, until the pseudo-membrane had disappeared, then from one to three times daily until the entire disappearance of the bacilli. For irrigation, the fountain or Davidson syringe was used.

In the second series, the cases besides receiving the treatment given in the first series, had their nares and throats thoroughly sprayed every three hours (except during the night) with solutions of peroxide of hydrogen, which varied from twenty five per cent. to five per cent. in strength. The special form of peroxide used was that known under the name of pyrozone.

The following tables show the results obtained by these comparative tests:

TABULATION OF ALL CASES, SHOWING THE DAY OF THE DISEASE ON WHICH THE PSEUDO-MEMBRANE DISAPPEARED.

* Before membrane. In these four cases bacilli disappeared one day before membrane. In those cases treated with bichloride irrigation only were cultures taken before disappearance of membrane, while in some cases treated with the salt-water irrigation examinations for bacilli were not made for two or three days after membrane had disappeared.

The third series of cases were subjected to the same treatment as the first, except that solutions of bichloride of mercury were substituted for the salt-water solution.

[1] Being the substance of a report to the Health Department of the city of New York, on a series of investigations relating to the duration of the false membrane and persistence of Klebs-Loeffler bacilli in the throats of patients subjected to systematic irrigation with antiseptic or cleansing solutions.

The nasal cavities were irrigated every eight hours with a warmed 1 to 4,000 solution, and the throat every three hours with a 1 to 3,000 solution.

Besides this local treatment, nearly all the cases received frequent doses by the mouth of the tincture of the chloride of iron and of alcoholic stimulants.

Total	10.4	2.3	5 8	8.2	9	17 2	60	24	84

In using the pyrozone three different strengths were employed, twenty five, twelve and one-half, and five per cent. solutions. With the twenty five per cent. solution the average time for disappearance of bacilli after disappearance of membrane was 6.8 days, a somewhat better result than with bichloride or salt solution, but it was very noticeable that the pseudo-membrane treated with the stronger solutions of pyrozone lasted much longer than would be expected from the severity of the disease, and certainly much longer than in those cases where the five per cent. solution of pyrozone or the salt or bichloride solution was employed. Out of 16 cases treated with the twenty five and twelve and one half per cent. solutions of pyrozone ten had membrane from ten to sixteen days, while in another quite bad case traces of the pseudo membrane persisted for twenty-three days.

The average time from first appearance of diphtheritic

membrane to the disappearance of bacilli in the twenty-five per cent. cases was 17.75 days, this not being quite as good a record as that made by the bichloride solution, and about the same as that made by the water irrigation. As all the pyrozone cases received, as mentioned before, thorough washing of throat and nose before and after treatment with the spray, the results as shown in the tables would certainly indicate that the addition of spraying strong solutions of peroxide to the treatment with plain water irrigation had no good results. On the contrary, it would seem from the long continuance of the diphtheritic membrane in those cases treated with the twenty-five and twelve and one half per cent. solutions that they acted as an irritant to the already inflamed mucous membrane.

The five per cent. solution caused no noticeable irritation. The pseudo membrane disappeared in the usual time, and it would certainly appear to be the best strength (if any) to use for this purpose.

Among the twenty cases on the bichloride treatment, one, a boy four years old, developed mercurial stomatitis in quite a severe form, and another showed symptoms of intestinal irritation; both of them were undoubtedly caused by swallowing bichloride solution during irrigation, as they had not been given internally mercury in any form. Both soon recovered after the cessation of the bichloride irrigation.

Laryngeal cases have not been included in this list, as the treatment tried in these cases could have no possible effect upon membrane or bacilli in the larynx. In six cases in which these three tests were tried, it apparently had no effect whatever, the bacilli being found in the larynx from thirty to forty days after admission to the hospital.

Since the tabulation of the cases in this report was made, I have had two cases in which the Klebs-Loeffler bacilli persisted for twenty-nine days and forty-eight days respectively after disappearance of membrane. These cases received the bichloride irrigation treatment as described above, until all signs of the bacilli had disappeared. This would make the average number of days for the persistence of the bacilli after disappearance of membrane and the entire duration of the disease about the same in the bichloride cases as in those where no antiseptic was used.

The results obtained in the special series of forty cases treated with plain or salt-water irrigation are similar to those obtained in over six hundred other cases treated in a like manner; while frequent and careful experiments with nearly all the well established antiseptics have given practically the same results accomplished by the pyrozone and bichloride of mercury in this series of experiments.

The conclusions derived from this series of cases, together with investigation and observation on a much larger number of cases, lead us to believe:

1. That frequent washing of the air-passages attacked by diphtheria lessens the duration and amount of diphtheritic membrane.

2. The addition of antiseptics, in sufficient strength to be germicidal, to the irrigating fluid is irritating to the mucous membrane, thereby causing extension and persistence of false membrane rather than the effect desired.

3. The addition of antiseptics to the irrigating fluid is liable to cause systemic poisoning and disagreeable complications from the swallowing and absorption of some of the fluid used, *e.g.*, the two bichloride cases cited above.

4. Spraying the throat (also the pernicious treatment of swabbing), whatever solution is used, can have no good effect, as the parts reached by the spray must necessarily be very limited, excepting possibly in the hands of an expert. Furthermore, the spray cannot be used with young children, as anyone can testify who has tried it. This is especially true of some solutions where it is necessary to use a glass syringe.

5. Frequent cleansing of the throat and nasal cavities with a bland solution, such as plain warm water or normal salt solution, is easier of application, is more agreeable to the patient, and does all that any antiseptic solution can accomplish, either upon duration of the membrane or the period of isolation.

A CONTRIBUTION TO THE STUDY OF MODERN AMPUTATION.

By W. L. ESTES, A.M., M.D.,

DIRECTOR, PHYSICIAN, AND SURGEON-IN-CHIEF OF ST. LUKE'S HOSPITAL, SOUTH BETHLEHEM, PA.

THE writer had occasion to search for some recent statistics of mortality-rates after major amputation, and he was disappointed in finding very few available contributions from American surgeons to this formerly very prominent and important, but now somewhat neglected, branch of surgery. Improved methods of conservatism have reduced very largely the necessity for amputating limbs, but aseptic practice and bloodless methods have also so reduced the mortality rate after amputation, that statistics of the older writers are obsolete and useless as standards of comparison, and misleading to students of surgery.

This study, based upon the statistics of a single operator, working in a modern hospital, and who has endeavored to carry out as strictly as practicable aseptic, and especially bloodless, methods, is offered as a contribution to what must still remain a very important branch of surgery, with the hope that it will stimulate other surgeons to report their results in this line, and so re establish the prestige of American practice in acute surgery.

This study is based upon 294 single major amputations, 38 complicated cases requiring two synchronous operations, 7 triple, and 1 quadruple operation, making altogether 340 major amputations.

Only 19 of these were amputations for pathological or diseased conditions, so that there were 321 amputations done for injuries to limbs, usually the result of great violence, as they were all cases from the railroad, mines, or factories. In many of the cases there elapsed several hours between the time of the injury and the reception of the patient at the hospital, and commonly they had to make pretty long journeys to reach the hospital.

In considering the conditions requiring amputation, pathologic conditions will be left out entirely, and only conditions resulting from violence will be considered.

Conditions Calling for Amputation.—Esmarch[1] very pithily sums up the whole matter, in speaking of injuries in war, by saying: "The removal of a limb is, as a rule, only indicated when by so doing the prospect of saving the life of the wounded is rendered essentially better than by the conservative treatment." I believe one would do well to follow this rule in civil practice also. Aseptic practice has made conservative attempts much safer than in former years, however, and conservatism ought therefore to be given a much wider range than formerly. Evulsion of a limb, of course, admits of no question. Compound fractures, if the bones were badly comminuted, formerly called for amputation. Now they rarely do, unless too great a length of bone be implicated, and unless the soft tissues have suffered severe laceration. It is my rule to attempt to save a limb if not more than two inches of the principal bone is comminuted. In attempting to estimate whether or not the soft tissues have undergone too great injury for any conservative attempt, I think the muscular laceration should receive less consideration than the degree of injury to the skin. I have over and over again saved limbs having comminutions of the bones, and bad lacerations of the muscles, but only slight injury to the skin. I have very rarely succeeded in saving a compound comminuted fractured limb having slight lacerations of the muscles, but extensive injury to

[1] Surgical Handbuch, p. 277.

the skin. I have found that one or two lacerations of the skin are not particularly hurtful; it is the complete death of the skin through immense pressure, as the weight produced by the pushing of a car-wheel, or heavy beam, or stone. If all the muscles at a given level are pulpified, amputation is of course indicated. As to whether injury to a principal vessel or system of vessels calls for amputation in a case of compound fracture in every instance, I should say decidedly—no. Serious injury to the femoral vessels or brachial vessels high up, by a compound fracture, usually requires amputation, but one system of vessels in the forearm or leg may be entirely destroyed at a given level, and yet the limb be saved. The following case will illustrate: A man about thirty years of age, of stout build, while plastering a ceiling of a public building, lost his balance and fell from his scaffold to the floor, a distance of some ten feet; he came down on his feet in a standing position; his right leg gave way and he fell in a heap on the floor. He was picked up bleeding profusely, his right foot turned outward so that the sole was in the position of extreme talipes valgus. He was brought as soon as possible to the hospital. On examination it was found that the tibia was projecting through the skin and his drawers on the antero internal aspect of the leg, at the level of junction of middle and lower thirds. This fragment of bone was large, with sharp jagged spicules projecting. The skin had been lacerated almost half the circumference of the leg at this point, but by the sharp fragment, which occasioned very little contusion; the anterior tibial vessels were torn and bleeding. The fibula was fractured about the same level. Upon enlarging the wound and investigating further, the tibia, for two inches, was found comminuted. These fragments were removed, the anterior tibial vessels tied, and the ends of the principal fragments squared off. By a lineal incision over the fracture of the fibula this was exposed, two inches of the fibula removed to correspond with the tibia, and then both bones were wired. The shortening of limb threw the soft tissues up in a transverse rounded ridge. The man made a good recovery with a perfectly useful limb.

Compound dislocation of a large joint is stated by Ashhurst, and indeed by most older writers, as an imperative call for amputation. I have treated compound dislocations of all the large joints of the limbs, except the shoulder, conservatively, with excellent results. These compound dislocations are usually accompanied, in the cases I have seen, by fracture of at least one, or a part of one, of the bony surfaces of the joint. It is necessary, as a rule, to remove the small fragments of bone, but unless the principal vessels are torn, or the greater part of the circumference of the skin killed by pressure, I should never amputate primarily.

Great contusion and laceration of muscles, without fracture of a bone and little injury to the skin, I have found very rarely require amputation. Certainly no primary amputation should be done. The important point is to relieve the immense tension of the skin on account of the hypodermal effusion of blood and serum, by immediate multiple punctures of the skin, in order to drain away the effused fluid. No drainage-tubes should be used, nor should even a strip of gauze be employed as drain—only canalization—as the least local pressure will usually cause necrosis of the already badly nourished skin, and from this point infection is apt to occur.

Injury to the skin without serious injury to the deeper tissues, I have never found call for amputation. Sponge grafting and, if need be, skin grafting, after separation of the necrosed skin, usually avails to bring about a useful healing.

Whenever there is a question as to the advisability of an amputation, or any reason to doubt that an amputation is actually necessary in a given case, there is very little danger in postponing the operation, in the meantime keeping the extremity in an aseptic condition by thorough surgical cleanliness and perfect drainage. Of 132 complicated fractures of the bones of the extremities which I have treated in the last eleven years, most of these compound comminuted fractures, associated commonly with other serious injuries, 113 were cured, 6 improved, and 12 died; 1 unimproved, as he refused to be operated upon and left the hospital. Of the 12 deaths one died of delirium tremens, one had also fracture of three ribs and injury to the lungs, besides a fracture of the humerus and extensive lacerations of the scalp. One had also a fracture of the ilium and dislocation of the sacrum; one had head injury and cerebritis, of which he died; one died of apoplexy. So that only seven deaths could be charged to the complicated fractures directly. Two of these died of septicæmia. Both cases persistently refused amputation until they were thoroughly autoinfected. One hundred and four of these cases were complicated fractures of the lower extremity; of these 88 were cured, 5 improved, and 11 died; 28 were complicated fractures of the upper extremity; 25 were cured, 1 died, 1 improved, 1 unimproved (left the hospital).

Thirty six of these cases were operated upon conservatively, that is for the purpose of removing pieces of bone, uniting fragments, etc. Thirty were cured, limbs restored to full usefulness, 2 improved, 2 required amputation afterward. One of these died after the amputation, of septicæmia. This man refused absolutely to have his leg amputated at first. It was clearly a case for amputation, as all the soft tissues were badly comminuted as well as the bones. The conservative operation was done as a forlorn hope. The other case requiring amputation was done on account of the coincident injury to the axillary vessels resulting in a thrombus of the vessels.

One died of cerebritis following a head injury received at the same time. So that, except in the one case of septicæmia (which was the result of the obstinacy and ignorance of the man, and ought not to be classed as a case of conservative attempt), there was no death which could be laid to the conservative attempts, and 30 positive cures.

Schede, in Pitha and Billroth's "Handbuch der allgemeinen und speciellen Chirurgie," Zweiten Band, Zweiter Abtheilung, p. 25, quotes Volkmann as saying he (Volkmann) had treated 75 complicated fractures of the large bones of the extremities conservatively, without a single death; and Schede himself (vid. ibid.) treated 37 cases conservatively with only one death, due to delirium tremens, and fat embolus of the lungs. Volkmann was obliged to amputate in three of his cases, and Schede in four of his, for beginning gangrene.

Having settled the fact that an amputation must be done, the next point to determine is when shall the operation be done; that is shall it be done as soon as practicable after the injury, or shall it be postponed for several hours? In my opinion this point should be determined entirely by the condition of the patient when seen by the surgeon. It seems to me the height of bad judgment, in this day of aseptic methods, to amputate a limb when the patient is almost moribund from loss of blood, or nearly exhausted from a long rough journey, or not yet recovered from psychical or primary shock. In short, whenever a patient is almost exhausted for any reason soon after injury, I have found that a major amputation undertaken at once is usually followed by death. I have convinced myself, at least, that the condition ordinarily observed by the surgeon a few hours after a major injury, and usually called shock, is really a condition of acute anæmia.[1] To operate while a patient is in this condition, as a rule, is followed by the death of the patient. If, however, the hemorrhage be thoroughly controlled by Esmarch's tourniquet, applied over the crushed tissues if practicable, and if not practicable, applied at a point just above them, and the comminuted tissues and the uninjured parts of the limb thoroughly cleaned and disinfected, and an antiseptic dressing applied over all, the amputation may be deferred for twenty-four or thirty-six hours, or even longer; while by

[1] See Lehigh Valley Medical Magazine, January, 1894.

careful feeding and stimulation the patient may recover some strength, and the blood-vessels shall again have time to fill with fluid. Of the three cases of hip-joint amputations I have done for injuries, each patient was so nearly exsanguinated when the hospital was reached that no radial pulse, or a bare flutter of a pulse now and then, could be felt, and the patient seemed actually moribund. By the treatment suggested above, the amputation was deferred in two cases for thirty hours, and in the other case forty hours, and all of them recovered after the amputation. The former classification of (1) primary, (2) intermediate, and (3) secondary amputations, has lost much of its significance. Now intermediate amputation refers rather to deferred (simply element of time) operation. The former terrors, suppuration, septicæmia, and pyæmia, are rare; so that in my experience a so-called intermediate amputation is no more dangerous than a primary one.

If the patient is in good condition I believe the proper time to operate is immediately, as nothing is usually gained by waiting.

The next point is, Where shall the amputation be done? The former rule and dictum of the authorities, to operate as far away from the trunk as practicable, has met with some modification, since the almost universal use of prothetical apparatus after amputations. It is generally conceded that it is best to leave as much as possible in amputating the upper extremity at any point. With the lower extremity there are certain "points of selection." In a painstaking and well-written paper read before the National Association of Railway Surgeons in 1891,[1] Mr. Truax argues against all tarsal or medio-tarsal amputations; he gives scant license to Symes's amputation, and finally selects the junction of the lower and middle thirds of the leg as the point of selection when an amputation can be done so low down. As this is the product of long observation and experience as a manufacturer of prothetic apparatus, the opinion deserves some consideration. Mr. Truax argues, however, from the premises that tarsal amputations are followed, as a rule, by a condition of pes equinus, on account of the contraction of the tendo Achillis unantagonized, or at least not "balanced," by the extensors. Furthermore, he states that the stumps of tarsal or medio-tarsal amputations are usually painful. Counting the double amputations, I have had 12 Chopart, and 7 Hay amputations; all of these 19 stumps have been painless stumps, and have generally preserved useful extension. I cannot admit Mr. Truax's premises, and therefore think his argument worthless with reference to this point. If the well-known fact with reference to the bearing of a false leg be remembered, namely, that the weight does not come on the end of the stump, but on the sides of the extremity a little above the end (as an obtuse wedge fits into a conical cavity), one will not go far astray in fashioning his stump. If he remembers that the false limb must owe all its motion to the stump, he will be convinced that as long an extremity as is necessary for good leverage should be left whenever practicable. I quite agree with Mr. Truax that the upper part of the lower third is the preferable point for amputations of the leg, when it can be done; 75 of my amputations of the leg have been at or near this point. I feel convinced as much of the thigh as possible ought to be left in amputating above the knee, but when at all practicable, the knee-joint amputation, I think, should be employed if an amputation must be done as high up as the upper third of the leg. The mortality rate of amputations at the several points below the knee are so nearly the same, that this factor has no practical weight in determining the point of amputation.

Indeed, my experience corresponds with that of Volkmann's and Billroth's clinics, namely, that the danger of an amputation is not so much the region (the locale of the operation) as the size of the limb at the point of amputation. An amputation through the thigh of a small, weazened, dried up man, whose thigh may be so small that it can almost be spanned by the fingers of one hand, is not nearly so much of an operation, nor nearly so dangerous (the general condition of the patient being good), as an amputation through the calf of a big, well-muscled, and well developed man. I believe, therefore, that the increased danger of an amputation of an extremity near the trunk is due chiefly to the fact that the area of the dissection, the bulk of the severed tissues, is so much greater there than farther away. The reason of this is, of course, the larger the limb the greater the traumatism of the operation, more blood-vessels, more nerves, and more muscles are cut. Also, the larger the area of the wound the greater the danger of infection, and the more difficult is it to make the operation thoroughly aseptic, and to make the tissues fit well together and to drain perfectly.

Method or Technique of Amputation.—The first and most important point is to establish an aseptic condition of the limb at and about the point selected for the seat of operation. This is sometimes an extremely difficult thing to do, in many instances almost impracticable. In cases of individuals who are habitually dirty, and who have been mangled on the railroad, in a mill, or in a mine, filth, grease, coal, and sometimes soiled clothing, are fairly ground into the tissues. To make such a wound surgically clean is impracticable. It is my custom, in cases of injuries, to have all clothing removed as soon as the patient is in a condition to bear this, after reaching the hospital. The patient having been carried first into a reception-room, near the operation-room, but separated from it by a hall, the assistants begin at once to cut off all his clothing, and to remove each article separately in such a way as not to rub against nor into the lacerated tissues if it can be avoided. The nude patient is then covered by a clean blanket, and the crushed extremity, which has been temporarily dressed by the ambulance surgeon before his arrival at the hospital, is now inspected and is washed, first with the German green soap and hot water, then carefully shaved, and again washed with the soap and water, then rubbed off with alcohol, and then thoroughly washed and rubbed with 1 to 1,000 sublimate solution, and then gauze thoroughly wet with 1 to 1,000 sublimate solution is put over the laceration or wound of whatever kind, and the limb at the point selected for the amputation also encompassed in this wet dressing. Then the patient is taken on a clean stretcher, with only clean blankets over him, to the operation-room, and put upon the operation-table, and covered by a fresh relay of blankets used only for the operation room, and those brought in with him are taken away. All instruments having been previously arranged and sterilized, the patient is now anæsthetized, and during this time the operator and assistants carefully wash, brush, and sterilize their hands and nails. As soon as the patient is anæsthetized an Esmarch's band is applied as a tourniquet, the blood being driven back by raising the extremity for a short time, rarely by the Esmarch band applied from below upward, as this bruises already injured tissues. Hæmostasis accomplished, the limb is isolated and protected from the other limb and other surroundings by pure gum tissue and sterilized towels, and only the seat of operation left uncovered. The temporary covering is now removed and another thorough scrubbing of the limb at the seat of operation is done with alcohol or turpentine, and then with a 1 to 1,000 solution of sublimate. If the patient has been very dirty and there was a large accumulation of dead epidermis on the extremity before it was shaved, I believe with Lister that carbolic acid penetrates the epidermis better than sublimate solution, so I commonly use a five per cent. carbolic solution as well as the sublimate for a final disinfection. During this last sterilization or disinfection, the wound is kept sedulously covered and bandaged by wet sublimate dressings, as it is regarded as hopelessly infected in most cases, and except the washing and douching it gets in the reception-room, no fur-

[1] See Transactions National Association of Railway Surgeons, 1891.

ther attempt is made to clean it when an amputation is to be done.

As to the operation itself, there are in my judgment and practice two cardinal points only to be regarded: first, the flaps must be long enough and wide enough to cover the stump thoroughly without tension; and second, there must not be any hemorrhage. As a matter of fact, like most operators, I have learned to have preferences as to the kinds of flaps to be employed and the manner of forming them. I cannot absolutely deduce from my experience, however, that in the ordinary amputation the methods I employ are better than those used by other operators. For the upper extremity I almost invariably use antero posterior flaps for the forearm, and the circular or modified circular for the upper arm. For the shoulder joint I also like antero-posterior flaps, with the anterior flap about twice as long as the posterior. This method enables one to tie the brachial vessels before they are cut without any further inconvenience than a little care in dissecting the inner edge of the anterior flap until the vessels are isolated, ligated, and cut through. It also furnishes good drainage. For the lower extremity, I have rarely used any osteoplastic method in the foot. For working-men I think these stumps require too long a time for healing, and are of doubtful utility afterward. Hay's, Chopart's, and Symes's are my preferences in foot amputations. In Chopart's, and in Hay's, indeed, I have found it of great advantage to leave the extensor tendons long, and to unite them with the anterior flap. This results in preventing disagreeable contractions of the tendo Achillis, and gives freely movable stumps, in extension as well as flexion. In the lower third of the leg, both antero posterior and lateral flaps have given me great satisfaction. I believe that Teale's operation is likely to give trouble by the fact of the long lateral cicatrix it leaves, which is just in line and at the point for pressure of a false limb. In later years I have never used it. I have found the lateral flap method the best for all the regions of the leg. It gives the best drainage, least tension, and results in the most useful stumps. At the knee, and in the lower part of the thigh, long anterior and short posterior flaps I have found best, and nearly always employ. For hip-joint amputations I would employ the Dieffenbach Volkmann method when long flaps could be obtained, and should always tie the femoral vessels before cutting them. When short flaps are to be used I believe the method recommended recently by myself[1] and called the gradual dissection method, the best. This is a modification or amplification of Rose's method. It consists essentially in first forcing the blood up by Esmarch's band, when this is practicable or expedient, else by elevation; second, deligation of the femoral vessels by double ligatures at Poupart's ligament, and incising the vessels between the ligatures; third, gradual dissection of an anterior and posterior flap successively, taking the utmost care to ligate all known vessels before they are cut, and always securing immediately all small muscular branches as soon as they are cut. Exarticulation is performed as in other methods, after hemorrhage is controlled.

I always form my flaps from without inward. I never transfix. The muscles are cut long enough to unite over the sawed bone and at different levels—in order to make a hollow cone—and a periosteal flap is almost invariably used when the amputation is through the shaft of a long bone. The greatest care is used in securing and ligating all vessels, veins as well as arteries. Whenever a point persistently oozes after the tourniquet is removed, and torsion, or torsion and pressure, for a short time does not suffice, this is also ligated. When the medullary cavity bleeds or oozes it is packed with a bunch of sterilized catgut, which is covered in by the periosteal flaps. Catgut is invariably used as ligatures. Recently I have begun to put in provisional sutures of silk, with permanent sutures introduced during the anæsthesia and tied in long loops, and then pack the stumps with iodoformized gauze for twenty-four hours, in cases of persistent oozing, as frequently happens after an Esmarch tourniquet has been on for a long time. The gauze is removed after twenty-four hours and the flaps apposed by the sutures already introduced. In these cases the muscles are always held by the silver-wire quilled suture, which I almost always employ for this purpose. Ordinarily, however, the apposition is accomplished at once, as follows: If there is good reason to believe that the wound is aseptic when the operation is done, no douche is used unless persistent oozing requires it, then hot sterilized water is employed. The periosteal flap is brought down and fitted over the end of the bone; no suture is necessary, as a rule. Then deep sutures of silver wire are passed, beginning about five to six centimetres from the edge of the flap, through the skin and muscles of one flap, into those of the other flap and out through the skin at a point corresponding to its entrance; by means of two short quills, in the shape of a small wooden peg 1.5 ctm. long by 2 or 3 mm. in diameter, the flaps are brought together and the muscles firmly secured, and their surfaces apposed.[1] From two to four of these quill sutures are necessary for the purpose. Then interrupted sutures of silk, lastly a continuous catgut or small silk suture to nicely appose the skin. A small capillary drain of iodoformized gauze is used, for forty-eight hours. Dressings—dry iodoformized gauze and dry sublimated or heat-sterilized gauze. Over all a pad of absorbent cotton, and the dressing completed by a splint to hold the extremity quiet and lessen muscular twitchings.

The table on the following page shows the operations performed, the result, and percentage of mortality. In the list of single major amputations I have not included amputations done for purely euthanastic purposes, in cases of evulsion complicated with other serious injuries, when the patients arrived at the hospital in moribund and utterly hopeless conditions. In the list of double and triple operations, all operations are noted. While in nearly every case the condition of the patient was desperate, yet in none of the multiple operations did the patient die on the table, and I have thought it but fair to include all of them. In the double amputations it has been my custom invariably, in the last few years, to have my senior assistant amputate one limb while I was operating on the other. Thus the double amputations were strictly synchronous. This method saves time, and markedly lessens the quantity of the anæsthetic necessary to be given; this in my judgment is a very important point. It will be noticed that the multiple operations are not always all of them amputations. Whenever it was necessary to do an operation of a gravity equal to another amputation, I have included it as multiplying the amputations. The cases mentioned of lacerations of the scalp, with comminuted limbs, were no ordinary lacerations, but very extensive, and in themselves very dangerous wounds, and the operations for their repair were extensive and more difficult sometimes than the amputation which accompanied it.

Of the deaths following the single amputations, two were from septicæmia. One case had septicæmia when he was admitted, an old-fashioned "intermediate amputation" was done; the patient was in an extremely weak condition when admitted, and he died about five days after the operation, of exhaustion. The other case was the one mentioned in speaking of complicated, compound fractures—who persistently refused to have his leg amputated until he was almost moribund from septicæmia.

A third death occurred from croupous pneumonia fifteen days after amputation at lower third of thigh, when the amputation wound was practically well. Besides these cases but one other case lived longer than two days; it was an amputation of lower third of thigh, complicated by crush of the muscles of the other leg; it died in nine days, of exhaustion. So that, barring

[1] See Lehigh Valley Medical Magazine, January, 1894, and the Philadelphia Polyclinic, March 24, 1894.

[1] This is a modification of Lister's lead-plate suture.

these four cases, all the deaths occurred from exhaustion within forty-eight hours after admission.

LIST OF AMPUTATIONS.

SINGLE MAJOR AMPUTATIONS.	Number of Operations.	Deaths.	Mortality percentages.
Amputations of arm	27	1	3.70
Amputations of forearm	37	0	0
Amputations of foot, Chopart's	7	0	0
Amputations of foot, Hay's	2	0	0
Amputations of foot, Pirogoff's	1	0	0
Amputations of foot, Symes's	9	0	0
Amputations of leg, lower third	47	1	2.12
Amputations of leg, middle third	28	0	0
Amputations of leg, upper third	22	1	4.34
Amputations of thigh, lower third	44	5	11.36
Amputations of thigh, middle third	25	2	8.00
Amputations of thigh, upper third	8	1	12.50
Amputations at hip-joint	7	1	14.28
Amputations at knee-joint	17	1	5.88
Amputations at shoulder-joint	13	1	7.99
Total	294	14	4.76
SYNCHRONOUS DOUBLE MAJOR OPERATIONS.			
Amputation at shoulder-joint, and the other arm, lower third	1	0	0
Amputation at shoulder-joint, and the other arm, middle third	2	0	0
Amputation at shoulder-joint, and the other forearm, middle third	1	0	0
Amputation at shoulder-joint, and a leg lower third	1	0	0
Amputation at shoulder-joint and operation for compound depressed fracture of the cranium	1	0	0
Amputation of both arms	1	1	100
Amputation of arm, upper third, and leg, middle third	1	0	0
Amputation of arm, lower third, and forearm, middle third	1	0	0
Amputation of both forearms	1	0	0
Amputation of both feet, Chopart's	2	0	0
Amputation of both feet, Hay's	2	0	0
Amputation of one foot, Chopart's, and other leg, lower third	1	0	0
Amputation of one foot, Symes's, and other leg, lower third	2	0	0
Amputation of both legs	7	3	42.8
Amputation at knee-joint, and other leg, lower third	1	0	0
Amputation at knee-joint, and other leg, middle third	1	0	0
Amputation at knee-joint, and other thigh, lower third	1	1	100
Amputation of one leg, lower third, and exsection of the other ankle joint	1	0	0
Amputation of one leg, lower third, and other thigh, lower third	2	2	100
Amputation of one leg, middle third, and other thigh, lower third	2	1	50
Amputation of one leg, upper third, and other thigh, lower third	1	0	0
Amputation of both thighs, lower third	2	0	0
Amputation of both thighs, middle third	1	1	100
Amputation of one thigh, middle third, and all the toes of other foot	1	0	0
Amputation of one thigh, lower third, and operation for removing fragments and apposing, and draining of compound fracture of other leg	1	0	0
Total	38	9	23.68
SYNCHRONOUS TRIPLE OPERATIONS.			
Amputation of thigh, lower third, left arm, lower third, and half of right hand	1	0	0

* Died of cerebritis, produced by the injury to head.

One of the deaths after amputation of both legs was from delirium tremens, on the fifteenth day, when the stumps were practically well.

Except one case, a man sixty-five years of age, who had both legs amputated in the upper third, and who died of exhaustion on the fifth day, all the fatal cases were young individuals—all under forty-five years of age, and three-fourths of them were under thirty years of age. A search through the records of my cases shows amputations done on individuals from ten to eighty years of age, and as stated above, only one of the fatal cases was past forty-five years of age. Age seems to have played very little part in contributing to the death rate. It has happened that none of my fatal cases belonged to the feminine gender.

Only one death followed amputation for diseased condition. That was a case of very large periosteal sarcoma of the upper part of the femur, which required amputation at the hip joint. The man refused to have amputation done until he was almost exhausted. He died on the third day after the operation, from exhaustion. His stomach refused to retain any food after the operation, and in his extremely weak condition rectal alimentation was not sufficient to support him.

It is shown by the foregoing statistics, that barring two cases of septicæmia, one of pneumonia, one of cerebritis, and one of delirium tremens—five altogether—all the fatal cases resulted from exhaustion following hemorrhage, and coincident injuries. The most common cause was hemorrhage. In order to make this apparent, and to emphasize the point I wish to make, I must divide my amputations into two series. These amputations were done in twelve years. My observation and study during the first part of this period convinced me that by far the majority of cases of crushes which were brought to the hospital were greatly reduced, in many cases moribund, from acute anæmia (from excessive hemorrhage), and I had been accustomed to operate before any sufficient time was given for the patient to recuperate. I reasoned, therefore, that if by any arrangement injured persons could be saved from excessive bleeding, and, in case of marked acute anæmia, if the operation be postponed for a period of hours in order to permit the patient to recuperate somewhat, results after amputations ought to be better. By far the greater number of injured persons brought to St. Luke's Hospital are transported over the Lehigh Valley Railroad. I had distributed along the railroad, at all the stations, on the wreck-cars, and on all the principal passenger trains, cases containing some simple antiseptic dressings, and especially two Esmarch elastic tourniquets. As surgeon-in-chief of the railroad, I had issued orders that in every case of serious injury, first aid, especially the stoppage of hemorrhage, should be accomplished by means of this apparatus. After this I also made it a rule to defer operating until a patient had thoroughly "reacted," if he was in a very weak condition when he arrived at the hospital. Results began at once to be better. The following statistics will show how much improvement there was. The apparatus has been in use, and the deferred operation method has been employed, during the last six years. The term of twelve years then ought to be divided into two periods of six years each. During the first period of six years there were 114 single major amputations and 9 deaths, giving a mortality-rate of 7.89 per cent. There were 9 cases admitted in hopeless conditions. In the last period of six years, during which the régime has been in operation, there were 180 single major amputations and 5 deaths—2.77 per cent. mortality. There were only four hopeless cases admitted. In the last period there were a larger number of operations, and the mortality-rate reduced almost one-third. Again, in the first series, having fewer cases, there were 9 hopeless cases ; in the last series there were only 4 hopeless cases, less than one half.

The double synchronous operations exhibit the difference in even a greater degree. There were altogether 38 double synchronous operations and 9 deaths, 23 68 per cent. mortality. In the first period there were 13 double operations and 6 deaths, 46.25 per cent. mortality. In the last period there were 25 double operations and 3 deaths, only 12 per cent. mortality. In the first period there were two triple synchronous operations, and both patients died. In the last period there were 5 triple synchronous operations and 2 deaths.

These statistics show 50 per cent. less mortality after amputations since the régime has been in operation. The argument seems to me incontrovertible. I urge, therefore, the saving of blood as the paramount necessity for recovery after major amputations, and in a line with this the immense importance of allowing an exsanguinated patient time to recuperate before attempting to amputate.

After-treatment and Result with Reference to Usefulness of Stump.—In forty-eight hours, usually, the stump is redressed for the first time, and the primary drain or packing is removed. If there has been oozing, or serum retained, then the drainage is continued; if not, all drains are removed and the flaps allowed to come together. After this a dressing once a week suffices. In a week the patient is usually out of bed. Of 100 cases analyzed with reference to this point (all cases for two and a half years taken), the average number of days in the hospital after amputation was 22.6.

There was one case of secondary hemorrhage—a dyscrasic individual; oozed most extraordinarily in spite of the greatest care, and finally a ligature gave way and the stump had to be reopened, clots turned out, and the vessel, a muscular branch of the popliteal, retied. This occurred after an amputation at the knee-joint. The man made a good recovery.

It has been quite impossible to keep track of all cases operated upon. So far, however, I know of only four cases requiring re-amputation. Three of these were in young boys, two having amputations through upper part of the femur and one through upper part of the humerus; developed conical stumps, and exsection of the end of the bone was necessary afterward. The fourth was done for necrosis developing in a compound fractured humerus after an amputation had been done lower down. It was necessary to re-amputate above the fracture. All the cases, as far as I have been able to find out, were able to wear false limbs comfortably, except one case of double amputation. This man's stumps looked typically healthy and well formed, but he said the constriction of false limbs caused him so much discomfort that he preferred to go about without the prothetic assistance. He was quite comfortable when not wearing the false limbs.

Mortality rate after Amputations.—Aseptic practice and the saving of blood during operation, have revolutionized the mortality statistics after amputations. Schede quotes Billroth as having said, with aseptic practice and Esmarch tourniquet, a surgeon should consider himself at fault if he loses a case of uncomplicated amputation, if the patient dies after he recovers from the immediate effect of the operation (writer's paraphrase). In other words, nowadays no patient should die after an amputation, unless he dies from the immediate traumatic effect of the injury or operation. I would go further and say, if a thoroughly bloodless method be pursued, and the operation be not done during the non tolerant stage of acute anæmia, statistics after major amputations ought to be as good as those of abdominal sections, and I believe they will finally be so.

The following statistics are far from complete, and are indeed meagre, but they will serve to indicate a comparison of results which I wish to urge in favor of the methods I have advocated.

Schede[1] gives 321 uncomplicated cases of amputations done after the Lister method of operation, and after-treatment by Socin, Volkmann, and himself (Schede), with a death-rate of 4 4 per cent. Of complicated cases, some requiring double operations and others having multiple injuries, there were 24, and 11 deaths—over forty-four per cent. mortality.[2]

Messrs. C. F. Dent and W. C. Bull[3] give the statistics of St. George's Hospital from October, 1874, to June, 1888, 400 major amputations, and an average mortality of twenty-one per cent.

Mr. A. E. Barker[4] performed 50 major amputations at University College Hospital, from 1876 to 1892—29 for disease and 21 for injury—with an average mortality-rate of eight per cent.

Mr. Frederick Page[5] gives 687 major amputations performed at the Royal Infirmary, Newcastle-on-Tyne, from April 1, 1878, to December 31, 1891, including 22 hip-joint amputations, with general mortality of eight per cent.; 272 amputations for injury, with 12.9 per cent. mortality; and 415 amputations for disease, with 4 8 per cent. mortality.

Dr. A. G. Gerster[1] gives a collection of 43 cases of his own, done mostly in hospitals, with a general mortality-rate of 4.65 per cent.

Ashhurst, in the 1893 edition of his "System of Surgery," gives the following statistics:

MAJOR AMPUTATIONS.

For Diseases.	Mortality.	*For Injuries.*	Mortality.
French hospitals.....	42.87	French hospitals.....	57.98
English hospitals.....	22.67	English hospitals.....	40.98
American hospitals.....	18.60	American hospitals.....	31.95

Wölfler[2] collects 704 uncomplicated amputations done by v. Bruns, Volkmann, Busch, Esmarch, Hunter, and Schede; the general mortality-rate was 15 6 per cent. He gives also v. Bruns's amputations from October, 1878, to October, 1880, 47 cases and no deaths. Also, Busch, 1873–1876, 57 cases, with 3.5 per cent. mortality. Billroth's Klinik, 1877–1880, 68 cases, 5.88 per cent. mortality.

Oberst[3] gives R. Volkmann's amputations at his Klinik in Halle, from 1874 to 1880. There were 73 uncomplicated amputations for injuries, and 10.5 per cent. mortality; 188 amputations for disease, with 3.7 per cent. mortality—a general mortality-rate of 5.3 per cent. Three hip-joint amputations done for injury, all died; 8 hip-joint amputations done for disease, twenty five per cent. mortality. There were 8 double amputations for injury, 3 deaths, and 5 double amputations for disease, no death; 13 cases, and general mortality twenty-three per cent.

My own statistics show, for the whole number of single major amputations, 294, with only 19 of them done for disease, and including seven hip-joint amputations, a general mortality-rate of 4.76 per cent. This is but a little higher than Schede's uncomplicated cases. Taking out the 19 done for disease with 1 death, there were 275 amputations for injuries and 13 deaths, 4.73 per cent.; and in nearly every case there were multiple injuries. Taking the last period, however, of six years, when the cases were exactly of the same character as before, but when hemorrhage was prevented, and when the operation was deferred until the condition of acute anæmia was somewhat relieved, there were during this period 180 single major amputations and only 5 deaths, or 2.77 per cent. mortality; these figures include six hip-joint amputations. This is the lowest mortality-rate I have ever seen reported for a series of 180 major amputations.

The multiple operations and extremely complicated injuries, in 26 cases, resulted in three deaths, 11.5 per cent. mortality. This is a small series of cases—these last—but the mortality-rate is less than the single operations in Ashhurst's statistics.

In conclusion, I beg to say these statistics speak far more impressively and eloquently than I could possibly do for the saving of blood and the conservation of strength.

Hospital Patients Poisoned.—An attempt was made recently to poison the inmates of a hospital in California by putting strychnine into the coffee. Twenty-two patients were poisoned and one man died. The wife of the superintendent was taken sick, but her life was saved. The coffee-pot was examined and traces of the poison were found in it. It is supposed that the work was done by a Chinaman who had trouble with the steward and had been discharged. He had made threats, and it is supposed that he took this means of venting his malice on the inmates.

TUBERCULOSIS OF THE ADRENAL BODIES UNACCOMPANIED BY BRONZING.

By WARREN COLEMAN, M.D.,

NEW YORK.

INSTRUCTOR IN BACTERIOLOGY AT THE LOOMIS LABORATORY.

THE value of this case depends upon the extent and chronicity of the lesion, and upon the fact that adrenal disease was not suspected during life.

The patient was a Danish sailor, thirty six years of age. He entered Bellevue from the Chambers Street Hospital as a case of constipation. Death took place about three weeks later, without any assignable cause. During his stay in the hospital, he attracted attention only as a case of obstinate constipation with marked inanition. The man spoke English imperfectly, and no interpreter could be found. Consequently nothing is known of his previous history, and the history of his last illness is incomplete.

There was marked asthenia without any apparent reason for it. On one occasion an attempt was made to get the patient out of bed, but it had to be abandoned because he complained so much of weakness. There is no mention of any attendant syncope.

He ran a temperature, but the range was low; it not rising at any time above 101° F. The heart action was feeble, and the surface of the body generally gave evidence of a poor circulation. The pulse-rate varied from 72 to 88.

The constipation continued, in spite of vigorous treatment, up to the time of his death. There is no record of an alternating diarrhœa. No vomiting or nausea was present during his stay in the hospital.

He manifested certain derangements of the nervous system The reflexes were much exaggerated; sensation was delayed; and during the last few days of life he became delirious, attempting several times to get out of bed.

At the autopsy the body was found anæmic, but not much emaciated. The heart weighs nine ounces, and its walls are pale. The valves are normal. The right lung is bound to the chest wall by a few old stringy adhesions. The upper lobe contains several tubercular masses of considerable size (1.5 ctm. in diameter), in a state of caseation, while throughout the middle and lower lobes a few small nodules are found. The pleura is adherent to the chest-wall over the apex of the left lung, and there is a large area of tubercular infiltration in the upper lobe which has undergone caseation. The rest of the upper lobe is studded with miliary tubercles. The lower lobe contains a few tubercles in its substance and on the pleura. The bronchial glands are enlarged and are cheesy at the centre.

The left adrenal body weighs an ounce and a half. Its original shape has been lost entirely, it being irregularly oval and somewhat flattened antero-posteriorly. On section it is found to be caseous, and a greenish-yellow pus exudes from several points on the cut surface. All trace of medulla or cortex has disappeared. The cheesy matter has become calcareous at many points. The capsule of the organ is much thickened. The right adrenal weighs only one half ounce, and has contracted down to about one-half the size of the normal gland. It is similar in shape to the left, and contains one large calcareous mass with numerous smaller ones scattered through its substance. Both glands are somewhat nodulated.

The process, as far as the adrenals are concerned, began in the right gland.

The other details of the autopsy are unimportant as regards the present report. Unfortunately, the semi-lunar ganglia and abdominal sympathetic nerves were not removed for examination.

Microscopic Examination.—The left adrenal only was submitted to examination, the right being too calcareous to permit the cutting of sections. The gland tissue has been replaced by amorphous masses showing only the remains of the nodules which originally characterized the process. No trace of a medullary or cortical cell can be found. In the outer portions of the gland, immediately under the capsule and between the nodules, a faint fibrillar structure may be seen with round cells, many of them dead or abortive, filling the interspaces. The appearance is distinctly different from a true inflammatory process. No giant cells are anywhere present, a fact which has been noticed in many cases. The capsule is much thickened and is the seat of inflammatory foci. The inflammation has extended beyond the capsule into the adjacent fat. Two moderately large caseous masses lie in the capsule, and appear entirely distinct from the inflammatory process. The capsule contains numerous small round cells and young connective-tissue cells.

The glands were not examined for tubercle bacilli while fresh, as it was intended to stain for them afterward in the sections. The difficulty, however, experienced in cutting the sections thin forced me to resort to another procedure. I thoroughly scraped the cut surfaces of the hardened gland, dissolved the scrapings in a dilute solution of liquor potassæ, fixed the sediment to slides with the ordinary albumin fixative, and after several attempts found the bacilli. Hence there can be no doubt as to the nature of the process.

The integument and buccal mucous membrane were carefully examined for evidences of discoloration without finding any but the normal pigment deposits.

No sufficient cause for death, aside from the condition of the adrenals, was found at the autopsy.

It is impossible to fix upon the duration of the illness, because the history is so incomplete. The Chambers Street Hospital is merely a reception hospital for medical cases, so the patient was transferred to Bellevue after a few days.

The most important conclusion to be drawn from this case is, that tuberculosis of the adrenal bodies, *per se*, though both glands be entirely destroyed, is not productive of skin discoloration.

According to Wilks,[1] "we have no data by which to determine the time necessary for the deterioration of the capsules. It is probable that this is very lengthened, and judging from the cretaceous deposit, it is fair to conjecture that the disease is extended over many years."

There can hardly be any question as to the seat of primary infection in this case. The appearances presented by the adrenal bodies leave no doubt that they became involved prior to the lungs or bronchial glands. Whether the disease in the latter situations was secondary to that in the adrenals, or whether the infection was primary from without, is an open question.

I have examined systematically the adrenal bodies in all the autopsies I have performed at Bellevue Hospital during the last two years, and this is the first instance in which I have found them to be tuberculous, though many of the cases have shown extensive tuberculosis in other parts of the body.

In conclusion, I wish to express my thanks to Dr. E. S. Farrington, formerly house physician on the fourth medical division of Bellevue, and to Dr. F. F. Russell, his junior, for the kindly interest they took in furnishing me with such facts in the case as were at their disposal, and the notes of the autopsy.

5 WEST THIRTIETH STREET.

A State Medical Law in Idaho.—At the session of the Idaho State Medical Society, held in September, the question of a State Board of Examiners was discussed, and a resolution passed urging the legislature to appoint such a board during the coming winter. A committee was appointed to draw up a bill for a medical practice act, after the model of that in force in Washington. Drs. Sweet, Watkins, Moore, Maxey, and Fairchild were nominated to represent the Society upon this board when created.

TUBERCULOSIS OF THE FRONTAL SINUS.

By J. FRANK, M.D.,

SURGEON TO THE COOK COUNTY AND ST. ELIZABETH HOSPITALS,

AND

S. KUNZ, M.D.,

CHICAGO, ILL.

Diseases of the frontal sinuses are of interest on account of their infrequent occurrence. In the past fifteen years there have been ninety-five cases reported, the analysis of which will follow.

Family history of the patient: The father, who is sixty-eight years of age, was not expected to live when thirty-three, physicians having diagnosed his case as pulmonary tuberculosis. The mother is fifty-eight years of age, and in good health. Two brothers; one of them well, the other had, about five years ago, some lung trouble; diagnosis of same not known. Two cousins died of tuberculosis.

Patient's history: Twenty-eight years of age, married, 5 feet 8 inches tall, and weighs 160 pounds. Has always been in fairly good health up to a year ago, when he began to lose in weight, had severe headaches, lasting for a day or two, recurring every week, the intervals being entirely free from any ill feeling. He continued in this way for three months, when he complained of the pressure of his hat across the forehead; he would frequently tilt his hat back and thereby gain relief. Three months later he consulted a physician for some growth on the left side of the forehead, which lasted three weeks. At about the same time the patient noticed a swelling in the region of the right frontal sinus, which caused him incessant pain. Hot fomentations, nasal douches, and anodynes were given, with no apparent relief. On the morning of June 16th, the patient noticed that his right eye was partially closed, and the upper lid was inflamed and painful. Dr. Frank was then requested to see the patient, who found, in addition to the above-mentioned facts, that the right eye was pushed downward to a slight extent; vision was not impaired. On outer right side of nose there was a faint blush creeping gradually toward the inner canthus, and mingling there with the redness of upper lid. The patient had a temperature of 100½° F.; pulse, 96. Kidneys and heart, negative; fingers are clubbed. About meatus urinaris, a tubercular ulcer was found, which healed promptly upon application of europhen. The lungs on auscultation revealed vesiculo-bronchial breathing; rhinoscopic examination gave negative results. A mild anodyne was given, and the patient was kept under observation. Four days later he was again examined, and in palpating the upper lid a fluctuating mass was discovered in the region of the lachrymal gland. Temperature was 100° F.; pulse, 96. Operation was advised, and on June 26th was performed in the presence of Drs. Verity and Edmunds, and assisted by Dr. S. Kunz. A curved incision was made, starting about half an inch to the left of the glabella, and extending to a point half an inch posterior to the external angular process, the incision being made down to the bone and one-fourth of an inch above the eyebrow. The pericranium was found thickened, the tissues having been pushed back, and the bone over frontal sinus being roughened. The sinus was opened with a hammer and chisel, and in the sinus there was found a yellowish cheesy mass, which was removed with a sharp spoon. On the posterior wall of the sinus there was found a focus, which had almost gained access to the vault. This focus was removed by the sharp spoon, and a small portion of the dura was all but exposed. At the right lower angle of the sinus, a small channel was found, which, upon being followed out, led the way to the fluctuating mass in the upper lid. The tissues now being pushed over the supraorbital arch, the fluctuating mass was reached, and was found to be about one drachm of yellowish pus, coming from the frontal sinus by means of a small channel on the inner surface of the frontal bone already described. The supraorbital arch was found diseased throughout its entire extent; four foci were found, which had undergone cheesy degeneration. The entire arch was chiselled away, the soft tissues being thoroughly scooped; the right nasal cavity was also scooped out through the frontal sinus by means of a small spoon. The sinus was packed with iodoform gauze, extending into the right nasal cavity, and the wound sewed up with interrupted silk sutures.

The wound was entirely healed on the eighth day, with the exception, of course, of the part immediately above the sinus. The air sinus lasted to the eighteenth day, when it also closed up. The patient felt free from pain from the day of the operation, and his temperature was normal after the first day of operation.

Anatomy of the Frontal Sinuses.—The frontal bump, as it is termed, does not exist in childhood, as the tables of the frontal bone do not separate until after puberty. Absence of the bump, even in middle age, does not necessarily imply absence of the sinus, since it may be formed by a retrocession of the inner wall of the skull. An adult, especially an elderly person, may have a large frontal sinus, without any external indication of it. A very prominent bump does not necessarily imply the existence of a large sinus, or even a small one. The bump may be a mere heaping up of bone, a degradation, as is often found in Australian skulls.

The cavities are larger in men than in women, the left being commonly the larger. They are lined by mucous membrane, and communicate with the nose by the infundibulum and occasionally with each other by apertures in their septum.

In the ninety-five cases reported, we find the following etiological factors: Mucocele, 24 cases; abscess, 51, 3 of them being double; fracture, 1; foreign body, 1; injury, 1; exostosis, 1; osteoma, 7; tumors, 3; cholesteatoma, 1; polypi, 2; periostitis, 1; cyst, 2.

In the cases reported as mucoceles, is it not possible that some of them at least were of tubercular origin? Had the contents of the sinuses been examined for bacilli, tuberculosis of the frontal sinus would be more often heard of.

Through the kindness of Dr. T. Gramm, the bone chips from the arch were examined for bacilli, the cheesy masses and foci having been accidentally lost; although no bacilli were found there seems to be no doubt about the diagnosis, from the character of the cheesy masses found in the sinus, from the cheesy foci in the bone, from the yellowish pus found in the cellular tissue of upper eyelid, and from the history of patient.

The various methods of operation are about the same, with the exception of the drainage, vulcanite rubber or soft rubber being used oftenest, but where these were used the air sinus remained for a long time, some even necessitating a plastic operation for their closure, the average length of time of duration of air sinus being about eight weeks.

CHOLECYSTOTOMY AND CHOLECYSTECTOMY FOR STONE IMPACTED IN THE CYSTIC DUCT.

By MAURICE H. RICHARDSON, M.D.,

VISITING SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL; ASSISTANT PROFESSOR OF ANATOMY, HARVARD MEDICAL SCHOOL.

THE two following cases seem of sufficient rarity and interest to be placed on record, for in a somewhat extensive experience in the surgery of the gall-bladder the writer has seen only those in which the symptoms depended upon the impaction of a single large stone in the cystic duct, and in which the diagnosis was so obscure that movable kidney was supposed to be present by several diagnosticians. In both cases the distended gall-bladder, which could be felt through the abdominal wall, was so tense and so movable as to suggest very strongly a floating kidney. In one case the symptoms were caused by a large stone, the removal of which, owing to its long and firm impaction in the cystic duct, was accomplished only by complete extirpation of the gall-bladder and cystic duct. In the other the stone was detached, after prolonged efforts, through the gall-bladder itself. In both cases a very gratifying recovery followed.

CASE I.—Tumor in the right side of the abdomen suggesting movable kidney; absence of pain and of other symptoms of biliary obstruction; tumor found to be dilated gall bladder, with large stone impacted in the cystic duct; cholecystotomy; cholecystectomy; recovery.

Mrs. W. C——, aged thirty-two, was admitted to the Massachusetts General Hospital on June 9, 1894. She was brought to me on May 10, 1894, by Dr. Zatæ Longsdorff-Straw, of Manchester, N. H., with the following history. Has had five children, the youngest aged three and a half. She was well up to a year and a half ago, when slight irregularities in menstruation began. With each period there was pain and tenderness, suggesting a mild localized peritonitis. During the past year there have been three severe attacks of what seemed to be a localized peritonitis with symptoms referred at one time to the right, at others to the left hypochondrium. In one of these attacks there was general distention and tenderness. In December, 1883, Dr. Straw discovered a kidney shaped tumor, somewhat movable, in the right side of the abdomen at the level of the umbilicus. The tumor was supposed to be a movable kidney. No surgical interference seemed advisable. During the next few months there was a rapid increase in the size of the tumor; it grew more tender and more movable, at one time extending toward the right groin. The idea of a tubal pregnancy was for a moment entertained. The mobility was so great that the tumor could be pushed well over to the left side of the abdomen. No constitutional disturbance complicated the condition, though there was marked local pain and soreness. There had been some loss of weight.

I found a small oval, tender, non-fluctuating tumor in the right side, under the liver, at the normal position of the gall-bladder. At first it seemed very evidently a movable kidney. Under prolonged and repeated examinations the fundus of the tumor was found to move in the arc of a circle about the attachments of the gall-bladder.

In this case the question of movable kidney was first considered. With the patient in dorsal decubitus a movable tumor could be felt in the right renal region. It could be grasped between the hands on deep inspiration, slipping upward apparently into the usual position of the kidney on loosening the digital grasp. The slight force necessary to retain the tumor between the fingers caused some complaint of pain. In the erect posture nothing could be felt. The urine was normal. Repeated examinations showed that the tumor could be moved in all directions about the normal position of the gall-bladder. This kind of mobility, differing materially from that of a movable kidney, suggested strongly a dilated gall-bladder, especially since the other physical characteristics were not incompatible with the latter condition. The absence of jaundice did not vitiate the diagnosis of obstruction to the cystic duct, nor did the normal urine preclude the possibility of movable kidney. Perhaps the strongest sign in favor of the gall-bladder as the seat of the disease was the direction in which the tumor could be moved. In a slightly movable kidney the only variation in position that can be detected is the downward dislocation. If the kidney can be moved into the epigastrium its downward displacement will be found excessive. In gall-bladder dilatation, on the contrary, the fundus will be found no farther from the centre of attachment in one direction than in another. That the kidney should wander farther in the downward direction than in the upward is natural, considering the viscera which hinder upward displacement. In the shape and size of the tumor, too, there are points of difference, though they may not be always present. An oval shape, smooth and uniform walls, absence of hilum, etc., favors the gall bladder. In spite of every precaution, however, it will be found at times difficult to distinguish between the two conditions, and preparations must be made to meet both at operation.

The diagnosis was made of an obstruction in the cystic duct. On opening the abdomen in the right linea semilunaris, over the tumor, a very large gall bladder, distended almost to bursting, was found. The contents were removed by aspiration until the lax and distended walls of the gall-bladder were easily delivered through the wound. The cause of the trouble was found to be a large stone impacted in the cystic duct. The fluid in the gall-bladder was perfectly colorless, the biliary pigments having been absorbed, as is usual in cases of long-continued obstruction at the cystic duct with dilatation of the gall-bladder. With one finger of the right hand

in the gall-bladder, and with the fingers of the left outside the duct, prolonged efforts were made to dislodge the stone. This proved impossible, however, although the calculus could be plainly felt both inside and outside. I was therefore finally obliged to lay open the duct and to detach the stone through the wound. The roughened surface of the calculus was so intimately connected with the changed structures of the duct that it was even then hard to lift the stone from its bed. It seemed best, therefore, in view of the great laceration of the parts, to remove the gall-bladder and duct entirely. This was done by passing a ligature about the duct just below the incision through which the stone had been removed. A small gauze drain was placed next the ligature and the external wound was closed, except for about an inch. This patient made a rapid recovery, and was discharged on July 21, 1894.

Case II.—Paroxysmal pain in the hepatic region, without jaundice, for three years; tumor; cholecystotomy; removal of great numbers of stones from the gall-bladder, with one large stone impacted in the cystic duct; drainage; recovery.

Mrs. S. B. M——, aged twenty-five, trained nurse for Dr. Donnel Hughes, of Philadelphia, who was present at the operation. Examined on July 13, 1894. First suffered from cramps in the stomach three years ago. They were transitory and seemed of little importance. At first the attacks of pain returned at intervals of several months, but within the last six they have occurred frequently — often seven times in two weeks. When suffering from the pain, which is always located in the right side, the patient is doubled up; relief has been obtained only by the use of morphine. After the cessation of this distress or agony there is a transient soreness which extends into the back. There has never been any jaundice. The exact region of the gall-bladder was indicated as the seat of pain.

On examination I found on the right side below the margin of the ribs and opposite the cartilages of the ninth and tenth, a tumor oval in shape, hard, tense, unfluctuating, movable, and tender. From physical examination alone it would have been impossible to distinguish between a tumor of the gall-bladder and one of the kidney if it had not been for the two following facts: first, the presenting rounded extremity of the tumor moved through the arc of a circle, the base of which was somewhere near the usual attachments of the cystic duct; secondly, the urine was perfectly normal.

The pain, described as transitory and resembling colic, was quite as suggestive of renal as of cholecystic disease. The peculiar kind of mobility was not incompatible with a floating kidney, although it seemed to me more like the mobility of a dilated gall-bladder than like that of a movable kidney.

The patient was advised to submit to operation, and she entered St. Margaret's on July 29, 1894. Under ether we obtained a much more satisfactory examination, by which almost all doubts as to the nature of the disease were dispelled. It was very evident that the tumor was a gall-bladder and not a kidney.

Assisted by Dr. Brewster, I began the operation by a small incision at the cartilaginous border of the ninth rib, along the outer border of the rectus abdominis. The tumor immediately presented itself in the wound, with the sharp edge of the great lobe of the liver, and it proved to be the gall-bladder. Its walls were tense and very much thickened. The presenting extremity was sewed into the small abdominal wound, and the gall-bladder was opened. A large number of gall-stones of all sizes, with a clear, viscid fluid, were washed out. The state of distention, with the altered character of the fluid, made it very evident that there was an impediment in the cystic duct, though no stone had been removed large enough to cause so firm and so effective an obstruction. Nothing could be felt in the cystic duct, with the finger in the gall-bladder. The parts were carefully dried by means of aseptic gauze, and the stitches by which the gall-bladder had been attached to the abdominal wound were removed. Explorations with the finger in the peritoneal cavity then revealed a large stone deep down in the cystic, near the common duct. By bimanual palpation the stone was slowly and with difficulty started from its bed and delivered through the gall bladder. Very soon after the removal of this stone the colored bile from the gall-bladder showed that the cystic duct was now patent. The gall-bladder was again stitched to the wound and drained by means of rubber tube and sterile gauze.

Though the prognosis seemed almost hopeless to some of those who were present, the patient made a rapid recovery, without a single unfavorable symptom. She was discharged well in three weeks, and on August 31, 1894, she wrote as follows: "I am getting along very, very nicely, and feel better than I have felt for years, and am gaining every day. I haven't an ache or a pain, and my side is entirely healed, and there is scarcely any soreness inside."

In these cases the diagnosis was interesting. The correctness depended more upon the situation and the kind of mobility than upon anything else in the physical examination or in the history. An interesting point in connection with these cases is the character of the fluid. In the first and only previous case in which I had noted this symptom[1] the gall-bladder contained about a quart of perfectly colorless, limpid fluid. Whether this fluid is decolorized bile or simply the accumulation of secretions from the mucous membrane I am unable to say. In view of the fact that in most cases of obstruction with jaundice the bile is thick and dark in color, it would seem that the presence of such fluid indicates a complete and protracted shutting off of the gall-bladder from the biliary passages. At all events, the existence of this symptom is a very clear indication that there is a complete obstruction in the cystic duct. With an obstruction in the cystic duct, however, it does not follow that there is not also an obstruction in the common duct. This combination was illustrated in the case of C. C. R——, above referred to, in which the disease proved to be cancer of the head of the pancreas extending into the region of the cystic duct, obstructing the latter as well as the common duct.

In operating upon a distended gall-bladder the subsequent manipulations are very much facilitated by aspiration. In both the cases reported it was very hard to feel the stones or to examine the cystic duct when the tumor first presented itself. On withdrawing a few ounces of fluid, the collapsed gall-bladder could be brought into and out of the wound with the greatest facility. The subsequent manipulations were, therefore, very easy and simple, even to the ligation of the cystic duct.

These cases, which perhaps in some respects may be deemed difficult, both as to diagnosis and as to surgical treatment, recovered without any untoward symptoms.

Operations upon the gall-bladder undertaken when the patient is in good health, before the obstruction has extended so as to check the escape of bile through the common duct, and before the patient's vitality has been impaired by prolonged illness, are followed by the most brilliant and gratifying results. Undertaken for prolonged jaundice, however, especially when it is necessary to remove from the common duct, a stone of the size, roughness, and fixity of that in Case I., these operations are inevitably attended by a very considerable mortality.[2] As in the removal of the vermiform appendix when there is neither local nor general peritoneal extravasation the mortality is practically nothing, so in operations upon the gall-bladder before the severity of the local condition requires the more formidable surgical manipulations, and before the long-continued impactions have resulted in the presence of pathogenic bacteria and the infection of the biliary passages, the results are gratifying in the extreme.

[2] Vide paper by J. W. Elliot in the Boston Medical and Surgical Journal.

The deplorable results in gall-bladder surgery which are sometimes unjustly placed at the door of the surgeon arise from our failure to heed the warning of the disease in its incipiency—in our neglect to remove the source of future disasters at a time when the procedure may be accomplished with very slight danger. Hence it seems to the surgeon folly, in cases of repeated and persistent biliary obstruction, to attempt the removal of gall stones by medicinal means. Sooner or later in most cases a stone gets impacted in one place or another. It grows, becomes rough, and not easily detachable, and finally, if it does not cause death by sudden rupture into the peritoneum, the grave symptoms to which it gives rise convince even the most conservative of the necessity of an operation—an operation which then must be done under the most unfavorable conditions, and with a prognosis infinitely graver than in the early days of the disease.

EPILEPSY—AT TIMES A BLADDER REFLEX.[1]

By HUGH K. AIKEN, M.D.,

LAURENS, S. C.

If you consult any work upon the subject of the "Causes of Epilepsy" the first statement you meet will be that heredity plays the most important part as a predisposing cause. Then follows the well-authenticated fact that peripheral irritation of various kinds will inaugurate and keep up the paroxysms. There is also a group of what we may call central or systemic causes producing the epilepsy that follows diphtheria, scarlet fever, malaria, tertiary syphilis, strong mental impressions, as excessive joy, grief, or anger. All these factors and others have by trustworthy observers been reported as first producing the disease. But most interesting of all the foregoing is the study of those cases in which epilepsy stands out clearly as a reflex, and while cases the result of reflex irritation from several organs have been recorded, the writer has never seen attention called to this particular reflex as a causative agent of any importance. The few cases to be cited would at least seem to prove that sometimes, when otherwise unable to account for the seizures, investigation in this locality might be successful and thus some light be shed upon what would else remain obscure.

There may be some who will regard as superfluous any further contribution to the literature of a disease of whose symptomatology we already know so much and whose etiology is so varied. But our treatment remains painfully deficient. The criticism of such readers reduced to few words is always "If you have not some new remedy to offer us, be silent." Such critics overlook the fact that the mastery of etiology is the first step to satisfactory therapy. Finding the cause and removing it is the ideal of scientific practice.

Reading a journal article recently on "Suprapubic Cystotomy," I was struck by the following, which I will call

Case I.—"A. M. W——, aged twenty-one. Ten years ago this patient was suddenly attacked with an urgent desire to urinate, which he could not explain. This irritation has persisted ever since. Three years after the onset of this attack he became subject to epileptic seizures, which would occur about once a month and in some manner seemed to be associated with his vesical trouble. . . . Since the latter has been relieved the convulsions have ceased."

This extract reminded me of a personal experience which constitutes

Case II.—Miss E. C——, aged thirty-eight, had been ill eighteen days with typhoid fever. I had, in a perfunctory manner, been examining the bladder daily and never found it distended. In the middle of the night I was hastily summoned, and informed that my patient was having convulsions. She had two after I reached her. Briefly described they were as follows: Coincident with a momentary loss of consciousness a wave of muscular spasm would pass over her, and then in an anxious tone she would ask, "Doctor, what is the matter with me?" I was puzzled. Groping about to find a cause, I felt over the bladder region and found the organ full. The catheter was used at once. She had no more convulsions, nor has she had any since. No antispasmodics were given.

What were these epileptic explosions if not the result of irritation of the hypogastric or sacral plexus?

Case III.—Muscroft reports a case of stone in the bladder which gave rise to epilepsy and a cure followed its removal.[1]

If phymosis causes infantile paralysis, may not irritation of the vesical nerves give rise to epileptic seizures? I do not lay claim to any great discovery in connection with the cause of epilepsy, and only record my limited observations as a working hypothesis by means of which something more valuable may perhaps be brought out. The modesty and diffidence with which I would advance this view will, I hope, save me from the rapacity of those fierce critics who delight to prick each little balloon labelled "Theory" just to see the gas escape.

If occasionally epilepsy be due to irritation about the bladder, this fact should be borne in mind, and this is all I would insist upon. I feel ashamed of our boasted advances in therapeutics every time a case applies for treatment. Every unrelieved sufferer from this disease is a reproach to our profession, and if we are ever to cure the morbid condition the energies wasted in the search for some new compound that will act as a specific must be diverted and applied to finding the cause at work in each case as it comes to us. In long-standing cases the best I have ever been able to do is to lessen the severity and decrease the frequency of the attacks by the use of sodium bromide, and while this is given in the smallest dose that will accomplish the purpose, even then I am deranging my patient's stomach and impoverishing his blood by the forced ingestion of an excess of alkali.

Trephining has not achieved the results at first expected from it. The cicatricial mementos of youthful exploits have been carefully excised and buttons of bone removed. At first, he who was before "possessed of a devil" went his way and perhaps sinned no more, but after one or two years the insidious petit mal returned.

Some hold that an operation of any sort upon an epileptic produces a temporary improvement in his disease. Tincture of horse-nettle will do very well to sell at three dollars per pint, as an enterprising (?) practitioner in Indiana advises me he is willing to do, but I have never seen any considerable number of cures to its credit. The profession would, no doubt, appreciate any further evidence in its favor from Dr. Napier, of Blenheim, S. C., who first called attention to this agent as a remedy. We are all too prone to prescribe a palliative and dismiss these unfortunates with the reflection that it is a case of idiopathic epilepsy and beyond the reach of curative effort. If we would associate the ideas of irritation and epilepsy, and search diligently for a cause in every case, removing it, where possible, the number of idiopathic and inexplicable cases of epilepsy would be reduced. There is irritation somewhere and somehow brought about but not always connected with a scar. Having seen the explosion, work back, following the fuse until we reach its beginning. There sit and watch until you see what it is that applies the spark, reasoning backward from effect to cause.

[1] Read before the Laurens County Medical Society, July 24, 1894.

Dr. Sathianadhan, the first and only native woman novelist in India, died recently at the age of thirty-one. Her parents were Marathi Brahmans; she herself was a Christian and the first woman to study medicine at the University of Madras. Her first book was entitled "Saguna," a picture of a high-caste girl's home life; another, called "Kamala," has just been published.

THE MANAGEMENT OF VALVULAR HEART DISEASE, WITH PARTICULAR REFERENCE TO THE USE OF STRYCHNINE.

By L. HARRISON METTLER, A.M., M.D.,

CHICAGO, ILL.

VALVULAR diseases of the heart all require about the same line of treatment. So long as compensation is complete and the accompanying hypertrophy or dilatation does not give rise to any very marked secondary symptoms, medicines should be withheld entirely, and none but general instructions given in regard to rest, diet, and hygiene. I do not deem it wise, as some authors do, to inform the patient, at this stage of his trouble, of the seriousness of his condition. The effect is apt to be depressing, and therefore deleterious, whereas no immediate benefit is to be obtained. From the treatment and instructions given he will soon enough suspect the nature of his malady, and the hope born of uncertainty will induce him to follow directions more closely than the despair awakened by a gloomy prognosis. I make it a rule always to inform the family. If, at the solicitation of the family and the patient himself, I am obliged to tell him the real state of his condition, I do so most guardedly, making the prognosis as reasonably hopeful as possible, but not belittling in one iota the nature of the cardiac lesion. Only in this way is confidence established, and in certain cases a foundation laid for the proper observance of the treatment deemed necessary.

Of the first importance is rest. Nothing so recuperates a tired heart as absolute rest. This does not mean merely to lie down whenever the feeling of exhaustion is experienced, but to keep regular hours in regard to rising and retiring; to regulate the daily exercise so that it falls short of producing weariness; to adopt the proper kind as well as amount of exercise; and to furnish the mind with congenial entertainment. A man may declare that he gets abundant exercise by walking in the open air all day in connection with his business. There is neither pleasure nor variety in that sort. An hour's stroll over the rolling ground of a park in company with a congenial friend, with mind free from business cares, will do more than a day of the former kind of exercise. Gymnasia are to be very cautiously recommended, for they are frequently badly ventilated, and competition with the other attendants is liable to lead to over-exertion. Any form of out-door sport may be approved of so long as no sudden or violent movements are required by it. The stomach must never be overloaded, and the nutrition must be kept at its maximum; hence frequent small meals rather than heavy dinners are to be commended. Fats, sugars, and succulent vegetables are to be indulged in very sparingly. The nitrogeneous, albuminous foods are the best. As a rule, I find that patients do better when they take as little fluid into the system as possible, and abstain entirely from all kinds of stimulating drinks. The following case illustrates the benefit derived from the observance of general treatment alone:

CASE I. *Mitral Regurgitation.*—J. P——, boy, twelve and a half years of age. Family history excellent. Has had none of the severe diseases to which all children are liable. Three years before he first came to me, June 24, 1893, he had his first attack of acute inflammatory rheumatism. The ankles, wrists, and other joints were successively swollen, painful, and immovable. The mother says she treated the child herself, chiefly with external applications. Every succeeding winter he seems to have had similar attacks, in some of which medical attendance was engaged. Immediately after his first attack his heart began to trouble him. At any time, most frequently at night, so as to arouse him out of his sleep, he will experience a sharp, intolerable, lancinating pain about the region of the heart, but never down the left arm. Sometimes this pain lasts half an hour, disappearing as suddenly as it comes. At the same time pains start up all over the body, chiefly in the neighborhood of the joints. These pains are of an aching character. The heart then beats laboriously and violently, so that he feels as though "it would beat out of his body entirely." He suffers continuously from a slight headache. For the last three years he has not been able to lie on his left side without bringing on an attack of cardiac pain and shortness of breath. There seems to be no dyspnœa under other circumstances. Respiration and digestion are as yet unaffected. Appetite is ravenous and bowels move regularly. Micturition is normal. Urine is pale yellow, feebly acid, specific gravity 1.028, with an excess of urates and earthy phosphates, no albumin, no sugar. The pendent parts of the body, such as the lower abdomen, are slightly erythematous. Passing the finger-nail firmly over the skin produces a white streak which slowly disappears before the returning redness. The feet are at all times slightly swollen and cyanosed. When the hands are allowed to hang down for some time they also become slightly swollen and congested. Hearing and eyesight are good, and there is no congestion of the conjunctivæ. He is very regular in all his habits, but has been indulging in violent exercise, such as base-ball, and drinking freely of tea and coffee. By a former physician his family was told that "something was growing over the heart." Upon inspection I found the left side of the chest decidedly larger than the right, and the intercostal spaces less distinctly marked. The area of cardiac dulness was considerably increased and the apex-beat of the heart remarkably pronounced. One could see it thumping against the thoracic wall like a caged creature striving to get free. Palpation revealed an irregularly acting, throbbing, violently beating heart. The pulsations were jerky and apparently performed with much effort. Upon careful auscultation I could distinguish nothing abnormal in the action of the tricuspid and semilunar valves, but the sound of the mitral valve, heard most distinctly near the apex of the heart, consisted of a coarse, grating, troubled murmur. It resembled a churning noise occurring synchronously with each systole. The second sound of the heart was sufficiently accentuated. The radial, femoral, and temporal pulse were all feeble and irregular. It would have been an unnecessary cruelty to have told this young lad the real state of his condition and its probable termination, though the parents were fully advised of the same. He was a sensible boy, and having won his confidence I had no difficulty in getting him to follow my instructions. As soon as he began to moderate his exercise, to study and lead a more sedentary life, to avoid all stimulants absolutely, and to live upon a plain, nutritious, dry diet, the cardiac pain diminished and left him almost entirely, the heart's action became steadier, and he lost his former expression of distress and anxiety. No medicines whatever were given, and up to the last time I saw him he was still doing well.

When, as a result of beginning failure of the compensatory hypertrophy of the heart with over-dilatation, attacks of dyspnœa and vertigo become troublesome, and other secondary symptoms begin to make their appearance, I find that strychnine in small and frequent doses steadies the heart's action in the happiest manner. The appropriate general tonic treatment with iron, arsenic, and vegetable bitters must not be neglected, but used in conjunction with the strychnine. Sometimes I have seen the strychnine assisted most materially by the so-called heart tonics, such as digitalis, strophanthus, and convallaria. The following case, kindly referred to me by Dr. Henry M. Lyman, illustrates what has just been said:

CASE II. *Mitral Regurgitation.*—Mrs. S. D——, aged about fifty-seven; mother of several living children. Family history good. Prior to marriage and in early life health was excellent. Never had any prolonged severe illness, but has suffered a number of attacks of acute and subacute rheumatism. At present there is general weakness, præcordial distress, nervous irritability, and some emaciation. Patient suspects heart trouble, but has never been told (fortunately, I believe) the seriousness of her condition. There is a

slight cough with occasional attacks of dyspnœa. Digestion is troublesome; tongue clean and red; bowels irregular. There is a constant tendency to diarrhœa. Constipation sometimes causes much distress. Vertigo with slight headache is not uncommon. The liver is enlarged and jaundice occasionally makes its appearance. The action of the kidneys is as yet but little affected. The hypostatic condition of the lungs produces shortness of breath and favors attacks of capillary bronchitis. Of these attacks she has now had several. The last while under my care, and from which she is now convalescing, was the severest she ever experienced. The cough was incessant, hard, and racking. Fever was high; pulse small and rapid. There was pain in the chest, extreme shortness of breath, and loud râles heard both anteriorly and posteriorly. Complete heart failure seemed imminent a number of times, a disaster which was only averted by the free use of hot poulticing and stimulation, together with the administration of such cardiac tonics as ammonia, digitalis, strophanthus, and convallaria. For the happy outcome of this attack not a little credit is due a good, careful nurse. The patient suffers occasionally from hysterical melancholia, for which the valerianate of ammonia is given. When convalescence began, the patient having been several weeks in bed with the present attack, I began using the tincture of nux vomica, but soon changed to strychnine and general ferruginous tonics. Almost immediately the improvement became pronounced and rapid. The cough diminished, the pulse grew stronger, the heart beat more steadily, the nervous excitement and distress were greatly allayed, and the appetite and digestion increased. Only small doses of the strychnine were employed, such as $\frac{1}{50}$ to $\frac{1}{60}$ grain three or four times a day. Soon I dispensed entirely with the digitalis, strophanthus, and convallaria, and depended upon the strychnine alone. When the patient began to go about the house she was advised to take maltine, with strychnine, quinine, and iron, which has continued to act as a most efficient tonic. She is now able to attend to her household duties, and is as well as could be expected with her heart trouble. Having tried many remedies and travelled both in Europe and California in search of health, she is naturally overjoyed at having found something that gives her greater comfort than she had yet experienced. She has gained somewhat in weight, is less nervous, and, as her friends tell her, looks better. I attribute the result chiefly to the strychnine, as I have seen it act similarly in other cases. Of course all these heart cases sooner or later fail to respond to any medicine or plan of treatment; the end is then close at hand.

In the text-books and general literature I find very little reference made to the use of nux vomica and its alkaloid in valvular disease of the heart. In view of my own experience with it, acquired during the last three years, I am not a little surprised at this. Digitalis is still the remedy *par excellence*, when the heart flags so as to produce alarming dyspnœa and beginning dropsy; but all authorities agree that this remedy should be withdrawn as soon as its beneficial effects have been secured. Even strophanthus must be discontinued after a time, though its administration may be continued longer than that of digitalis. It is singular that authorities do not recommend the use of nux vomica and its alkaloid at this stage of the treatment, when the heart, having regained its tone under the influence of the digitalis or strophanthus, is so liable to relapse unless supported by a steady and gentle stimulant. Flint says that "nux vomica or strychnia appears, either directly or indirectly, to have a tonic influence upon the heart," and there he dismisses the subject.

Loomis, writing upon mitral reflux in Pepper's "System of Medicine," asserts that "small doses of quinine and strychnine, alternating with the administration of iron, are often of service." Bartholow suggests the use of nux vomica merely for its stomachic effect. Fagge, as well as many other authors, does not even mention it as a heart tonic. As most of these patients are anæmic and debilitated, every remedy that will strengthen the general system and improve the nutrition will have a most beneficial effect upon the heart. There is universal agreement, therefore, that chalybeates and stomachics are always useful. As digitalis disturbs the stomach and interferes with digestion, it is evident that it should be avoided as much as possible. A steady, continuous support afforded the heart and its nutrition, is far more desirable than the use of "digitalis and active hydragogue purgation repeated from time to time." In regard to this all clinicians are of one mind; but there seems to be a lack of opinion in regard to strychnine as a direct heart tonic and stimulant favorable in these cases. Other things being equal, the nutrition of the heart is better conserved by a steady, continuous, gentle stimulation, such as is afforded by small doses of strychnine, than by an occasional powerful propulsion produced by digitalis and its congeners. The former better favors the nutrition of the heart muscle, while the latter, prolonging the diastole, only occasionally gives the heart-muscle a rest. There can scarcely be any doubt about nux vomica and its alkaloid being a heart tonic. In the words of Bartholow, "increased action of the heart has been experimentally demonstrated to be caused by strychnine." It has been proved that in large doses strychnine prolongs the diastolic pause and augments the force of the systole, and that these results are due to an action on the cardiac ganglia and on the pneumogastric. The blood-pressure and rapidity of the blood-current are increased by contraction of the arterioles. In overdose the heart is arrested in tetanic rigidity. These effects are all similar to those produced by digitalis. The latter, however, is not a general tonic, but rather the reverse, whereas nux vomica in small doses may be administered a long time with the happiest results to both the heart and general nutrition.

Though far advanced toward a fatal issue, the compensation having long been ruptured, the following case illustrated up to the very moment of death the benefit derived from the use of nux vomica.

Case III. *Mitral Regurgitation.*—H. G. T——, aged sixty-six, married, two children living, and one dead of pulmonary tuberculosis. Family history neurotic and tuberculous. Patient was much exposed to hardship during service in the Mexican War. Denied specific disease. Up to the time he entered the army his health was excellent. Twice during campaigns he suffered severe attacks of rheumatism, chiefly in the arms. On account of exposure and the intense heat, he was several times returned to the hospital with severe diarrhœa. His bowels have been weak ever since. Later on he was unsuccessfully operated on for external bleeding piles. He is now troubled with costiveness. When he first consulted me, January, 1893, he was suffering from a great deal of headache and vertigo. When he arose in the morning his sight was blurred. He had frequent attacks of nausea with a desire to vomit. Digestion has always been bad. Has never used tobacco or stimulants of any sort. There was a constant hard cough and much difficulty with breathing. There was no pain, but a good deal of præcordial distress. He said he felt as though his lungs were "filled up;" had no appetite whatever, and felt exceedingly weak. He was obliged to sit up most of the night to feel at all comfortable. Micturition was difficult, but not so bad as six or seven years ago, when he had to catheterize himself. The patient was pale and emaciated. There was no swelling of the arms and legs, though the abdomen was slightly enlarged. Dropsy had not shown itself yet to any very marked extent. The liver was enlarged, the lungs congested, the conjunctivæ red. Eyesight and hearing were good. The scrotum was slightly enlarged with hydrocele. Upon inspection and palpation the apex-beat of the heart was violent and lower than usual, while the area of cardiac dulness much increased. With the ear over the cardiac apex, could be heard a loud, rough, grating sound. At none of the

valves except the mitral, could I distinguish a murmur. The mitral murmur, however, was pronounced and associated with systole. The second sound of the heart was feebly audible, though not sharp. The pulsations were irregular, tumultuous, and labored. The radial pulse was the same in both arms, though markedly irregular, like that of the heart. Examination of the urine revealed nothing abnormal, but a trace of albumin. The present attack began two weeks prior to my first visit, and had come on very gradually. About ten years ago the patient fell suddenly to the floor in an unconscious state, and was thereafter confined to his bed for a month. A year later he had a severe attack of vertigo without unconsciousness, which also caused him to fall. On account of his heart trouble he was unable to attend to his business for the last few years. He was thoroughly acquainted with the seriousness of his condition, so that, in spite of a certain degree of obstinacy and nervous irritability which gave rise to more or less impatience, I succeeded very well in getting him to follow instructions. Absolute rest and a light dry diet were enjoined, while hydragogue cathartics, digitalis, and chalybeate tonics were administered pro re nata. In a couple of weeks he was relieved of many of his symptoms; could lie down and sleep through the entire night; and was able to go out and take a little exercise each day. As soon as I withdrew the digitalis, I replaced it with the tincture of nux vomica or strychnine, to the well-expressed comfort and satisfaction of the patient. Thus he was treated for more than a year, coming every now and then to my office for advice, and doing as well as could be expected. He declared that he believed it was the nux vomica that helped him more than anything else.

Several weeks ago I was hurriedly sent for, and found the patient in bed with a return of all the old distressing symptoms. I had not seen him for a few weeks prior to this attack, and was therefore surprised to note the distressing cough, marked weakness, anasarca of the lower extremities, and the presence of small ulcers in the mouth. The state of the patient was indeed serious, and I so informed the family. The usual treatment with cathartics, digitalis, strophanthus, and convallaria was instituted, but with only slight and temporary benefit. It was clear that the man had taken to his bed now for the last time. In spite of every effort he soon became water-logged, and died quietly in a semi conscious condition on the morning of April 26, 1894. Up to the moment of his death he begged for, and was given, frequent small doses of tincture of nux vomica, as that gave him the most comfort. The widow afterward informed me that, in spite of all entreaties on the part of his family and friends, he had gone to one of the advertising dispensaries of this city, where they promise cures for monthly payments; almost immediately he began to fail, so that he had to take to his bed and send for me a couple of weeks before his death. Death is liable to occur at any time in valvular disease of the heart, but I believe this man's life might have been prolonged a while longer if he had not suddenly broken off, for a much-promising advertised treatment, one which was helping him but not doing it as rapidly as his impatience could endure. While under my care the patient had to resort less frequently to digitalis than he otherwise would had he not taken the continuous small doses of nux vomica which had been ordered him.

My notes record a number of other cases in private practice in which nux vomica and its alkaloid in small doses gave great satisfaction. As a stomachic tonic, a respiratory stimulant, and heart tonic, it fulfils three of the most important requirements in the treatment of valvular heart disease. Under the head of treatment of senile heart, Balfour lauds strychnine as a "most valuable remedy, especially when venous congestion and a tendency to catarrh exist, as is so constantly the case when the circulation is feeble. In a great many cases, even of well-marked senile irregularity, the continuous use of strychnine is sufficient of itself to promote a cure, while it is a powerful adjuvant to digitalis; and the combination of these two drugs often enables the most admirable results to be obtained, quite unattainable by either separately."

What Balfour finds true of the use of strychnine in senile heart, I have found almost equally true in cardiac valvular disease. The prolonged use of digitalis and strophanthus has its disadvantages. The former is supposed to have a cumulative action and certainly disarranges the digestion; the latter is not always effective in relieving the dyspnœa, and is powerless in preventing or removing œdema. Nothnagel says that in a few cases convallaria and adonis vernalis do very well, but that as a rule the so called substitutes for digitalis are of little use. Caffeine is more of a diuretic than a cardiac tonic, and therefore cannot be relied upon alone. Coronilla is slow in its action and is not always certain. One feature of the Oertel treatment I have found of inestimable value in this class of cases, and that is the rigid adoption of a dry diet. In two or three cases a withdrawal of fluid from the diet, as much as could be borne, produced in a short time a noticeable improvement in the dyspnœa and pain. I have allowed milk in small amounts as the only beverage, varying it with kumyss, matzoon, and buttermilk. Remembering the overburdened condition of the circulation, with the attendant dropsy and defective renal function, the use of a dry diet seems to me eminently rational.

In conclusion, my best results in the management of cases of valvular heart disease have been obtained by the following outlined treatment: Physical rest, associated with light, regular, pleasurable exercise; absence of all worry, mental anxiety, and sudden emotion; plain abundant, nutritious diet, dry as possible; absolute avoidance of all stimulants; the use of general tonics and hydropathic measures conducive to the building up of the general constitution. For the heart, the continuous use of small doses of nux vomica or its alkaloid, reserving the more powerful heart stimulants like digitalis for threatened dropsy. In two of my cases I obtained better results from the combination of digitalis, strophanthus, and convallaria than from either alone. In others I have found that either of these special heart tonics alone produced the greatest comfort when assisted by minute doses of strychnine. I believe it is bad treatment to use larger doses of any drug than is absolutely necessary, and ofttimes three to five drops of digitalis with $\frac{1}{100}$ or $\frac{1}{60}$ grain of strychnine will act better than the larger doses of either alone. The use of strychnine alone is, in the majority of these cases, the best for prolonged treatment. I have said but little of the management of such special symptoms as dropsy, dyspepsia, etc.; for these, of course, will require special treatment as they arise. They will present themselves less frequently, however, the more the general health is built up and the action of the heart strengthened and steadied.

Columbus Memorial Building.

The Price of a Physician.—Under the Roman Empire the prices paid for slaves were ruled, as prices always are, by the relations of supply and demand, the capture of a province being followed by a glut in the market, and a consequent fall in value. The value of an ordinary slave without special accomplishments, fluctuated between five and eighty dollars, but that of a physician remained nearly constant, for a long period, at the very respectable figure of $10,000.

Tuberculosis in Domestic Pets.—Dr. Foehner, of Berlin, has examined some seventy thousand sick domestic animals in the past seven years, and of this number only two hundred and eighty-one suffered from tuberculosis. The parrots were relatively the most frequently affected, twenty-five per cent. of those coming under his care being tuberculous. Of the cats, only one per cent. showed symptoms of the disease.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 3, 1894.

ANÆSTHESIA BY ETHYL BROMIDE AND CHLOROFORM.

DR. W. S. MAGILL, of Chicago, describes a new and rapid method of anæsthesia by bromide of ethyl and chloroform (*International Medical Magazine*). The procedure is as follows:

"Everything being in readiness for the operation—instruments in order, the surgeon and aids prepared for immediate action (for the patient will be ready in about one minute if anæsthesia is performed on the operating-table)—draw out all pillows from under the patient's head. Note pulse and respiration, and the time exactly. Opening the bottle of ethyl-bromide, pour a few drops upon the folded towel and pass it over the nose of the patient to accustom him to the odor. Immediately, upon the upper side of the towel, pour out about three grammes of the reagent, and, rapidly reversing the towel, apply it closely to the nose and mouth, so that every inhalation may be taken through its meshes. For a moment the patient holds the breath, perhaps making a slight effort to pull away the towel, at the same time swallowing in rapid succession the saliva which is secreted abundantly. In an instant a long inhalation is made, followed by others, especially if so commanded in a decisive voice by the anæsthetizer, the face becomes red, sometimes violently congested, the eyes fixed, the eyelids frequently difficult to raise with the finger, the lines of the face are drawn, the under jaw firmly set, and a general muscular contraction of short duration may be manifested. After three or four long inhalations the patient has lost all sense of pain or touch, but is still conscious. This is the moment for operation, if ethyl-bromide alone is used. A few grammes again poured on the towel and inhaled result in complete unconsciousness, if not already obtained with the first dose. Time, one-half to one minute and a half; pulse, rapid and strong; respiration, deep, and of about normal rapidity.

"At this moment pour out upon another folded towel about ten drops of chloroform, throw aside the ethyl-bromide, and immediately apply the chloroform towel in the same way. Watch carefully the pulse and respiration. At this time the operation should commence if the patient be already on the operating-table.

"The iris should be carefully watched. At the commencement of the ethyl-bromide administration, from normal contraction the iris dilates the pupil by its relaxation. The dilatation is rapid, and at the moment of analgesia reaches the maximum, and alone indicates the instant to change the reagent. The dose of chloroform indicated above is the first and only strong one; the anæsthesia must be maintained by pouring frequently one, two, or three drops of chloroform upon the towel, which is immediately reversed and applied over the nose and mouth, taking care that the patient has no chance of inhalation during the change."

Dr. Magill finds records of sixteen alleged cases of death from the administration of bromide of ethyl. Six of these he finds were really caused by bromide of ethylene, and of the other ten he finds that only one can be fairly attributable to the ethyl. He adds:

"The practical advantages of successive anæsthesia—the rapidity, the elimination of the disagreeable phases of chloroform or ether which precede or retard recovery from anæsthesia with these reagents, the diminished quantity of the toxic agent required—all these elements of superiority combine to invite the notice and experimentation of surgeons. Its advantages have, on two occasions, been discussed recently at the Société de Chirurgie of Paris—on May 2 and 9, 1894—where Dr. Segond relates its introduction into his wards by Dr. Malherbe, coming directly from Professor Terrier's service. With Segond the method was immediately preferred to all others, and at the meeting of the Society his official statistics of one year's use of successive anæsthesia are given—four hundred and forty-three cases without an accident of any kind. Dr. Bazy related his first acquaintance with the method in the wards of Dr. Brun, and its immediate adoption by him. Dr. Monod spoke in much the same way. Dr. Richelot was already on record as endorsing the method to the extent of preferring it in all cases of heart or pulmonary troubles which might be contra-indications of chloroform or ether.

DANGERS OF PRACTICAL BACTERIOLOGY.

A PRACTICAL but unfortunate illustration of the truth of the old adage that "Familiarity breeds contempt" is shown by the death from cholera recently, in the Hamburg Hygienic Institute, of Dr. Oergel, one of the assistants in that Institution. The facts of the case are stated in great detail, by Dr. Reincke, in the current number of the *Deutsche Medical Wochenschrift*, and would seem to prove that the ill-fated young physician inadvertently swallowed some suspected water which had been sent to the laboratory for examination. And although subsequent bacteriological examination could not prove the presence of the cholera bacillus, it was not at all improbable that the water had become contaminated from cholera cultures with which he had been working.

Knowledge is too often the result of dearly bought experience, and the fact of one such case as this should go far to counteract the opinion, which has been growing apace since the last cholera epidemic, that the comma bacillus is a much-maligned organism, and is really not nearly so dangerous as was its repute. Although Von Pettenkofer and others may believe that cholera organisms may be swallowed with impunity, and Dr. Ernest Hart may avowedly prefer the shelter of a well-directed cholera hospital to any other during the prevalency of this disease, it is a fact notwithstanding that a too intimate association with the vibrios of this dis-

ease is liable to be followed by disastrous and lamentable consequences.

The opinion that no pathogenic germ can act other than in a favorable soil is continually gaining ground; but the fact that a person is apparently in a healthy state is no safeguard. A slight local departure from the norm in some part of the body may give the germ a hospitable point of entrance, and then sinister manifestations rapidly follow.

In the case of Dr. Oergel, general health and resistibility may have been impaired by confining and exacting laboratory work, and chances that were taken with a greater exemption from consequences when in a vigorous condition proved fatal when taken after a period of confining labor.

As Dr. Reincke remarks, it is to be hoped that this sad event may not be without warning to those who would treat the cholera organism with too great familiarity.

ST. LOUIS AS A MEDICAL CENTRE.

St. Louis is just now the centre of a very considerable depression of spirits and harrowing self-analyses. The trouble began when Professor Chaplin, Chancellor of Washington University, said publicly some unkind words about the disproportion between the quantity and the quality of the St. Louis medical colleges. Then an esteemed practitioner of St. Louis, Dr. Thomas O'Reilly, a little later is said to have addressed to the Health Commissioner an eloquent protest against the reckless surgery and the excessive cœliotomic zeal of the much-professored city. The editor of *The Medical Mirror* has been devoting his most alluring alliterations and his elegant and eulogic eloquence to the purpose of refuting all charges and restoring the self-esteem of his justly celebrated townsmen.

"St. Louis," he says, "has been charged with possessing eleven medical colleges, but there are really only six regular schools. And why are there so many as that? Simply because the two oldest medical colleges (both being over fifty years old) were not possessed of a generous spirit in the direction of encouraging and utilizing [illegible]" the awkward terms "lady doctor," "woman doctor," "female practitioner," etc., has been started in the *Glasgow Daily Herald*. "Doctor" indicates the male practitioner; "doctoress" is felt to be inadmissible. "Doctorein," plainly of quasi-German parentage, is suggested. "Doctorein Mary Walker" would be distinctive enough, but slightly clumsy and un-English. The irreverent correspondent thinks it reminiscent of margarine—an objection which may weigh with the students of the Glasgow Queen Margaret College.—*Lancet*.

The Physiological Effects of Cycling.—The physiological effects of cycling have recently been studied by Dr. Blazhevitch, of St. Petersburg, who publishes his results in his "Graduation Dissertation." He tabulates [illegible] or St. Louis in particular should be characterized as a "hotbed of medical anarchy." And we are quite in agreement with the *Medical Mirror* in denying that the charge of "surgery run mad" has any special truth as applied to that locality There has been some reckless surgery no doubt ever since surgery began, and especially since anæsthesia was introduced. There always will be foolhardy people in every class of society, but probably fewer among surgeons proportionately. There has been a wave of zeal for laparotomy which has swept over nearly all parts of the country. It certainly rose very high in New York at one time, as we have often remarked. We doubt if the high-water mark has ever reached an equal point in St. Louis.

We trust that the remonstrances of the *Mirror* will clear the atmosphere and perhaps be successful in condensing the colleges, improving their status, and making of St. Louis what it ought to be, a great medical centre.

WHO IS PROFESSOR ZAKHARIN?

A great many curious stories have been published about the eccentricities of Professor Zakharin, the Czar's physician. His name is not familiar outside of Russia, although Russian medical literature so far as it is valuable is quickly turned into German, English, or French. The conclusion of many of the profession has doubtless been that Zakharin was an errant and eccentric man who had gained position and notoriety rather through his bizarre character than any solid scientific merits. A St. Petersburg correspondent of the *British Medical Journal* says, however, that, though eccentric, the Professor is distinguished by something more than eccentricity. He has the most extensive and lucrative consulting practice in Moscow, he fills with distinction the Chair of Medicine in the University of Moscow, he is the author of "Clinical Lectures," which is a classic in this country; and he has done more, I am assured on the best authority, to raise the status of the medical profession in Russia than any other man living.

We are glad to learn that the Professor is really the leader of medicine in Russia. Still it is remarkable that his fame has heretofore been so local.

News of the Week.

Disappearance of Cholera.—Latest advices announce such a decrease of Asiatic cholera in Europe as to deprive the disease of any further interest this season to public health authorities. For the week ending October 10th, Surgeon Fairfax Irwin, U. S. M. H. S., reports a decline of nearly fifty per cent. in the number of cases in Austro-Hungary, which has been the principal seat of the disease in Europe outside of Russia. In this latter country, also, the decrease has been marked, and the belief is expressed that the advent of cold weather will put an early end to the epidemic. The port of Marseilles has been declared free from the disease, and inspection of vessels has been discontinued; "sporadic" cases continue to occur elsewhere in France, and in Holland and Belgium, but these excite no alarm, and the cholera epidemic of 1894 in Europe is practically at an end.

Dr. George M. Sternberg, Surgeon-General of the Army, received the degree of LL.D. from the University of Michigan at its last Commencement.

The New York State Association of Railway Surgeons will hold its fourth annual meeting at the New York Academy of Medicine, on Thursday, November

15th, at 9.30 in the morning. At eight o'clock in the evening of the same day, there will be a joint meeting of the Section on Medico-Legal Surgery and of the Medico-Legal Society.

The American Academy of Railway Surgeons will hold its first meeting in the Grand Pacific Hotel, Chicago, on November 9 and 10, 1894. The Academy has adopted a motto, which is: "The higher the order of railway surgery, the greater the protection to the employee, the passenger, and the company."

The Mississippi Valley Medical Association will hold its next annual meeting at Hot Springs, Ark., on November 20, 21, 22, and 23, 1894.

The French Public and the Serum Treatment for Diphtheria.—A correspondent of *The Lancet* writes that public interest in the new treatment for diphtheria has taken a very practical form at Paris. The subscriptions now being received for the foundation of an antitoxin department at the Institut Pasteur, whose business it will be to supply the vaccine to the practitioners of France, have reached the total of $51,100. The Budget Commission has, on the proposition of M. Rouvier, voted 100,000 fr. as a subvention to the Assistance Publique for the same purpose. It remains for the Chamber to confirm this vote. The Municipal Council has instructed its special commission to arrange with Dr. Roux for the distribution, at the Council's expense, of serum to different depôts to be created in Paris. The Comité Consultatif d'Hygiène Publique de France, at its meeting yesterday at the Ministry of the Interior, resolved to address a congratulatory letter to Dr. Roux and his illustrious master, M. Pasteur, and also to ask of the Government an annual credit to facilitate the diffusion of the antitoxin. The enthusiasm shown in favor of the movement is extraordinary. For example, a livery-stable keeper offers a horse to the Pasteur Institute to serve for the preparation of the serum. A vote of 10,000 fr. will be proposed at the next meeting of the Conseil Général de la Seine. Numerous prefects of departments having addressed inquiries to the President of the Council, who is also Minister of the Interior, on the value of anti-diphtheric seropathy, the Minister referred the question to the Academy of Medicine, which body named a commission to study the matter. The commission, composed of MM. Bergeron, Proust, Cadet de Gassicourt, and Strauss (reporter), to-day delivered its conclusions, which I transcribe *verbatim*: "Votre commission vous propose donc d'émettre un avis favorable sur l'emploi du sérum antidiphthérique, et de formuler, en outre, les vœux que l'Institut Pasteur soit mis en mesure de faire face aux demandes qui pourront lui être faites, soit par les médecins, soit par les pouvoirs publics."

Monument to Charcot.—The pupils and former associates of Charcot, in Paris and throughout France, are engaged in raising a fund for the erection of a bronze statue of him in the Salpêtrière. This movement is now receiving cordial and material support in Germany, in England, and in Italy.

It has therefore seemed desirable to the New York Neurological Society that the profession in America join in this testimonial.

For this purpose the society has appointed a committee consisting of Drs. Edward D. Fisher, E. C. Seguin, M. Allen Starr, Charles L. Dana, and C. A. Herter, to bring the matter to the attention of the profession and to receive contributions, which will be duly acknowledged and forwarded to the central committee in Paris.

Death of Dr. George W. Moody.—Dr. George W. Moody, of Huron, N. Dak., died of cerebral hemorrhage October 13th, aged forty-two years. He was educated in Chicago, graduating from the Chicago Medical College in 1878. He moved to Huron, Dak., in 1880, and became surgeon of the Central Dakota Division of the Northwestern Railroad. A widow and one son survive him.

Professor Carl Fraenkel, of Marburg, has been elected to the Chair of Hygiene in the University of Halle, rendered vacant by the transfer of Professor Renk to Dresden. Professor Fraenkel will not assume the duties of his new position until some time next year, his place in the interim being occupied by Professor Behring, of the Institute for Infectious Diseases in Berlin.

Hospital Beds for Cases of Appendicitis.—At the last meeting of the Board of Managers of the University Hospital, the Director was authorized to set aside certain beds to be used by Professors William Pepper and J. William White for cases of appendicitis, those gentlemen being engaged in a special investigation of the symptoms, treatment, and pathology of that disease.

Perhaps we will next have special hospitals for appendicitis.

The Practice of Medicine by Women in 1572.—In an address before the Yorkshire Branch of the British Medical Association this summer, Mr. W. H. Jalland stated that York seems to have been ahead of most places in countenancing the practice of medicine by women. In closing his address (*Quarterly Medical Journal*) he says: "I find on reference to the Corporation Minutes dated 1572, Elizabeth XIV., the following entry: 'And for as much as it appeareth that Isabel Warrick hath skill in the science of surgery and hath done good therein, it is therefore agreed by these presents that she upon her good behaviour shall use the same science within this city without let of any of the surgeons of the same.'"

[illegible], in the current number of the *Deutsche Medical Wochenschrift*, and would seem to prove that the ill-fated young physician inadvertently swallowed some suspected water which had been sent to the laboratory for examination. And although subsequent bacteriological examination could not prove the presence of the cholera bacillus, it was not at all improbable that the water had become contaminated from cholera cultures with which he had been working.

Knowledge is too often the result of dearly bought experience, and the fact of one such case as this should go far to counteract the opinion, which has been growing apace since the last cholera epidemic, that the comma bacillus is a much-maligned organism, and is really not nearly so dangerous as was its repute. Al-

The Four Years' Course at the College of Physicians.—In the College of Physicians the new four years' course commences with the present season, but notwithstanding this fact the registration indicates that a larger class will enter this year than last year, when the highest number yet recorded was reached. In the session of 1893–4 the

total enrolment of students numbered 766, a gain of 112 over the previous year. To the development of the four-year curriculum much attention has been devoted by the Faculty. Each student will be examined, each year, upon the work of that year, and each student of the four-year will be required to elect from a list of elective courses either one course or more, as may be hereafter determined.

Mission Hospital in China.—President Seth Low, of Columbia College, and his brother, have just built for and presented to the mission station of the Protestant Episcopal Church in Wuch-ang, China, a well-appointed hospital for the use of the mission and the people of the town.

The New House of Relief of the Society of the New York Hospital, at the corner of Hudson and Jay Streets, was opened for inspection on Tuesday, the 30th ult. It is to take the place of the emergency branch of the New York Hospital, commonly known as the Chambers Street Hospital.

Bellevue Hospital.—It is announced that Dr. Lucius C. Adamson has been appointed to succeed the late Dr. Stuart Douglas in the charge of the insane patients.

The New York Cancer Hospital.—Dr. Charles N. Dowd has been appointed a surgeon to the hospital.

St. Luke's Hospital to be Moved Next July.—At a meeting of the Board of Managers of St. Luke's Hospital, held October 29th, it was stated that an agreement had been made with the purchaser of the hospital property on Fifty-fourth Street and Fifth Avenue, by which the delivery of this property is deferred until July 5, 1895. The work of the hospital will, therefore, be continued without interruption during the coming winter at the present site. The new hospital buildings in 113th Street and Morningside Avenue are being pressed rapidly forward, so that the work of the hospital may be transferred there next July.

"Doctorein."—Wanted, a handy and convenient name for the "lady doctor." A discussion having for its aim the discovery of an appropriate title to take the place of the awkward terms "lady doctor," "woman doctor," "female practitioner," etc., has been started in the *Glasgow Daily Herald.* "Doctor" indicates the male practitioner; "doctoress" is felt to be inadmissible. "Doctorein," plainly of quasi-German parentage, is suggested. "Doctorein Mary Walker" would be distinctive enough, but slightly clumsy and un-English. The irreverent correspondent thinks it reminiscent of margarine—an objection which may weigh with the students of the Glasgow Queen Margaret College.—*Lancet.*

The Physiological Effects of Cycling.—The physiological effects of cycling have recently been studied by Dr. Blazhevitch, of St. Petersburg, who publishes his results in his "Graduation Dissertation." He tabulates 270 observations on 104 individuals of both sexes and various ages, distinguishing between ordinary riders and those who train themselves for, and ride in, races or attempt to cover long distances. He finds that the play of the chest is diminished immediately after riding, especially in the cases of women and children, and of men racing or commencing cycling, the diminution amounting in these cases to from 1 to 1.5 centimetres. In men accustomed to the exercise the effect was scarcely perceptible. The general effect of the summer's riding upon the male votaries of the sport was, according to Dr. Blazhevitch, practically *nil.* In women and children the effect was slightly to increase the vital capacity. The arm power was found to have increased more than the leg power in young persons and in beginners, but in the case of men of mature age who had previously been accustomed to cycling this was not so evident. Speaking generally, the effects of cycling on the system were found to be very similar to the phenomena noticed by Tsymkovski in soldiers who had been running, and by Gruzdeff and Passover as resulting from rowing.

Fin de Siecle Treatment of Gonorrhœa.—Among the numerous suggestions on the treatment of gonorrhœa with which the medical press abounds, none has appeared which is so entirely unique as that presented by Dr. Burnside Foster in a recent issue of the *Journal of Cutaneous and Genito-urinary Diseases.* The method proposed is described as follows by the author: "As soon as may be after we have established the diagnosis of a first gonorrhœa, the patient should be etherized and properly prepared; a buttonhole opening made in the perineum, and drainage of the bladder established. Through a properly contrived apparatus the anterior urethra could then be thoroughly flushed with any antiseptic or cleansing fluid and treated on surgical principles. The details of the local treatment would vary with the fancy of the operator. The feasibility of packing and distending the anterior urethra with iodoform gauze suggests itself to me; but any one of a great number of methods would, doubtless, be efficacious."

Longevity and Drink.—The British Medical Association has been investigating the question of longevity in connection with the use of alcoholic beverages. Deaths to the number of 4,234, taken at random, show the average age of temperate drinkers to be sixty-three years; careless drinkers, fifty-nine years; free drinkers, fifty-seven years; intemperate drinkers, fifty-three years; total abstainers, fifty-one years. The analysis in the case of those who reached the age of over eighty shows that fifteen per cent. were total abstainers, ten per cent. heavy drinkers, and seventy-four per cent. moderate drinkers. Of those who lived more than ninety years, fifteen per cent. were total abstainers, nine per cent. were hard, and seventy-five per cent. moderate, drinkers. These figures must be applied with some caution. A certain large proportion of total abstainers are so, because of some form of ill-health or natural weakness.

The Correction of Urinous Odor.—It is well known that the essence of turpentine gives, when taken internally, an odor of violets to the urine. This fact has been put to good account by a learned professor, who has for some time been in the habit of giving the essence in ten-drop doses three times daily to persons afflicted with incontinence of urine. In a short time the disagreeable odor of the secretion is replaced by the characteristic odor of the violet, to the great satisfaction of those about the patient. The treatment can be continued without inconvenience for several weeks, and is only counter-indicated in gastric catarrh and nephritis.

Clinical Department.

DOSES OF MORPHINE HABITUES.

By L. S. OPPENHEIMER, M.D.,
BARTOW, FLA.

In a recent number of the MEDICAL RECORD Dr. Groom, of Iowa, contributes a note on the case of a lady who was supposed to be taking an extraordinary daily quantity of morphia—thirty grains. My experience is, of course, limited in these cases, but I may safely say that in a general practice of twenty years I have seen not less than twenty persons who were taking a full drachm of morphia every twenty-four hours. The reason that the physician so rarely knows the actual quantity of morphia taken by his patients and friends is because the latter usually try to conceal the fact from everybody, and the druggist who furnishes the article is the only person who can approximate the quantity consumed in the majority of these cases.

A man of my acquaintance, Mr. B. C. T——, has authorized me to use his name in reporting the fact that he to-day began his thirty-second drachm of morphia in thirty days, all purchased from one store. He attends to his daily business about as well as the average business man. This is not a rare case, but is mentioned because of its illustrating the above.

PILOCARPINE IN URTICARIA.

By L. B. McBRAYER, M.D.,
ASHEVILLE, N. C.

On Monday, September 17th, I read your valuable journal of September 15th, and found therein an article by R. Abrahams, M.D., on "Pilocarpine in the Treatment of Acute and Chronic Urticaria."

My little boy, aged two years and nine months, happened to be suffering very badly from this very unpleasant malady just at this time. The wheals would cover his face at times and seemed to have a special liking for his nose, which they would distort terribly. At one time the wheals coalesced until they covered nearly the whole of the posterior surface of the thigh. He had slept very little the previous night, although I had given him two grains Dover's powder. In fact it was the worst case of the kind I have seen. The itching was very annoying. I had cleared the bowels out well, and he had eaten almost nothing for the past twenty-four hours. He had been bathed in solution of soda bicarbonate and several other things, yet he continued to grow worse. After reading the article I gave him on Monday night, at bed hour, $\frac{1}{16}$ grain of pilocarpine muriate. He slept very much better, and on Tuesday morning there was no evidence whatever of the urticaria.

Last night (Tuesday) he slept as well as he ever did in his life, and is perfectly well, and all this with only one dose $\frac{1}{16}$ grain of pilocarpine. I have written this hoping to emphasize the article referred to, and hope that the profession may profit by it.

A CASE OF ORBITAL CELLULITIS ABORTED.

By GUY C. M. GODFREY, M.D.,
FIRST LIEUTENANT AND ASSISTANT SURGEON, U. S. A., POST SURGEON FORT WASHAKIE, WYO.

Private S——, Hospital Corps, U. S. A., aged twenty-two, a large man, dark-complexioned, and of a good family history, had a boil near the outer corner of his right orbit. He had opened the abscess before he came to me, but was alarmed at the condition of his eye. The skin over the orbit was red and the subcutaneous tissue much infiltrated. The lids were swollen and the conjunctiva injected. There was considerable chemosis, and the cornea was beginning to be cloudy. He also had a slight fever. In short all the symptoms of incipient orbital cellulitis. I immediately ordered the boil to be dressed antiseptically and had a wad of cotton placed in the orbit, and over that a snug roller bandage. The patient was then put to bed. In about an hour I had the dressings removed. I then made a free incision downward and outward in the line of a wrinkle, so as to provide for drainage and leave no disfiguring scar. I afterward painted the skin over the entire orbit with a five per cent. solution of nitrate of silver. The abscess was then dressed with powdered boric acid, a compress of cotton was placed in the orbit, and over all a tight roller bandage. The patient was then put on strong tonic treatment. At the end of three hours I removed the compress and found that, though there was still some redness in the skin, the swelling had mostly disappeared and that the chemosis was going down. I again painted the skin over the orbit with the solution of nitrate of silver and had a new compress put on.

The next morning all the signs of inflammation had disappeared. The skin was normal in color except where it was darkened by the solution. There was no chemosis; the cornea was clear and the patient felt much better. The abscess was washed with a solution of bichloride of mercury (1 to 1,000) and dressed with boric acid. The compress was not reapplied, but the tonics were kept up. The patient had an uninterrupted recovery, and has had absolutely no trouble with his eye since then.

This method is easy of application and most potent in results, if the disease is taken early. When the danger of the inflammation travelling along the ophthalmic vein to the meninges is so great, it would seem that the method used in this case would be much better than that of causing pus to form, and then draining through the conjunctiva or through the lower lid.

SYMPTOMS OF POISONING FROM A PROBABLE OVERDOSE OF PHENACETINE.

By FRANCIS E. KNOWLES, M.D.,
SOUTH ORANGE, N. J.

Miss B——, aged about thirty, rather stout, and very healthy, had a severe attack of migraine. She was recommended by her friends to take one of Dr. C——'s magic headache powders, which she did, but obtained no relief, and in about an hour and a half repeated the dose; this also did not produce the desired effect. She was then advised to try phenacetine; she drove down to the drug store, and took ten grains, drinking with it a glass of carbonic water. She drove directly home, about a mile distant from the village, and in a few minutes was taken with a well marked chill. Her friends foreboding evil, I was sent for immediately. On arriving, and before being able to ask any questions, I was told the history of the case as related above. I found the patient prostrated from what seemed to be muscular weakness; there was great cardiac depression; pulse forty per minute, scarcely perceptible at the wrist; respiration was labored and slightly quickened; there was general cyanosis, which was particularly marked at the extremities; cold perspiration; feet and hands were nearly cold; she had an anxious expression, and was trembling from nervous excitement. She said her whole body felt numb. Heat was applied, and the limbs rubbed vigorously, and five-minim doses each of tincture of digitalis and nux vomica in a teaspoonful of brandy were administered every fifteen minutes, to stimulate the heart and respiration. Her condition commenced to improve immediately, and in three hours she felt well again.

I examined one of Dr. C——'s magic headache powders, which of course is a patent medicine, and was satisfied that it contained phenacetine or some other coal-tar derivative. The patient had been used to the homœopathic treatment all her life, and the doses which her allopathic friends prescribed for her proved entirely too large. It has been my experience with people who have had homœopathic treatment for a number of

years that smaller doses will produce their physiological effect than with those whose systems have become accustomed to larger potions.

SIXTY GRAINS OF MORPHINE AT A DOSE.

By M. J. SWEENEY, M.D.,

KANE, PA.

I NOTICED in the columns of your excellent paper of September 15th, under heading "A Large Dose of Morphine," an account of a case using thirty grains a day. The final sentence in that article was "One ounce of P. & W.'s morphia every sixteen days beats the record of any case I ever heard of." Allow me the privilege of establishing a new record. I have under my notice now a case of morphinism, cured by Mattison's method of treatment, who took sixty grains each day, not hypodermatically but by the mouth. When he came to me for relief from his habit, with the story of sixty grains per day, I could not believe it and told him so. I, however, gave him four 15-grain powders, with instructions to take one every four hours, intending to watch the effects of the first dose and be guided accordingly. He deliberately took the four powders, emptied them into the palm of his hand, and ate the morphine like so much flour. To say I was horrified is putting it mildly. I instantly loaded up my hypodermic with a tenth of apomorphine to emetize him, and when he objected I felt like sending for the undertaker at once. His perfect *sang-froid* and smiling assurances allayed my fears a little, so I sat down and decided to watch him, interfering forcibly, if necessary. I was more than surprised, after eight hours' observation, to witness no untoward symptoms whatever. He is entirely off the drug now, in good condition, and I see him every day.

A CASE OF ANOPHTHALMIA DEFECTUS OCULORUM.

By LEONARD LANDES, M.D.,

NEW YORK.

I DESIRE to put the following case on record on account of its great rarity.

About July 1st I was called to see a Mrs. G——, a healthy woman, thirty years of age, who had just given birth to a female child. I found her in no worse condition than ordinarily is the case after a very hard labor, as in this case. She asked me to examine the child, saying it could not open its eyes. I found a perfectly developed child, weight about six pounds. There were eyelids, eyebrows, and ocular cavities, but when I succeeded in opening the lids I found no eyeballs. It was evident that the child was born without eyes. The woman's family history was good, and she had previously given birth to two children; both of them died a few days after birth. Her husband is a healthy-looking man of about thirty-two years of age, but I found, later on, that he had been an inmate of an asylum, having been afflicted with melancholia. He is now perfectly well, and his family history is also good. I took the case to Dr. F. F. Reyling, who kindly examined it for me, and he also concluded that the child was born without eyeballs. Another peculiarity of this child is that it has six fingers on each hand and six toes on each foot. Dr. Reyling tells me that he never saw or heard of such a case before.

Since I have had this case in hand my attention has been called to some other cases of a like character. There is now in the Missouri School for the Blind, at St. Louis, a girl, aged eleven, the daughter of a clergyman, who was born without eyeballs, but with eyelids and sockets well developed. This case corresponds in every respect with the one above recited, except as to the supernumerary fingers and toes. This St. Louis case was examined by Dr. Green, of St. Louis, the celebrated oculist. The report of the school superintendent shows that this child is bright in intellect, she having a very high percentage in all studies.

Dr. V. Condory, of Hot Springs, Ark., has called to my attention a similar case that came to his notice when he was on board the steamship Fatherland, in 1871. Among the third-class passengers, five hundred in number, was a young woman, eighteen years of age, an Israelite, who gave birth to a female child without eyes.

Dr. Edward Frankel, of this city, refers me to what is said on this subject by Dr. Karl Assmund Rudolphi, Professor of Anatomy in the University of Berlin, 1816 to 1840: "Anophthalmia defectus oculorum is found in various degrees; occasionally both eyes, with all the adjunctive parts, are absent, as in cases where the heads of one monstrosity are so joined together that only the occiputs are visible laterally; while on the other hand I have on one occasion seen a well-developed, mature fœtus, which died after birth—case published in the Reports of the Berlin Academy, 1840 to 1850—where the right eye was totally absent, so that there were neither ocular cavities, eyeball, eyelids, nor optic nerve, and the skin was smooth from the forehead to the cheeks; in the brain the thalamus opticus was rudimentary, etc. I have also observed the absence of both eyes in an otherwise well-developed child, in whom the eyebrows, eyelids, and all relative parts, were completely developed."

I have also noticed in Bruneau's "Old French Natural History" a case of this kind in a male child. The child died a few weeks ago. I tried very hard to get an autopsy but did not succeed.

A CASE OF HYDRAMNION, WITH ATRESIA ANI IN THE CHILD.

By FREDERIC H. PLUMMER, M.D.,

PLYMPTON, MASS.

I WAS called at 4 P.M., on September 20, 1894, to Mrs. S——, in labor with her fifth child. On reaching her I found that she had been in labor for three days prior to my being summoned, the pains having been rather weak but wearing. The abdominal examination revealed an enormously distended uterus, and extreme suprapubic œdema. Palpation failed to elicit any definite information as to the position of child, and the fœtal heart-sounds were inaudible. Vaginal examination showed an unruptured amniotic sac protruding through a fully dilated cervix, with breech presenting, but not engaging; after a moment of exploration the presenting part disappeared and its place was taken very quickly by the head. Rectum and bladder were empty, and passages well lubricated and dilatable. Concluding that the case was one of hydramnion, I waited until the head again came within reach, and after the pain subsided ruptured the membranes. I had a Marcy pad under my patient, which quickly filled, but from the hollowing of the bed only a small part of the fluid passed through the outlet, the major part overflowing, soaking a quilt folded under her, and also the feather-bed through to the under mattress. The head engaged L.O.A. after rupture of the membranes and the labor was rapidly completed, the child weighing five pounds. He was extremely cyanotic, and the cord being so short as to prevent my getting his face from between his mother's thighs, I thought best to sever it immediately. Then after I had cleared out the mouth and fauces, and given a few mouth-to-mouth insufflations, the child commenced to cry and breathe. A few drops of urine were voided during his toilet. The mother had rather a free hemorrhage, and the uterus was slow in retracting. Firm manipulation controlled both hemorrhage and relaxation, the placenta being expelled by Credé's method twenty minutes after delivery of the child. On account of possible danger from hemorrhage, the uterus was carefully manipulated for an hour, and then, as contraction seemed good, a binder was applied and the patient's toilet made.

These being the incidents, let me call attention to the abnormal quantity of the amniotic fluid and stricture of the child's intestine. The receptacle beside the bed

contained two quarts of fluid, the folded quilt weighed 12½ pounds as taken from the bed, its dry weight as afterward ascertained being 1½ pound, and there was an indefinite amount of fluid in the feather-bed, probably half as much as was in the quilt. From the quantity collected and the weight of the absorbing materials, we will find that the amount of fluid was approximately twenty pints, which seemed to me to be an unusual amount.

The next morning I found that the nurse (one of the traditional old women who know it all), no meconium having been passed, had administered a dose of castor-oil before my arrival. The next day, the oil being inoperative, I injected half a drachm of glycerine, which brought away a mass about two inches long and three-eighths of an inch in diameter, of a light brownish color, and appearing like a small earthworm folded upon itself enough times to make up the bulk of the mass. This was followed by several small pellets, about the size of split peas, and slightly darker in color than the larger mass. During the day vomiting set in, which soon became dark in color, apparently from containing meconium, and this continued, with increase in number of ejections and darkness of color, till death, on the sixth day.

During this time he lay in a comatose condition, and after third day refused to take any nourishment per orem. Gavage was tried but proved unsuccessful, all ingested matter being vomited almost immediately. The bowels never moved spontaneously, and injections only brought away a few of the small pellets of the same character and color as the first evacuated.

An autopsy was denied, so that I was unable to verify my diagnosis of a stricture of the gut about two inches above the internal sphincter, but think the occurrence of these abnormalities of mother and child make the case of sufficient interest to warrant my reporting it.

I suggested an operation for the making of an artificial anus, but it was refused by the mother, the reputed father having died of phthisis pulmonalis in the early part of January.

A NEW TREATMENT FOR ERYSIPELAS.

By W. V. GAGE, M.D.

M'COOK, NEB.

At the risk of being assailed, after the publication of this article, with numerous letters disputing my claim to originality in the method of handling the above-named disease, I beg leave to call your attention to the treatment of erysipelas with the wet carbolic-acid dressing. The treatment, as far as I know, is original; but I am more than willing that you should demonstrate to me that it is in no way new. Every physician has often experienced a conflict with erysipelas, and has probably many times arrived at the conclusion that his local applications did harm, not much good, or were absolutely inert. Strumpel says, "The chief indications for treatment will be to check the unceasing advance of the disease; but, unfortunately, the means recommended for this purpose too often fail."

Iodine painted over the healthy skin at the border of the inflammation seldom arrests the progress of the local manifestation; and the old-fashioned method with the nitrate of silver pencil is certainly as barren of results. In regard to internal medication, iron has, no doubt, been exhibited more than any other one medicine. Probably no one, however, can state that he has noted any marked diminution in the severity of the disease under the influence of its administration. The same may be said of camphor, benzoate of soda, and salicylic acid.

In the treatment of erysipelas with the wet dressing I have practically discarded internal medication, treating the disease as a local manifestation, which it certainly is; and only in cases where the patient has been treated in a previous attack by the use of both local application and internal medication, have I given some placebo "for the blood." I might add, however, that I have employed sulfonal for sleeplessness and delirum, in some cases, with marked results. For the cure of the disease I rely wholly, however, upon the local use of the wet five-per-cent carbolized dressing. I make my own dressing from the bleached cheese cloth, and the method employed for the preparation of this gauze is so familiar as to need no repetition here. I use a dressing of my own preparation, as the manufactured article which we get in the shops is too dry for the purpose, while that which I keep in my office is put up in a large earthen crock and covered with a five-per-cent solution of carbolic acid. The treatment can of course be applied to any case of erysipelas, but we will take for example a case of the facial manifestation of the disease. If the area of inflammation has encroached upon the line of the beard, the face should be shaven, as should the head if the region of the hair be involved. I have found it best, even though the eyes are not yet affected by the disease, to close them and place over each one a fluffed pledget of the wet gauze. If the ears are involved a small portion of the dressing should be placed back of each one, so that they shall not be pressed against the head by the bandage which is to be applied. Now apply the main dressing, which should envelop the head and face, including all parts which have a tendency to show the blush of the extending disease, being careful to let the dressing extend over the area of redness in all directions. Over the dressing a sheet of rubber tissue or oiled silk should be placed, the edge of the protective lapping well over the edge of the gauze. A bandage is now applied to hold the dressing in place. Care should, of course, be taken to so fix the dressing that the mouth and nasal cavities shall be free, although the eyes are to be covered. You have now converted your patient's head into an object somewhat resembling an Armour ham, but he feels better at once, as the gauze has, by mere contact, removed a considerable amount of heat from the diseased area. This dressing should be allowed to remain on for twenty-four hours, when it is to be removed and replaced by a similar one. I think, if you have never employed a like treatment, that you will be surprised at the marked diminution in the heat and redness over the area covered by the dressing, even after the first twenty-four-hour period. The dressing is to be reapplied as long as the least suspicion of redness of the skin remains.

Compare the last case treated by you with the first one treated by the above method, and notice the difference. Mark the shortening in the course of the disease, and the diminution of all disagreeable symptoms. It is absolutely essential that all signs of inflammation should disappear before the dressing is removed for good, as you will otherwise often be disappointed to notice a return of the disease which you had supposed cured. Better a day too long in a bandage than a repetition of the trouble. In order to satisfy myself as to the efficacy of the treatment, I have, after applying the dressing for twenty-four hours, removed it and left the case without treatment for a short period, on the return call finding, instead of the soft, pale, moist surface, the hot, tense, dusky skin of well-developed erysipelas. I have, up to date, handled eleven cases of the disease after the manner set forth above, and have yet to be disappointed in a single instance. The cases have included, besides the facial type of the disease, three cases of traumatic erysipelas, and I am inclined to think that, if anything, the success of the treatment was more fully demonstrated in the last-named cases than in the so-called idiopathic variety. I would like to receive a report of cases in which there has been a failure to effect a prompt cure after pursuing the wet-dressing treatment.

Preventable Deaths.—A statistician of Moscow has estimated, from a study of the death returns of the States of Europe, that at least forty per cent. of the inhabitants of that portion of the world die of preventable infectious diseases.

MALARIAL INFECTION.

By A. SCHIRMAN, M.D.,
NEW YORK.

During a residence near the Russo Persian boundary beyond the Caucasus it fell to my lot to see a great deal of intermittent fever. Malarial diseases in that region are very similar in their symptoms and course to those endemic in many parts of the American continent. My experience there and elsewhere has led me to regard the presence of potted plants in living apartments as productive of much malarial fever. It has been abundantly shown that this disease prevails often in places which are free from swamps or any bodies of standing water. All that is necessary to the propagation of the malarial poison is a small quantity of moisture in the soil and a vegetable growth in somewhat high temperature. The development of the poison is arrested when the air does not penetrate the soil and when the average temperature is not high. Both excessive dryness and excessive moisture seem to be inimical to the propagation of malaria. The cities of Vladi in the Caucasus, of Susal, where is the grave of Haman, and of Erinan, near Mt. Ararat, and their environs are noted for excessive heat and moisture and a great variety of vegetable growth. During my practice in these cities I often had occasion to observe that malarial fevers were more prevalent on days following a warm rain, and especially among those living in unsanitary dwellings where there were many plants and much decaying animal and vegetable matter. The relation between house plants and malaria was well shown in a case seen by me in Moscow. A woman from the Caucasus, who had always enjoyed the best of health, was taken ill with intermittent fever. She was treated for the fever and soon recovered, but another paroxysm occurred soon after she began to go about the house. After a succession of these attacks I made an investigation. I found that she had a large number of plants in a sitting-room which was well heated but not ventilated. She was very fond of her plants and passed the greater part of her time in this room, but during the attacks of illness remained in her bedroom, which was large and well ventilated. I insisted upon the removal of the plants from the house, and from that time the attacks ceased.

PERMANGANATE OF POTASSIUM AS AN ANTIDOTE FOR RATTLESNAKE BITES, A RECENT CASE.

By F. W. MALONEY, M.D.,
ROCHESTER, N. Y.

About three months ago, a Mr. P. G——was bitten on the right middle finger by a fair-sized rattlesnake which he was handling at the time.

He immediately put the snake back in the cage, and applied suction with his mouth to the wound, this was continued for about fifteen minutes, when he used a strong solution of ammonia. At the end of half an hour the finger began to swell. He tied a string on the finger above the bite, but the swelling continued, in two hours it had reached the wrist; he then removed the string and made an incision through the wound with his pen-knife. After partaking of a large drink of whiskey he set out to obtain medical aid. Not finding the person he desired he went to the City Hospital, where the house surgeon made several free incisions on the finger, hand, and forearm, as by that time the swelling had extended as far as the elbow-joint. The wounds were then dressed with iodoform gauze, and bandaged.

The free bleeding relieved the pain and some swelling. The after treatment was dressings, changed every day for four weeks; when all the wounds were healed he had no constitutional symptoms, as the swelling did not go beyond the elbow-joint.

I read Dr. Moor's article in the Medical Record stating the antidotal properties of permanganate of potassium in morphine poisoning, and a short time afterward another article on a case of snake poisoning treated by permanganate hypodermatically. I suggested the idea to Mr. G—— and he said he would get it, and be prepared in case he was bitten again. He secured a hypodermic syringe and some permanganate of potash; taking a two-ounce bottle he made a dark purplish solution of the permanganate. He also has a rubber bandage he keeps in the same box with the syringe and solution. These are near the case which contains the rattlers.

An opportunity presented itself on Friday afternoon September 28th, by which he clearly demonstrated the value of permanganate of potash as an antidote to rattlesnake poisoning.

Mr. G—— very often exhibits the fangs of a rattlesnake to the visitors of his place. This he does by catching the snake just behind the head with one hand, and by a sort of tongue depressor opens the mouth of the snake with the other. This day the snake might have been a little hungry, and while handling it Mr. G—— felt a sharp sting in the joint of the left index finger; he dropped his pet back in the cage, and reached for his syringe and solution; an assistant filled the syringe while Mr. G—— tied a string round the finger above the wound. He then injected the solution into the finger near the bite. In a few minutes the finger began to swell, and when the pain became severe he used the rubber bandage at the wrist and loosened the string, and again injected another syringeful of the solution. There was no further swelling and very little pain. In two days there was no sign of the bite; he used the finger as usual. He stated that he was more at home now than ever with the rattlers.

PREGNANCY; CONTRACTED PELVIS; DOUBLE DERMOID CYST; PORRO'S OPERATION. RECOVERY OF MOTHER AND CHILD.[1]

By NEIL MacPHATTER, M.B.C.M., L.R.C.P. Edin.,
DENVER, COL.
PROFESSOR OF CLINICAL GYNECOLOGY IN GROSS MEDICAL COLLEGE; GYNECOLOGIST TO ST. ANTHONY'S HOSPITAL; FELLOW OF THE BRITISH GYNECOLOGICAL SOCIETY.

I believe the part assigned to me for discussion this afternoon is a consideration of the unusual methods or extraordinary measures that may be legitimately resorted to in difficult parturition, when the difficulties assume such proportions that the woman cannot be delivered by any of the ordinary means. My sphere is limited to a still narrower margin than this, for I have been requested by the gentleman who so kindly invited me to participate in this discussion to endeavor to confine my remarks more particularly to that part of the obstetric art which calls for the use of cutting instruments, *i.e.*, when there exists such a disproportion between the natural passages and the size of the fœtus as to render it absolutely impossible for the child to be delivered in the ordinary manner. Here we come upon a peculiarly interesting and tremendously responsible situation, for it is one in which the lives of mother and child are placed in imminent jeopardy, and one that calls for the most evenly balanced judgment on the part of the attending physician. In the remarks to which I give expression I trust I shall approach the subject free from the thralldom of preconceived ideas and unbiassed in the advocacy of any one method of procedure only in so far as the merit of such a method demands.

Fortunately for mankind, more particularly for those who are obliged to bear the burdens and dangers of parturition, nature in her own inimitable ways and by ordinances that far surpass in beauty and perfection of design the imagination of man, is usually quite competent to fulfil this trying ordeal. Occasionally, however, the pelvis of the mother or unnatural development on the part of the fœtus may render it absolutely impossible

[1] Read before the Colorado State Medical Society, June 19, 1894.

for the woman to be delivered normally, and it is here that the cunning hand of the surgeon may be of the utmost importance to life. It is highly commendatory to the standing of the profession at the present time that the principles we advocate have been so beneficial to mankind. The method in vogue not many years ago of resorting to the operation of craniotomy, with the appalling disasters that followed in its wake, forms one of the darkest pages in the history of obstetrics. When one contemplates the frequency with which this operation was resorted to in preference to others much less dangerous, it would seem that the spirit of scientific midwifery was long lulled to sleep and that nature had become emasculated. The operation of eviscerating the yet warm and quivering body of an innocent babe from its mother's womb should be reserved for very rare and exceptional cases, such as hydrocephalus, or where the child is already dead. Much more satisfactory and humane methods are the Cæsarean section and Porro's method of operating.

Porro's operation, unlike the majority of recent triumphs in surgery, is not one which has been resuscitated after having been performed and discarded many years before, but is of comparatively recent origin. The first successful case on record was performed in the year 1876 by Porro, of Batavia. It has since been performed a great number of times with comparatively good results. Heretofore, and even at the present time, this operation and the Cæsarean section had been indiscriminately advocated when the condition present called for one or the other method. I believe this to be a mistake. Whether the Cæsarean section can have any advantages over its recent rival rests wholly upon a question of morals. Certain it is that there are well-defined conditions and complications in pregnancy when Porro's method is the only scientific course to pursue.

Each method may possess well-defined advantages over the other, and in estimating the relative values of Porro and Cæsarean sections a number of important conditions should be remembered. In all cases where pregnancy is complicated by tumors, such as fibroid of the uterus, ovarian, or dermoids, as was the condition in this case, hysterectomy is the preferable operation. Where labor has proceeded for a long time and the uterus becomes putrid, Porro's operation ought to be the one selected. In certain operations begun as Cæsarean sections, but which become complicated by difficulties in the detachment of the placenta, uncontrollable hemorrhage, or complete atresia of the vagina, Porro's is the operation indicated. These are some of the advantages that this operation possesses over the classical one. In straight, uncomplicated cases I doubt very much if the Cæsarean method is superior to the Porro. The advocates of the Cæsarean section maintain that because Porro's operation forever renders the woman sterile, the Cæsarean method has the advantage. This question again is one altogether of morals; but given a woman with a deformed pelvis and a contraction of its diameters so that one or the other operation was absolutely demanded, and believe the fact that one would save her life equally as certain as the other, the one that would place her in such a condition that pregnancy could not again occur would be the preferable one. I look upon this point alone as a decided advantage of Porro over its rival. Such a proceeding would leave the life of the mother absolutely free, so far as any future chances were concerned. I am well aware that this is at variance with the opinions of many able minds, but nevertheless it is one that I have long maintained, and is at least one of honesty.

There can exist no reason why this operation, if properly planned and carried out with as much care and precaution as other abdominal sections, should not be almost entirely free from risk, as far as the lives of mother and child are concerned. It is to be regretted that in a great majority of instances the idea of the operation does not enter into the head of the physician until the patient becomes almost entirely exhausted from the reiterated efforts of the uterus to expel the fœtus. An operation of this character above all others should be done opportunely and not left until the rough manipulations have exhausted the woman and materially reduced her chances. It can readily be understood why the mortality of this operation has remained so high in view of the fact that it is usually done as a forlorn hope.

An operation that has recently sprung into prominence, and one that is receiving considerable attention, is that of symphyseotomy. This method of delivery is not of recent origin, but is one that was described and advocated by a French medical student as far back as the year 1768. At first his method was received with incredulity and doubt, but subsequently having performed the operation successfully upon a woman who had previously given birth to four dead children, his method was at once admitted and he became the recipient of much adulation and marks of esteem. He was looked upon as the benefactor of mankind, and the neglected student became in the eyes of the nation an illustrious personage. From that period the operation seems to have lapsed into neglect until recently revived.

The conditions calling for this method of operation are necessarily limited. It is only in slightly contracted pelves that any benefit can be looked for, and the necessity for Porro's method or the classical Cæsarean section will begin where the operation of symphyseotomy ends. In well-marked contracted pelves this operation gives way to the suprapubic methods, and finds its advantages in such cases where the question of premature labor may be meditated.

Whether this operation will ultimately supplant the necessity for inducing premature birth, will rest with the future. At present, according to the most recent arguments, it is frequently beset with disastrous results, sufficient to raise a doubt of its surviving. The most frequent risks seemingly are septicæmia, hemorrhage, ossification of the symphysis, laceration of the bladder, with fistulæ, and prolapse of the vagina.

On August 16th I was called in consultation by Dr. E. J. Rothwell to see a patient who was eight months and a half pregnant. The history given was that she was thirty-two years of age, had always enjoyed good health, and had been delivered of twins a few years previously by Dr. E. J. Rothwell, weighing three and a half pounds each. Dr. Rothwell at that time noticed the condition of the pelvis. She afterward became pregnant, and after the repeated effort of days Dr. Rothwell removed the child by craniotomy. She was confined to her bed for three months afterward. Upon examination the cervix was so high that I could not detect it with my finger; I could, however, make out that the fœtus was alive and that it was in the fourth position. It was of large size, and we felt certain it was physically impossible to deliver the patient by the normal channel.

This we explained to her and her husband, and advised the removal of the child by abdominal section as the method attended by the least risk. The following were the pelvic measurements: Between anterior-superior spines, 9¾ inches; between crests of ilia, 10 inches; conjugate vera, 3½ inches.

A few days subsequently she was removed to my private hospital on Vine Street and was prepared for the operation. We decided to operate several days before the expected time of labor.

Thursday morning, August 23d, she was put under the influence of an anæsthetic by Dr. Leavitt. The abdominal incision was made in the median line and was continued above the umbilicus. Any bleeding points were caught up by pressure-forceps and secured. The transversalis fascia was cut through to the full extent of the abdominal wound. The subperitoneal fat was caught between two pairs of forceps and gently cut, layer after layer, changing the forceps for a deeper layer as each one was cut. This process was continued until the peritoneum was opened and the uterus bulged forward into the wound. Whether to apply the temporary ligature before raising the uterus from its position, as is re-

commended by the majority of operators, or doing so afterward, as advocated by Müller and others, is yet under discussion. In this case I decided upon the latter alternative, for the reason that it can be more properly adjusted and the risk of including a loop of intestine or a piece of omentum under the rubber is obviated. The increase in abdominal incision is more than compensated by the advantages gained.

Before the incision into the uterus was begun, several warm, flat sponges were placed between the uterus and intestines, for the double purpose of keeping them from cooling and preventing fluid from escaping into the abdomen. The incision was vertical, beginning near the fundus, cutting toward the cervix about four inches. I went carefully through the whole extent of the incision, layer after layer, until I came to the membrane, which was intact. The uterine walls retracted, exposing the fœtus as through tissue paper. I ruptured the membrane and the uterus contracted, the child entered the world head first, crying lustily, and was turned over to one of the attending nurses. Here I was confronted by the unexpected complication of two dermoid tumors of the ovaries, and decided to remove them also, together with the uterus. As in hysterectomy for fibroid tumors of the uterus, experience has taught us that the extra-peritoneal method of fixation of the pedicle is the one followed by the most favorable results. The simple method of converting the temporary elastic ligature into a permanent one is as good as any, and saves time. The pedicle was now fixed in the lower part of the wound after all clots were removed from Douglas's cul de sac. In order to prevent the pedicle from retracting, a staple was passed through it, immediately above the constrictor. The peritoneum was then sutured separately. The deep sutures to close the abdominal wound were inserted subsequently. Stitches were inserted as in other abdominal sections and the wound dressed. The patient made a very satisfactory recovery. Her temperature remained normal for nearly two weeks. She and her baby, as you may see, are enjoying the best of health.

405 California Building, Seventeenth Street.

PERMANGANATE OF POTASSIUM IN MORPHINE POISONING.

By HILBERT B. TINGLEY, M.D.,

Rockaway Beach, N. Y.

On July 30th I was hastily summoned to see baby C——, eighteen months of age, who had taken two morphine pills, one-quarter grain each. On arriving at the house I found the child still conscious with pupils contracted almost to pin point and as it was about 8.30 P.M. I decided that I had an excellent case for the trial of permanganate of potassium. I sent across the street for the bottle of permanganate in the drug store immediately opposite, and gave about one grain at once, and as I wished to give this drug a thorough trial, gave no other medicine, not even an emetic. About 11 P.M. I allowed them to put the child to bed, as it was then two hours later than its bedtime, but before they did so, I gave about one grain more of the permanganate. During the night the child had some delirium of a wild nature and had little sleep, but next day appeared none the worse for its overdose of morphine. The result has given me great faith in this drug in these cases.

To Elevate Woman.—A writer in an ethical journal has a new idea for the benefit of women. It is that men and women should deliberate together and establish a rule that the woman's child bearing years should be very much reduced in number, also that they should agree to allow a longer period between the birth of children. The lady does not go into particulars, so we are unable to give the details by means of which these reforms are to be made effectual.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 18, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Reports.—Dr. A. B. Judson, statistical secretary, and Dr. M. Allen Starr, corresponding secretary, presented reports. The recording secretary read a written report from the Committee to the State Constitutional Convention, presented by its secretary, Dr. W. R. Pryor, a synopsis of which has been published. Allusion was made to the necessity for a committee on legislation, and the President said he would at some other time gladly entertain a motion to appoint such a committee, as he felt there was great need of one in order to prevent the passage of bad laws relating to medicine, as well as to urge the passage of good ones. It was desirable, however, in case there were any who might oppose such a motion, to first give notice of its introduction, in order that all might have a chance to vote on it as their consciences dictated. But the fact could not be repeated too often that the profession must make its wants known if it would have them granted.

Defective Vision, in its Relation to Crime.—Dr. Frank Van Fleet read a paper bearing this title. He believed the human race had not altered since the beginning; that, at any rate, there had been no change since the earliest time known to history. At one time man roamed over the globe in herds, there being no family ties, no laws, consequently no criminals. As people multiplied, it became more convenient to settle, to live in towns, and in families; to have laws; and these being violated, crime came into existence. There was a change of environment, not a change of man. Heredity was a misnomer. Everything was due to environment. One who could control the education and environments of a child could make of it what he pleased. An English child put in Germany, and taught only German, would grow up with no English characteristics, and differ in no way from German children. If one were to expect criminals to beget criminals, he should also expect intellectual persons to transmit to their offspring greater intelligence than those not intellectual. The author asserted, however, that the only influence which good parentage could have was to give better training and set a better example during the developing period; the sole influence of criminal parentage was the bad example set during growth.

Man received his education through the senses. Any of these might be defective, and warp his view of things, or interfere with the race of life. But it was with defective vision that the author was concerned. His idea of the way in which this produced criminals seemed to be chiefly, at least, that it detracted from the individual's power to compete with his more fortunate fellows. Mention was made of the fact, however, that defective vision might cause one to take a warped view of things. Examination of the eyes of a part of the juvenile delinquents on Randall's Island, led him to think there was defective vision in a larger percentage of these persons than the average. Ocular defects should be corrected as far as possible, and those which were acquired, such as ophthalmia neonatorum, should be prevented or arrested at once. A certificate of ocular examination and proper treatment was more important than one of vaccination among school children.

The discussion was opened by Dr. H. D. Chapin, and continued by Drs. Joseph Collins, Frederick Peterson, John E Weeks, the President, and the author. As far as the gentlemen expressed their views, all disagreed with the author, except with regard to the importance of attention to defective vision wherever it existed.

Drs. Collins and Peterson especially criticised the stand taken with regard to the overwhelming influence

of environment as compared with heredity, and failure to refer to any other authority than an article by a police superintendent, when so many scientists had studied and written upon the subject. Dr. Peterson had observed that eye troubles were very common among the Egyptians and Arabs, while crime was extremely rare.

Dr. Weeks thought the author had adopted a very superficial way of examining the eyes at Randall's Island institution, considering the point which he was trying to prove. The fact that more than half of those examined had been found to have defective vision was not astonishing, when it was remembered that astigmatism was present in about two thirds of all persons, while perfect vision was very rare. In his opinion defect of vision was not more productive of crime than defect of any other sense.

Dr. Chapin spoke feelingly of the want of accommodations in the eye hospitals and other institutions in the city, for children suffering with inflammatory eye troubles, especially those of a contagious nature.

Dr. Weeks and the President said this was not the fault of the existing ophthalmic institutions, but of the city officials, in failing to provide hospital accommodations for these patients. Dr. Weeks had found it possible to cure nearly all of the cases at the out-door department, where the mother followed instructions and brought the patient back for treatment daily.

SECTION ON GENERAL MEDICINE.

Stated Meeting, October 16, 1894.

William H. Porter, M.D., Chairman.

Case of Sporadic Cretinism. — Dr. Morris Manges presented a case of sporadic cretinism which had once been on exhibition in a dime museum and had once been demonstrated before a medical meeting by Dr. Leszynsky. The subject was a male, twenty-five years of age, forty-nine inches in height, weight sixty-eight pounds. He was born of healthy parents in Posen; the father was six feet in height, the mother of ordinary size. Other children in the family were healthy and normal. When carrying the child the mother had hæmoptysis. She described him as a little old man when born. He was always dull and stupid. The eyes were small, the forehead small, the bones prominent, the folds on the forehead deep, the scalp loose, the gait waddling, the hair dry and wiry, thyroid gland apparently absent. Before treatment with thyroid extract there was some infiltration of skin, particularly of eyelids. When irritated, the boy used vigorous language. Since beginning treatment with thyroid extract over two months ago there had been loss of nine pounds in weight, the eyelids had lost their œdematous appearance, the voice had become less stridulous, the patient gave more attention to his surroundings, the daily excretion of urea had increased from 0 8 to 1.2 per cent. It was very doubtful, however, whether at this late date the thyroid extract could manifest curative properties or do more than somewhat ameliorate the patient's condition.

The speaker expressed surprise that so few cases of sporadic cretinism had been reported in this country, the whole number since Osler's first paper a few years ago amounting only to sixteen, whereas it was pretty certain that a good many cases were in existence.

Among the preparations of the thyroid gland which had been tried on this patient were those of Parke, Davis & Co., of Armour, and of Burroughs, Welcome & Co. The latter had given the best results with the least disagreeable effects. Twenty-five grains were now being taken a day.

Dr. George W. Crary, to whose case Dr. Manges had referred, said that since the publication of his case he had received letters regarding sporadic cretinism from all over the United States, which showed that the condition was not rare, notwithstanding the paucity of the reported cases. By the use of the thyroid preparations we could easily get rid of the glandular growths, could render the skin moist, and produce certain general improvements in the patient's condition within a short time, but it had not been at all decided that we could cause these diminutive persons to go on and develop into complete human beings. He had been disappointed in the slowness of the improvement in his case. It was quite different, however, with myxœdema, in which condition the agent possessed wonderful curative properties. Like Dr. Manges, his experience with other preparations of the thyroid gland, including that which he had himself for a time made, had been less favorable than with the tabloids of Burroughs, Welcome & Co. Unlike the former, the tabloids did not cause rise of temperature and disagreeable effects upon the gastro intestinal tract, and the dose with these was determined by the frequency of the pulse instead of by the temperature.

One of the staff at the Vanderbilt Clinic said they had been treating a child there a few months with thyroid extract, and it had shown marked improvement.

Dr. Caillé had seen some cases treated by thyroid preparation, but could not say that there had been special improvement.

Early Local Treatment of Diphtheria and other Affections of the Throat.—Dr. Francis H. Williams, of Boston, read the paper. It was based on studies in diphtheria in the hospital at Boston; also in private practice. It was assumed that at the beginning diphtheria was a local disease. These studies had shown the value of bacteriological examinations of the juices in the throat in making an early diagnosis, especially in apparently healthy members of a household in which there was one known case of diphtheria; of determining whether the patient had become fully convalescent; of the efficiency of treatment by its destruction of the bacilli. All patients, however, should be warned of the possibility of communicating diphtheria even after bacteriological examinations had ceased to show bacilli or diphtheria.

A few years ago the author had become convinced that many local treatments were useless or injurious, and to determine what was best turned to the laboratory. Many germicides, while capable of killing the germs, did so only in poisonous doses to the patient or by injuring the local parts. He found peroxide of hydrogen a weak germicide in ordinary strength. He then found that the efficiency of this agent was increased by the presence of an acid. The two mixed acted more strongly as a germicide than either did separately. The preparations in the market were not reliable either as to the strength of the peroxide or of the amount of acid which they contained. He made careful study and found that where the membrane was thick and the case severe a fifty-volume solution of the peroxide was not too strong if one would disintegrate the membrane and reach all the germs. For the hydrogen dioxide acted not only as a germicide, but was specially valuable as a disintegrator of the false membrane. The paper contained a series of cases, showing that the fifty-volume solution was more efficient than the ten, and that where the former was used the throat was free of germs of diphtheria and other germs by about the fourteenth day, as against the twenty-seventh day where the weaker solutions were used. Of course the persistence of the germs varied with the severity of the case. The strength of the solutions which he now used varied from twenty-five to fifty volumes, according to the severity of the case. In a few days the bacilli were found much diminished in number, and he was strongly inclined to believe that where the Klebs-Loeffler bacillus was present after the tenth day under this treatment it was due to its being concealed in some crypts, or other hiding-place, and should be sought out carefully. In some cases membrane remained after the Klebs-Loeffler bacillus had disappeared, and was due probably to the presence of the staphylococcus, which was not so easily killed, and required the use of some other germicide, as chlorinated soda.

Dr. Williams had used the stronger solutions of hydro-

gen dioxide in one hundred cases of diphtheria, of varying severity, in all the diagnosis having been confirmed by bacteriological examination. It did not injure the mucous membrane. It could be used along with other compatible germicides, or alternately. It should be used early and until the germs disappeared. Applications every hour or two. The operator should always see the parts when making the applications. Use a spray, not more than six pounds pressure. An ingenious apparatus was exhibited for spraying the liquid. All gentleness should be observed, and then harm would not be done, and the patient would call for the treatment, since it cleansed out the throat and nose and made breathing easier.

Dr. George L. Peabody being called upon, made a few remarks, but said he did not see enough cases of diphtheria to speak with authority on local treatment. The author had properly emphasized the importance of early diagnosis and treatment, whatever the treatment might be, if it were only beneficial.

Peroxide of Hydrogen Found Injurious.—Dr. A Caillé mentioned the following facts: diphtheria is endemic here; some years it is more plentiful than others; it may be a mixed infection, and may kill by the presence of either the streptococcus or the diphtheria bacillus; every local abrasion favors the development of the germs, which may be present even in seemingly healthy throats; prophylaxis by attention to the teeth and mild germicides and cleansing of the throat and mouth should be observed. Regarding peroxide of hydrogen, Dr. Williams's experience had not been in harmony with that of New York physicians. Beginning with the meeting of the American Pediatric Association in Boston a few years ago, the profession had given expression to its experience that peroxide of hydrogen applied to the throat in diphtheria caused irritation, gave rise to new patches of membrane, and made the case more formidable than it had been before. It seemed impossible to apply chemical antiseptics to the mouth and naso pharynx without doing injury, and he had come to content himself with gentle mechanical removal and cleansing by mild solutions of salt, boracic acid, or pure water, through the nose.

Impossible to Disinfect the Air-passages.—Dr. W. H. Park said he would only give his personal experience, and remarked that it was seldom that any two persons agreed in all respects. At Willard Parker's they had tried whether it was possible to completely disinfect the air passages, using even strong solutions of bichloride and other agents for twenty-four to forty-eight hours, in some persons who had no membrane in the throat, in others in whom a membrane was present, but in no case could they make the throat perfectly aseptic. In a certain number the Klebs-Loeffler bacillus did disappear, but in others they were as numerous as if nothing had been done. Even if the membrane quite disappeared from view, germs would still remain and cause its development elsewhere. He hoped to hear from Dr. White, who had carried out treatment at Willard Parker's to test the comparative value of bichloride, of peroxide, and of simple salt solution. Bichloride, 1 to 2,500 in the throat, 1 to 4,000 in the nostrils was used in one class, peroxide of hydrogen up to twenty-five per cent. in another, salt solution in a third. In all, the bacilli persisted about the same length of time, or even longest where the strong solutions were used. As to results, Dr. White had noticed little difference.

It was very difficult to apply a swab without injuring the member. They now tried simply to use a cleansing solution, and to avoid irritation. He had been told by Dr. White that very rarely did an adult or a person over ten years old die of diphtheria.

Dr. Joseph E. Winters also thought that Dr. Williams's experience with peroxide of hydrogen was entirely different from that of physicians in New York. In fact the frequent use of the agent increased rather than diminished the symptoms. He regarded it as impractical to use any spray or atomizer in diphtheria in a child; as to adults, they almost always recovered, as Dr. Park had stated. It seemed to him that he could not resort to any form of local treatment in the mouth of a young child suffering from diphtheria without running contrary to the first indication in the management of these cases, namely, not to exhaust the patient.

Experience at Willard Parker Hospital.—Dr. White, resident physician at the Willard Parker Hospital, said that his experience with peroxide of hydrogen in diphtheria at that institution had been very unfavorable. All the cases showed some signs of irritation from the peroxide. His remarks confirmed those of Dr. Park with regard to the danger of irritation in local treatment of the mouth in children and with regard to the rarity of death in adults with diphtheria. Cleansing with plain water or normal salt solution was best.

Dr. A. Jacobi dwelt upon the danger of making local wounds in diphtheria of any size or nature, as they absorbed diphtheritic poison very rapidly and formed new centres of infection. For twenty or thirty years he had impressed the danger of wounds in the throat in times of diphtheria. Bacilli were ubiquitous. The discussion at the American Pediatric Association referred to by Dr. Caillé, regarding the dangers incident to irritation caused by peroxide of hydrogen, was based on a paper presented by Dr. Jacobi. A striking example in which the continued use of this agent had prevented perfect convalescence and caused renewed attacks of diphtheria, was that of a child which the speaker had been requested to see in consultation with Dr. Caillé. He advised discontinuance of the peroxide, whereupon the child got well.

Dr. Jacobi used only physiological salt solution, or possibly mild boracic-acid solution, or lime-water, introduced gently through the nose. It was criminal to bore into the mouth of a child and try to pry open its jaws while it was struggling and becoming exhausted. Besides the affected parts could not be reached in that way, while they could through the nose.

Dr. Williams, in some concluding remarks, reiterated the points in his paper, that the peroxide must be strong, it must be acid, and the treatment must be carried out with gentleness. Only the remarks of Drs. Park and White had a real bearing upon his paper, for they alone had used a strong solution of peroxide, but that was neutral, and therefore not efficient.

An Ectromelic Monster.—Dr. A. Schirman, of this city, writes concerning a monstrosity which he saw about two years ago in Baltimore. He was called to attend a woman in confinement. The child, a female, was born dead. The frontal bone was undeveloped, the parietal was flattened, the occipital was horizontal in position, the temporal bones were very prominent. There was a cleft palate, and the narrowed cranial cavity contained no hemispheres. The mother was about thirty years of age, and had given birth to several healthy children and to two with cleft palate and hare-lip. No dissection of the monster was allowed.

The Way of the Health Officer is Hard.—In Brooklyn there has been much dissatisfaction expressed in some quarters with the health officer, and a petition for his removal was circulated, and obtained a number of signatures of those who thought he was too strict in enforcing quarantine and vaccination during the prevalence of small-pox. In Detroit the health officer has been deposed because it was said that he was too lax in enforcing quarantine and vaccination during the prevalence of small-pox. In Milwaukee, also, impeachment proceedings have been begun in the common council against the health commissioner, for the manner in which he handled the small-pox epidemic in that city last winter. It is not said whether he is accused of being too severe or too lenient. The sanitary *via media* is a very narrow path, apparently.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OLIVER WENDELL HOLMES—OBSTETRICAL SOCIETY—ABSCESS OF OVARY—MEDICAL SOCIETY OF LONDON—THE PLEASURES OF MEDICINE AND SURGERY—BERIBERI—CHELSEA HOSPITAL SCANDAL—MEDICAL DEFENCE UNION—SMALL POX—DIPHTHERIA—DEATH OF MR. BUNCH—SIR JAMES PAGET AT THE ABERNETHIAN SOCIETY—THE CLINICAL SOCIETY'S FIRST MEETING—SMALL-POX—DIPHTHERIA.

LONDON, October 13, 1894.

My first word this week must be to express the sense of loss we feel here in the decease of Dr. Oliver Wendell Holmes. England, as well as America and all English-speaking countries, were delighted by his genius, and medicine may well be as proud of him as literature. Since his last one hundred days in Europe he has been, if possible, more one of us than ever, and his death is the one talked of topic of the week among medical and literary men.

The Obstetrical Society was the first to meet this year, and set to work with a full programme on October 3d. Specimens were exhibited of tubal abortion and of pregnancy in a rudimentary uterine horn, by Dr. Remfry; of myoma removed by abdominal hysterectomy, by Dr. Cullingworth; of fibro cystic tumor, by Dr. Lewers; and the following by Dr. Duncan: dermoid of left ovary with pedicle twisted from left to right, cystic sarcoma of omentum, sarcoma of ovaries, and malignant disease of omentum. There were some interesting remarks on these specimens by Mr. Bland Sutton and others. Dr. Cullingworth read the paper, which embodied three cases of pelvic inflammation attended with abscess of the ovary and some clinical remarks on the terminations of such abscesses, the illusory character of temporary subsidence of the symptoms in some cases of severe pelvic inflammation. He said that an analysis of eighty three cases, in which he had performed abdominal section for non-cellulitic pelvic suppuration, showed that in a large percentage there was ovarian abscess which was, next to salpingitis, the most frequent form of non-cellulitic suppuration. Dr. Galabin supported the view held by the author, that the suppurative inflammation was communicated from the tube to the ovary, but this was controverted by Dr. Hayes, and Dr. Griffith believed that the ovarian suppuration was usually the result of septic inflammation of the broad ligament. Dr. Lewers recalled a case in which he found the inflammatory process between the layers of the broad ligament in the stage of phlegmon, but in the adjoining ovary a small abscess containing about a drachm of pus. The president (Dr. Herman) mentioned two cases differing somewhat from Dr. Cullingworth's, one of which showed the chronicity of the process, and proved that with our present knowledge the patient might have been saved twenty years of suffering.

The Medical Society began work on Monday last, when the president (Sir William Dalby) delivered an address on the "Pleasures of Medicine and Surgery," in which he proposed to show that our pursuits may so occupy us as to raise them to an art in its highest sense, and will then give us all the delights which art gives to its votaries. He limited the pleasures to mental processes, excluding those of sensation and, therefore, those which appeal to the eye and the ear. The exercise of the imagination, he said, was one of the greatest pleasures, and he saw in some the enthusiasm of the explorer, and gave illustrations from both medicine and surgery. The activity of the imagination is the mark of genius in poets and artists. If the mental processes are the same in one who establishes a great advance in medicine, should he be denied the attribute of genius? He wished to place our art side by side with literature and the arts, and held that it is worth cultivating not only for its utility but for the pleasure of those engaged in it. Poetry and literature give pleasure of two kinds, emotional and intellectual, and although in some instances they are both operative, there are forms of literature of which the enjoyment is purely intellectual, the emotions remaining untouched. So he claimed for medicine a family relationship with the arts and literature, and a share in the intellectual pleasures they give.

The outbreak of beriberi in the Richmond Asylum, Dublin, continues. There have been 149 cases, of which 17 have died. Possibly some other cases have occurred, for in some of these it came on so insidiously that it would have, perhaps, been overlooked but for attention being directed to the epidemic. Some army surgeons who have seen beriberi in the East have visited the asylum and they observed differences in the clinical manifestations of the Dublin cases, but these they seem to think may be accounted for by the difference of climate. If the disease is really beriberi it has for the first time obtained a footing in these countries. Some cases have, indeed, been brought in ships, but it has never spread. Yet this outbreak at Dublin, whatever it may be, has spread very rapidly. This is attributed to overcrowding, always an important point in this disease, and temporary hospitals are being erected to relieve this.

On Wednesday last (October 10th) there was a general meeting of the Governors of the Chelsea Hospital for Women, when the committee gave a report and offered their defence and resignation. Some sarcastic criticisms were offered on the conduct of a Board which had been publicly condemned proceeding to elect a new staff and offer suggestions for improved management. This Board actually asked for power to suspend or dismiss any medical officer who had acted in a manner detrimental to the interests of the hospital. What this means is obvious from the declaration of the Chairman that some of the staff who had not been re elected had injured the hospital by circulating a statement of their own defence. And yet men are to be found ready to accept this ignominious position with the glaring fact of the injustice to their predecessors confronting them. And we call ourselves a united profession and prate about ethical conduct!

The Board also announced their intention of appointing consulting physicians of eminence from those who held office at the general hospitals. Now Sir Spencer Wells, Dr. R. Barnes, and Mr. Hutchinson were the consulting officers. They have resigned and evidently in disgust. It is well known that they disclaim any part in the election of the new staff, and condemn the conduct of the Board in proceeding to the election. If this condemned Board can find obstetricians attached to general hospitals ready to succeed these celebrated consultants, such fresh consultants ought to be ostracized by the rest of the profession.

Notwithstanding the conduct of the Board a resolution was carried not to accept their resignation—so the hospital is left to the same management which has been condemned in two special reports as well as by the Home Secretary—a strange comment on our methods of management and an agreeable prospect for the physicians who are willing to accept appointments terminating yearly as the humble servants of such a Board.

Meetings of members of the Medical Defence Union have been held in London, Manchester, Birmingham, and Bristol to discuss the steps taken by the council in the litigation respecting Drs. Bloxam and Collie. At these meetings suggestions were offered as to the avoidance of such litigation in future, and at each meeting confidence was expressed in the council. So we may hope that controversy is closed. It is a pity that all concerned in medical defence do not unite their forces.

Small-pox has abated lately, but diphtheria has increased. This last disease has carried off another promising young member of the profession, Mr. F. V. Bunch, F.R.C.S., Surgical Registrar of University College Hos-

pital, who contracted diphtheria from a patient in the wards and died on the 5th inst.

LONDON, October 19, 1894.

Sir James Paget opened the one hundredth session of the Abernethian Society on the 11th inst. with one of his felicitous addresses. He said he was not aware that it was the centenary of the Society or he might have prepared some account of its history. It was quite as well that he did not, though he would, I doubt not, have been able to make the dry bones of such a history live. He said it was sixty years since he joined the Society. It is rather rare certainly for anyone to address a society after sixty years' membership, though I believe outside the profession this from time to time occurs. Sir James repudiated the notion that a man could not be a scientist and general practitioner at the same time, and urged his audience to add well-observed facts to the general store, illustrating the necessity of this by myxœdema, first observed twenty years ago when little was known about the thyroid gland, but the result of that observation was now a larger knowledge of the thyroid than of many other organs. The questions as to relations of mixed diseases were brought forward and tuberculosis and cancer named as to which facts were needed. Then the fallacies of diagnosis were spoken of, and as they might lead to unexpected actions of drugs, a natural transition was offered to the subject of therapeutics. Then Sir James urged that all the sciences must work together not as enemies or rivals perhaps, but the practitioner must avail himself of the knowledge afforded by all without allowing himself to be unduly influenced by any one of them.

But I need not give any further account of the address. Suffice it to say that Sir James received on the occasion one of those enthusiastic ovations to which he has long been accustomed, and that the crowded audience seemed more than usually delighted.

The Clinical Society of London opened the session Friday last with distinctly practical work. Dr. J. M. Bradford related a case of aneurism of the basilar artery. On admission, at 7 P.M., the patient was partially unconscious, axillary temperature, 98° F.; pulse, 70, irregular and intermittent. No paralysis. Respiration, irregular. Abdomen not retracted. Pupils equal and medium sized. Deep reflexes increased. Patient rather restless. At 9 P.M. he became comatose, and the respiration became infrequent, ceasing at 10 P.M. Artificial respiration was kept up for four hours, but the pulse then failed, and he died at 2 10 A.M. Temperature at midnight 97° F. No convulsions occurred. Autopsy showed numerous gummata in the liver and a fusiform aneurism of the basilar artery, which had ruptured, the extravasation forming a blood-clot one-fourth of an inch thick on the under surface of the pons and medulla, and extending round the sides of the medulla into the fourth ventricle.

Dr. W. Hale White described two cases of intra cranial aneurism. The first was that of a woman, aged thirty-four. There was a large amount of clot on the under surface of the brain, it extended to the fourth ventricle and was one-eighth inch thick all down the spinal canal in the subarachnoid space. The second case was that of a man who suddenly fell down insensible and was brought to the hospital. On admission he was unconscious, the pupils were fixed and dilated, the eyeballs were prominent. The breathing became difficult and he died seven and one half hours after admission. Blood clot was found in both the subdural and subarachnoid cavities nearly all over the surface of the brain; and it had extended along the sheath of the optic nerve, ultimately getting under the retina. The hemorrhage came from a small aneurism springing from the right internal carotid just at its termination The whole of the rest of the body was absolutely healthy.

Dr. J. E. Paul read the notes of a case of acute pancreatitis in a man of forty-three years of age, who died eight hours after admission. Temperature rose to 104° F. just before death. The peritoneum covering the pancreas was found to be glued with recent lymph to the posterior surfaces of the stomach. The pancreas itself was much swollen, and hemorrhages were to be seen, most numerous in the tail. Stomach and duodenum healthy. The rest of the organs healthy, except cloudy swelling of kidneys. No fat necrosis. Microscopic examination showed considerable disintegration, with total destruction in parts of the structure of the pancreas. Numerous hemorrhages were to be seen, and clumps of crystals of hæmatoidin.

Dr. Soltau Fenwick described two cases of fatal form of tetany associated with chronic dilatation of the stomach. One was that of a carpenter, aged thirty four, who stated that for six months he had suffered pain in the stomach after meals, and attacks of vomiting. The other had had symptoms of ulceration for four years, was suddenly seized with tonic spasms of the extremities after an unusually severe attack of vomiting. The condition closely resembled true tetany, and the seizures were repeated several times.

This complication of chronic dilatation of the stomach was first recorded by Kussmaul in 1869, and twenty-six cases have been published since. In the majority the gastric symptoms had been present for years, and in ninety-two per cent. of the cases which came to a necropsy a chronic ulcer in the vicinity of the pylorus was found to be the cause of dilatation of the stomach. In every case the tetany followed severe vomiting, the attacks lasting from one hour to several days. In seven cases the condition was further complicated by seizures of a tetanic nature, in which trismus and opisthotonos were usually marked symptoms, while in three others epileptic convulsions supervened. The disease is extremely fatal, out of the twenty-six instances eighteen terminated in death. The rational treatment which has met with some success is the regular employment of lavage, either warm water or a weak solution of resorcin being used.

Dr. Holman said that Dr. Ogle, of Reigate, had described to him a case of a patient who was admitted to the Cottage Hospital for severe vomiting. The stomach was found to be much dilated. The patient had two attacks of tetany and died in the second. At the autopsy no sign of ulceration was found, but the stomach reached far below the umbilicus.

Mr. Eve then read the notes of a case of tuberculosis-lymphangitis of the arm following a sore on the finger. The patient was in good health three years later but was afterward lost sight of. It appeared probable that an ordinary whitlow had been inoculated, perhaps in washing a handkerchief soiled with tuberculous sputum. For the purpose of establishing the diagnosis, guinea pigs were inoculated with pus from the abscesses, with positive results. The case was illustrated by colored drawings and photographs.

A similar case, described by Tuffier, was quoted, in which the patient succumbed to general tuberculosis; and this or phthisis is the usual termination of such cases. Tuberculosis lymphangitis almost invariably follows superficial lesions and usually the cutaneous inoculation of tubercle. In one case it was an anatomical tubercle, in another a warty tubercle on the back of the hand, and in three other cases the patients were women who developed nodules on the fingers while nursing their phthisical husbands. Stress was laid on the necessity of an early diagnosis so that the disease might be extirpated as soon as possible by erasion of the abscesses and removal of the nearest chain of lymphatic glands.

The President, Mr. Hulke, referred to the account of tuberculosis following inoculation in a surgeon, who accidentally inoculated his own hand, which ultimately ended unfortunately.

Small pox has declined in London. No deaths from it were registered last week and only nine fresh cases were notified. The cases remaining under treatment for the last four weeks have been respectively 100, 98, 84, and 63.

Diphtheria has also declined. The deaths for the last three weeks have been 67, 66, and 54. This number is 19 more than the corrected average for the week. The disease is widely distributed over the different districts.

CAR SANITATION.

To the Editor of the Medical Record.

Sir: The short reference to Dr. Cann's paper on "Car Sanitation," prompts me to write you of some of the observations made by myself recently regarding this matter.

What the Doctor says of the all prevailing amount of carbonic-acid gas in the cars is beyond question the rule in all cars save the drawing-room variety, especially in winter time.

Sufficiently noticeable, however, is this great amount of poisonous gas for those of us who took a train each day from early spring during all the summer months to note the fact, and seek an unoccupied car put on a station above where we boarded the train. Of course before our car had gone far it was as bad as the rest, but the system so quickly adapts itself to circumstances that we did not particularly notice the fact—but did, of course, have the headaches that go with the inhalation of this vitiated air.

Bad as all this is, it is by far the least objectionable of a lot of other unhealthful things to be noticed upon the trains. Not long since I noticed a filthy looking spot on the plush-covered back of a seat in front of me, and it took only a glance to see that some "filthy hog," as the lady with me observed, had been riding there before us, and had expectorated very disagreeable looking pus or muco-pus on this seat back.

If one's mind reverts to the fact that the germs of any one of several diseases may have been lurking in that dried sputum he feels uneasy and wants to change his seat, which, if the car is full he cannot do, and if he can accomplish it how shall he know that the next seat is better than the one vacated, since not all disease germs require a visible medium of transportation.

The unfortunate custom of covering that portion of the back of the seat which presents itself in front of each seat with plush or some other dirt-absorbing substance is a thing easily remedied, for there is no reason why thin hard wood should not be used instead.

As to the disposal of germs in the cars there is a very simple and not very expensive way of doing this. If a compartment into which each car could be run and remain for two hours after each trip should be so constructed that a temperature of, say 240°, could be maintained, all animal life would thus be destroyed.

There are many other things tending to convey disease and death. Take the matter of the handling of the ice for the ice-water tanks. You shall see men with dirty, ill-kept hands, handling the ice in those filthy hands and putting it at once into the tank, wiping their hands on already very-much soiled trousers, and then repeat the operation with the tank in another car.

Then too there is the question of where the water itself is obtained. On one of our leading railroad through trains for the West, the water is supplied from the Jersey City water, which is taken from the lower Passaic River, a notably unhealthy stream because of sewage from further up, as note the cases of typhoid fever in Jersey City and Newark until recently.

All this is easily avoided, and the State should see to it that the water be taken from pure sources and the ice also, besides seeing to it that the companies provide suitable means of carrying ice without the men handling it.

Minor matters, like the ridiculous custom of the one sitting next a window being the sole arbiter of whether the window shall or shall not be open; if open it may chance to let in very objectionable draughts on every one, as very many suffer bronchitis, etc , from it, or possibly smoke, cinders, and dust may cloud the car, and all suffer because of the carelessness or stupidity of the one passenger who claims the right to control this particular window.

It is quite true that all these matters would entail some care, possibly some expense on the companies if they are to be corrected, but certain it is that these matters all require attention and none of them are at all trifling, but of grave moment to the lives and health of the travelling public. W. Washburn, M.D.

THE DANGERS OF NIGHT CALLS.

To the Editor of the Medical Record.

Sir: In the daily papers of Thursday and Friday of last week appeared sensational reports of my appearance in the Jefferson Market Police Court as complainant against a man whom I believed had robbed me. The injustice which this publication has done me is of so grave a nature that I beg you to print the actual facts of the case, which are as follows:

At about 3 A.M. Thursday morning I left my house to visit a patient, in answer to a messenger call to West Forty-second Street. I went directly there, arriving about 3.30. I left there at about 5 A.M. Arriving in Seventh Avenue on my way home I stopped at a public house and ordered a sandwich. While paying my check at the cashier's desk I was jostled by three men, and a roll of bills which I had returned to my pocket was taken by one of them. The man ran out upon the street and I quickly followed. I called a policeman, and, together we started in pursuit of the fugitive, who sought refuge in a public place one or two blocks above. I identified the man, and caused his arrest. I went to the station house with the policeman and his prisoner, and made my charges against him. A little after eight o'clock I appeared against the prisoner in Jefferson Market Court, before Justice Hogan. I was asked by the Justice if I was drunk at the time of the robbery. I indignantly and truthfully answered "No." The policeman was then ordered to make the charge against the prisoner. In his written statement, I found the following: "Defendant was arrested on the complaint of Dr. Phelps, who had the appearance of being drunk, and was under the influence of liquor." I quietly asked the policeman to charge me with being drunk, and to sign his name to it. When he declined to do so, I tore up the statement, not knowing that it had been signed by the Justice—if it had been. The Justice then held me in $200 bail for contempt of court. By permission I went for bail to the house of Dr. George Evans, 49 West Thirty-ninth Street, and soon returned. The Justice imposed a fine of $5 and discharged me.

In support of the above I can furnish statements—1. From my patient, showing that I had not been drinking and was not intoxicated when I left the house soon after 5 A.M. 2. From Dr. W. O. Plimton, 19 West Eighty-fourth Street, my medical associate, showing that I was not intoxicated immediately before I went to the police court; and 3. From Dr. Evans, showing that I was not intoxicated thirty minutes after the trouble in court—however excited I may naturally have been at that time.

I would deem such explanations entirely unnecessary for those who know me, but in view of the widely published statements in the public press I deem it incumbent upon me to put in a general denial.

With this brief presentation of the case, showing that I was assaulted and robbed while in the performance of professional work, such as calls a physician to any part of the city, I will say nothing more, but will leave the whole matter to the judgment of the reader.

A. M. Phelps, M.D.

[It is obviously unnecessary to dilate on the facts of the case. To anyone who knows Dr. Phelps the charge of drunkenness is ridiculously absurd. Indeed it would scarcely be worthy of notice save to offset a widely published scandal, in which insult was added to injury, and proper redress was apparently out of the question.—Ed.]

New Instruments.

A NEW NASAL FORCEPS.

By SAMUEL GOLDSTEIN, M.D.,

NEW YORK.

SENIOR ASSISTANT SURGEON, NEW YORK THROAT AND NOSE HOSPITAL; ASSISTANT SURGEON, OUTDOOR DEPARTMENT, MOUNT SINAI HOSPITAL.

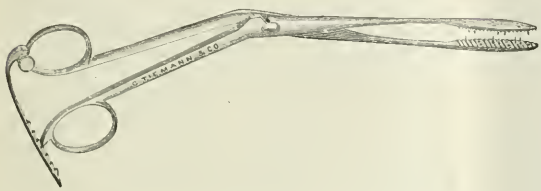
How frequently, in the examination of the nose, the surgeon finds hypertrophy or exostosis of the inferior turbinated bone, of such a nature that only removal of this obstruction will afford the radical relief the anxious patient seeks.

The patient comes to you and enumerates his symptoms: of having cold upon cold in the nose; the nostrils being alternately obstructed; obstructed very often to such an extent that he does not breathe through one nostril, and barely with the other. He seeks radical relief.

In a large majority of cases we are told that all forms of treatment have been tried, including cauterization with chemical caustics, and the actual cautery. These methods of treatment have given him temporary relief, as the mucous membrane, which was only part of the trouble, was reduced in size; the main cause of the trouble being still *in situ*. He further tells us that he does not wish to be continually under treatment, but wants such operative measures enacted as will rid him of his nasal obstruction.

The question naturally arises, can we place such a patient in a condition that when we discharge him we can truly say that his nasal obstruction has been removed; that he may still contract a slight nasal inflammation, not as readily as before, and of such a nature that very simple treatment will be effectual? How are we to accomplish this end, should the cause of the trouble be due to hypertrophied inferior turbinated bone?

The answer to this query, from the results experienced at the New York Throat and Nose Hospital, and my own, is in the removal by saw and forceps of a sufficient amount of the hypertrophied inferior turbinated bone. The objections that are usually made to the operation are, I fully believe, of little weight. I will enumerate such as I usually hear, and endeavor to meet them in detail.



We are told that this bone has a function, and should not be removed, even in part; that the operation is attended with too much shock; that the hemorrhage is excessive, often uncontrollable, and is so great that the patient becomes exsanguinated; that the operation, as done under cocaine anæsthesia, is too painful for the ordinary patient; finally, that the results do not justify the means.

I fully concur with the statement that the inferior turbinated bone, in its normal state, has a function, and appreciate that thoroughly. May I, however, ask, what surgeon would hesitate to remove an extensive exostosis in any other region of the body? It is only when the inferior turbinated bone is so hypertrophied as to cause obstruction, that this part is to be removed.

In all of the operations that I have witnessed, and in those that I have performed, there has been so little shock, that the patient, in a comparatively short space of time, was able to retire, and in some cases, resume his usual vocation. Hemorrhage, there necessarily is, greater or less, depending upon the condition of the nose; but never so great as not to be within the control of the operator; in the main so slight as only to ooze for a short time after the operation, and perhaps for twenty-four hours later. That there is some pain attending the operation is most true; but it can be minimized by the skilful surgeon, who performs the operation in a comparatively short space of time; and furthermore, much more quickly by the aid of a forceps that will grasp the detached segment of bone firmly, and permit immediate withdrawal of the same.

I hardly believe that it is necessary for me to state that the operation is done in a worthy cause, that the end amply justifies the means. Anyone who has seen the mouth breather, whose nostrils were obstructed with hypertrophied inferior turbinated bone, and who has removed such obstruction, knows the gratitude felt by his patient for the immediate relief afforded.

For the purpose of making the time consumed in operating as short as possible, to minimize the pain, possible shock, and hemorrhage, I have planned and had this forceps made. The nasal forceps now in use have their inner flanges serrated, or partly serrated and tunnelled.

There is always a flow of blood resulting from sawing through the bone; after the bone has been sawn, and the segment hangs pendent, attached only to mucous membrane and perhaps some cartilage, the forceps is applied to grasp the segment for removal. Here considerable difficulty is met. The blood fills in the serrations, making the surfaces of the flanges of the forceps slippery; upon their withdrawal we are surprised not to find the segment in its grasp. We tell the patient to blow his nose to clear the field, and readjust the forceps, and repeatedly meet with similar disappointment upon their withdrawal. This is disappointing and discouraging to the average operator. By this time the segment may be entirely detached, and slipped to the floor of the nasal fossa toward the posterior nares. The forceps is applied and re applied often fruitlessly. This having consumed much time, much, if not all, of the cocaine anæsthesia has worn off, and further manipulation of the parts becomes painful to the patient, who has also been made nervous through delay.

To prevent this delay, unnecessary manipulation, and contusion of the parts and subsequent pain, I place this forceps before you, hoping that it will prove as satisfactory and efficient with you as it has been to me in my work. The forceps consists of two blades with scissors handles. The flanges at the end of the blades are about the size of the hypertrophied portion of bone usually removed. The inner surfaces of the flanges have five pointed uprights, and between the uprights are perforations through which the uprights pass when the forceps is clamped. The inner surfaces of the flanges are also serrated to make the clamping more secure The blades are bent and strong, the joint connecting them especially so. At the handle is a spring catch that can be used at will, to insure a more thorough grip after the forceps has been clamped.

The working mechanism is simple: After the hypertrophied segment of bone has been sawn through and hangs pendent, the forceps is clamped over it, and when once placed properly, the pointed uprights piercing the bone, the forceps is closed, the catch sprung tightly, and then there is no possible chance for slipping to take place. Then the segment can be twisted off and removed from the nostril; or if not sufficiently sawn, the forceps is twisted toward the septum, the saw re-introduced at the side of the forceps, the remnant detached, and the segment removed. This, when properly done, renders the operation expeditious and successful. This part of the operation, usually occasioning so much delay, with the aid of this forceps consumes the least amount of time. All parts of the forceps can be detached for cleaning.

I am indebted to Messrs. George Tiemann & Co. for the skilful execution of the plans.

166 East Ninety-third Street.

Medical Items.

Placarding Contagious Diseases in Tenements.—The following official document has just been issued by the Health Department of New York:

"CHARLES F. ROBERTS, M.D., *Sanitary Superintendent.*

"SIR: We desire to direct the attention of the Board of Health to the necessity for the adoption of some more adequate means to prevent the extension of contagious disease in tenement houses and apartment-houses, and particularly for the enforcement of isolation of persons sick with these diseases. The methods which have been long employed in the Health Department, *i.e.*, frequent visitation and instruction by Department inspectors, have been found to be only partially effective. It has been the custom for years in cases of contagious disease for the inspectors of the Department to visit the families of the sick persons, inform them as to measures of disinfection and methods of isolation, and at the same time to notify other families in the house of the existence of a case of contagious disease in a given apartment. This method of giving publicity to the case and of warning other occupants of the house is ineffective in the accomplishment of the desired end; *i.e.*, the complete isolation of the patient and the prevention of further infection. Notifying all the inmates of a large tenement is a very difficult matter, and, if notified, experience has shown that they soon forget the existence of illness in the house. Repeated inquiries have demonstrated the fact that frequently many of the inmates of a house where there is a case of contagious disease do not know of the existence of any sickness. Further than this, this method fails entirely to protect strangers or visitors who may go to the house or apartment. Ladies in search of servants have been repeatedly found in houses or in apartments where cases of contagious disease were present, and servants who have been living with families where there are cases of contagious disease, on obtaining situations frequently go to their employer's house carrying infection with them; or, when relieved from duty for an afternoon or evening, visit families where there are cases of contagious disease, and not infrequently carry infection back to the houses in which they are employed. Very commonly washing or various kinds of sewing is secretly done by other members of the family in apartments where such cases are ill, and the garments thus infected on the premises are later returned to the owners. In small shops business is sometimes carried on, and in one of several instances recently a number of cases of diphtheria were directly traced to an infected candy store.

"Notifying inmates of the house is ineffectual, further, because it has been found that, as a rule, intercourse of families in tenement houses is not with others in the same house, but with families which live in other houses, and the latter are entirely unprotected by the methods at present followed. It has seemed to us, after careful consideration of this subject, that the desired object would be best obtained by the placarding of apartments in tenement-houses where cases of contagious disease exist, and we therefore have the honor to recommend that hereafter the Chief Inspector of Contagious Diseases be authorized, in his discretion, to placard apartments in tenement houses where there are cases of contagious disease. The following considerations may render still more apparent the necessity for this action: 1. Under the present conditions it is impossible to prevent strangers and visitors from entering apartments where there are cases of contagious disease, and they or their clothing thus frequently become infected and either they contract the disease themselves or they transmit it to others. These strangers or visitors are usually not aware of the existence of disease in the house or apartment, and unwittingly expose themselves and act as media for the dissemination of the disease. If the apartments were placarded, this means of dissemination would be prevented. 2. In diphtheria, as has been repeatedly and abundantly shown by the investigations of this Department, patients are often apparently well long before they are free from the infectious agents, and in spite of repeated warning from Department inspectors these patients, especially when children, mingle with other children and thus transmit the disease to them. This is one of the most common and important means for the dissemination of diphtheria, and it is of no less importance in scarlet fever and measles, as in the latter diseases desquamation frequently continues many days after the patient has apparently quite recovered. 3. There are at present no means by which other inmates in tenement-houses can know when convalescent cases of contagious disease have ceased to be dangerous. They can only be governed by appearances, which, as we have seen, are deceptive. If apartments where cases of contagious disease existed were placarded, isolation would be enforced by the other occupants of the house until the department inspectors allowed the placard to be removed. 4. The moral influence of such placards, both upon the inmates of the apartments, the inmates of the house, and strangers or visitors to the house, would be of as great service in enforcing isolation and preventing extension of disease as the visits and instruction of our inspectors. It has been found impossible, even where daily visits were made by medical inspectors, assisted by the sanitary police, to enforce the isolation of children convalescing from diphtheria and scarlet fever after the serious symptoms have disappeared. It is undesirable at such times, unless absolutely required, to remove such patients to the hospital, and yet in the eruptive fevers this is the period of the disease when there is greatest danger of transmission to others.

"During the last year we have had a serious epidemic of diphtheria to deal with. The number of cases reported weekly during the last months, however, has steadily decreased. The schools have just now opened, and it seems to us that the most strenuous efforts should be made to prevent a new outbreak of the disease or its reintroduction to the schools. This measure would be of undoubted service in accomplishing the desired object. We would recommend, therefore, that placards should be nailed to the outside doors of the apartments in which cases of contagious disease are present, when in the judgment of the Chief Inspector of Contagious Diseases this course seems to be desirable, and that the placards should bear the following inscription, differing as to the name of the disease in question and as to color. The color for diphtheria should be white; for scarlet fever, red; for measles, blue.

DIPHTHERIA.

All persons not occupants of this apartment are notified of the presence of diphtheria in it, and are warned to avoid entering it until this notice is removed. The persons sick with diphtheria must not leave the apartment as long as this notice remains here.

The removal or defacement of this notice is forbidden.

By order of the Board of Health,

..... *President.*

..... *Secretary.*

"For some months in certain classes of tuberculosis the system of placarding apartments has been authorized and employed by the Health Department, and has proven very satisfactory in the attainment of the object desired. The only objection apparently to be urged against this measure is that the inmates of the apartment may object to the publicity thus entailed. This, however, is exactly the object which the measure is justly and properly designed to subserve, and is, in our opinion, the strongest argument in favor of its adoption.

"(Signed) Respectfully submitted,

"HERMANN M. BIGGS,

"*Pathologist and Director of the Bacteriological Laboratory.*

"A. H. DOTY,

"*Chief Inspector of Contagious Diseases.*"

ON SYMPHYSEOTOMY, WITH THE REPORT OF A NEW CASE.[1]

BY HENRY J. GARRIGUES, A.M., M.D.,

CONSULTING OBSTETRIC SURGEON TO THE NEW YORK MATERNITY HOSPITAL; GYNECOLOGIST TO ST. MARK'S HOSPITAL OF NEW YORK CITY, ETC.

WHEN I had the honor of reading my last paper on symphyseotomy before the Obstetric Section of the Pan American Medical Congress, in the month of September, 1893, I said that taking the *pros* and the *cons* into due consideration, I thought that the next time I had the opportunity of performing the operation I should try the Italian method first, and so I did in the following case, that presents several points of interest in regard to the indication, the operation, the course, and the result.

Pelvic Tumor; Large Child; Italian Method; Waddling Gait.—Mrs. G. V. D——, aged twenty-nine, German, married, was admitted to St. Mark's Hospital on June 27, 1894. She had had one child, eight years ago, which died at the age of eleven weeks. She had been suffering from dysmenorrhœa for years, and menstruation had been very irregular of late. She last menstruated in August or September. For three months she had been suffering from lumbar pain, and for two from anasarca. Labor pains began at four o'clock in the morning. She had been examined by a midwife, who said she was pregnant, and by a doctor, who said she had an ovarian cyst, and abstracted some fluid with a hypodermic syringe through the abdominal wall. She had considerable anasarca all over, especially the face, hands, abdomen, and legs, and on boiling about one-sixth of the urine coagulated. She was in labor. The os was situated far forward over the symphysis and measured two inches in diameter. Bag unbroken. Vertex presentation. Fœtal heart very distinct, one inch to the left of and above the umbilicus.

At 4.30 P.M. the os was fully dilated, but the head made no progress, being pressed forward over the symphysis pubis by a soft, non-fluctuating mass in the rectovaginal septum, extending nearly up to the cervix. The heart-sounds had become so weak that they were heard with difficulty. I proposed to perform symphyseotomy, in which my colleague, Dr. Boldt, who happened to come to the hospital, and whom I requested to examine the patient, concurred. After thorough disinfection and the patient being in the dorsal decubitus with bent knees and raised feet, I made an incision in the median line two inches long and ending one-half inch above the symphysis. Small transverse incisions were made right and left, just above the pubic bones, and just long enough to admit the left index finger, which was easily inserted down to the lower end of the symphysis. A few small blood-vessels were clamped. Next, Galbiati's falcetta was introduced along the finger. The bones were in close contact and the notch at the lower end of the symphysis could not be felt. There was slight difficulty in finding the symphysis, but once found it was easily cut from below upward, and from behind forward, using the left index finger as a guide in the vagina, and having the urethra held by an assistant over to the right side with a metal catheter. By reintroducing the finger into the wound I felt that the ends of the bones were only separated one inch, especially at the upper end of the symphysis, and less at the lower, where they were bound together with a sinewy tissue (part of the subpubic ligament) which was easily ruptured. The head descended immediately and was easily extracted with forceps without any tear of the vagina or the perineum. The child, a female, weighing ten and three-quarter pounds, was dark blue, the heart-beat very slow, no respiration, and the meconium pouring out from the anus. Seeing the great danger of the child, I removed it to another room and concentrated my whole attention on its revival, leaving the care of the mother to Dr. Boldt, who saw a large artery spurting in the cervix, which he tied with catgut carried round it with a curved needle. The placenta was expressed by Credé's method, and two hypodermic injections of twenty-five minims of fluid extract of ergot given.

The child having been revived I returned to the mother and found by actual measurement a distance of five inches (12.5 ctm.) between the pubic bones, merely due to the weight of the thighs, which were being kept bent, but without pressure on the trochanters. Then two assistants were directed to bring the ends of the bones together by pressing on the trochanters, while I held back the bladder and vagina. There was slight venous bleeding from the bottom of the wound. Four silk sutures were inserted through the edges of the wound in the soft parts; nothing was done to the ends of the bones; the wound was packed with iodoform gauze, the end of which was led out at the lower end of the wound while the three upper sutures were tied. The vagina was likewise tamponed with iodoform gauze. While the pelvic bones were kept together, and the legs were kept extended, three straps of rubber adhesive plaster, two inches wide, were drawn round the pelvis and the trochanters, and crossed in front above the wound. The vulva was covered with my pad.

The next morning the gauze was removed and the last suture tied. The child was large and in excellent condition.

	Centimetres.	Inches.
Occipitomental diameter	14	5½
Occipitofrontal diameter	12.5	5
Biparietal diameter	10	4
Bitemporal diameter	8	3¼
Circumference of head	38	15
Length of body	56	22
Circumference of chest at arm-pit	38	15
Bisacromial diameter	13.5	5½

On the third day after the operation the mother developed incontinence of urine, which lasted a few days. The urine contained many cells from the kidney epithelium and numerous casts from the circumvoluted, straight, and narrow tubules; but these, as well as the anasarca and albuminuria, disappeared soon.

July 3d (Sixth day).—She had a rise in temperature reaching 103° F., probably due to mastitis, hard, tender nodules forming in both breasts, but disappearing in four days under the use of ice-bags. But the fever may also have been partly due to suppuration at the wound.

July 4th.—There appeared slight suppuration round the stitches, which were removed. The edges were united by first intention, but the following day half an ounce of pus was pressed out from an opening at the upper end of the wound, and a thin drainage tube, three inches long, was inserted.

July 7th.—The patient, who was rather self willed,

[1] Read before the New York County Medical Society, October 22, 1894.

lifted herself on the bed-pan by arching herself on her shoulders and heels, without any pain.

July 10th (Thirteenth day).—She took a few steps, supported under her shoulders, and felt solid. On the 12th the upper two thirds of the symphysis were felt in perfect apposition, while at the lower end there was just room for the tip of the finger. The plaster straps being loose were renewed.

July 18th.—The distance between the bones was only one-eighth to one-sixth inch. The tumor in the pelvis had entirely disappeared, and must, therefore, probably have been due to serous infiltration, like that forming the anasarca. Only the left ovary was felt swollen way up in front of the left iliac synchondrosis.

July 20th.—She walked alone by holding on to the furniture; on the 26th she walked without support and amused herself by carrying food to other patients.

July 31st (Thirty-fourth day after the operation).—She left the hospital by her own request.

On October 9th I saw her and her child. The latter was in excellent condition, and the mother could lift it, but she had a waddling gait, some cystocele, and off and on pain in all the three joints of the pelvis; but she said she was improving. By vaginal examination I found the greater part of the ends of the pubic bones in apposition, but at the lower end the diastasis had increased to half an inch.

The subject of symphyseotomy has attracted so much attention during the last two years that I may suppose every member of this Society is familiar with the chief features of it, and I have twice treated it at some length.[1] I shall, therefore, to night, limit myself to the discussion of some particular points upon which opinions differ much among the different authors engaged in the discussion of this operation, basing my opinions not only on the limited experience I have had with it myself, but on a somewhat extended study of the cases reported by others.

First, however, I shall briefly call attention to some features of the case I have just reported. The distance of five inches between the ends of the pubic bones is quite unusual. As a rule it is only one and one-quarter to one and one-half inches when you hold the legs flexed without pulling. How much it was before and during extraction of the large child I could not tell. The child being in the greatest danger of dying, there was no time for such investigations. What I can state for sure is that I did not meet with any resistance in extracting, and that no cracking sound was heard, such as is reported invariably to be distinctly audible when the sacro-iliac joints are overstretched and ruptured. Perhaps the great serous infiltration which produced the anasarca of the whole body and the swelling in the pelvis for which the operation was performed may have caused an unusual laxity of the sacro iliac joints.

Secondly, I would notice the miserable condition of the patient's kidneys, the microscopical examination showing that all parts of the same were affected, and the circumstance that the patient had been examined by one midwife and three doctors without antiseptic precautions.

Either of these circumstances would have excluded recourse to the Cæsarean section, and if Porro's operation had been performed, she would undoubtedly have died. Forceps and version being out of the question, on account of the disproportion between the size of the child and the space left in the pelvis by the tumor, the only alternative would have been to kill this splendid child, weighing nearly eleven pounds, while symphyseotomy allowed us to save both mother and child.

It is true the mother has a somewhat unsatisfactory gait, but it is better to waddle through life than to be put at rest under ground.

Passing to the consideration of the operation in general, I shall limit myself to remarks on its prognosis, its indications, its methods, and the question by whom and where it ought to be performed?

[1] American Journal of the Medical Sciences, March and April, 1893, and American Journal of Obstetrics, November, 1893.

Mortality.—A chief point to be taken into consideration in ventilating the advisability of performing a certain operation is, of course, the prospects it offers as to life and health. In his large work on symphyseotomy Neugebauer[1] has collected 213 cases of modern operations performed between the beginning of 1887 and the middle of 1893. Of the mothers 183 recovered, 27 died, and in 3 cases the result was unknown; that is, a maternal mortality of 12.85 per cent. As to the children the results were unknown in 8 cases. Of the remaining 205 children, 7 were dead before the operation; 9 died during parturition; 189 were born alive; but of these 31 died soon, leaving 158 as permanently saved. The direct infantile mortality was, therefore, only 4 54 per cent., but counting those who died within a few days as lost the mortality among the children was 20.2 per cent.

In connection with these general statistics it must however, not be overlooked that the operations were performed by a very large number of operators, *e.g.*, the first twenty-eight American operations by twenty-three different operators, and often in private houses, so that very few men have acquired a large personal familiarity with the operation, and that it often has been performed with deficient antiseptic precautions. At the hands of men accustomed to obstetrical and gynecological operations there has hardly been any maternal mortality. Thus we find Pinard operating 18 times and Zweifel 23 times without losing a single mother, and the Italians have, since January 1, 1886, had 55 operations with a loss of only two women.[2] We are therefore warranted in saying that performed under the most favorable conditions there is practically no maternal mortality inherent in the operation.

For the child the outlook is not so good, but still better than in most other methods of delivery, not to speak of craniotomy, with which symphyseotomy especially competes, and by which the child is deliberately killed, and here again the skill of the operator has diminished the mortality considerably. Thus in the above-mentioned 55 Italian operations only 8 children were lost, *i.e.*, 14 55 per cent.

Injuries.—Several operators, especially German, have reported cases in which the soft parts of the mother sustained considerable injuries—the urethra, the bladder, and the vagina being torn during extraction. On account of the greater firmness of the tissues this is more likely to happen in primiparæ. The bladder and the vagina may also be caught in bringing the pubic bones together. The sacro-iliac joints have been ruptured and separated. Such accidents may, however, to a great extent, be avoided by extracting the child slowly and in the proper direction; by avoiding pressure in front; if necessary, by performing episiotomy; by keeping the protruding vagina and bladder back during approximation of the bones; and by not passing the proper limits of the indications. Most of these injuries were successfully repaired either by immediate suture or by a consecutive fistula operation.

On the other hand, it cannot be denied that a certain number of women develop a waddling gait. That this is not so very rare will appear from the fact that I have had one such case in two operations, Grandin one in four operations, Zweifel three in twenty-three operations, and Fritsch even four in four operations.[3] But if this waddling gait does not look well, it need not interfere with perfect health and strength, even allowing the woman to do the hardest field-work and carry her eleven months' old baby many miles, as in a case reported by Fritsch.

Indications and Comparison with Other Methods.—Since only a few years have elapsed from the time of the new impetus given to this old operation in 1892, it is quite natural that opinions in regard to its proper field should vary much among leading obstetricians, and one

has even the impression that national tendencies to prejudice in favor of or against it have not been without influence on the bias of the different authors. Thus, while Leopold rejects the operation altogether in primiparæ, and wants it limited in regard to the flat pelvis to cases of 6 to 7½ ctm. (= 2½ to 3 inches) true conjugate, with both mother and child perfectly healthy;[1] Pinard thinks it must replace introduction of premature labor and every operation which exposes the head of the child to a pelvic resistance that cannot be overcome by uterine contractions.[2]

Personally I think symphyseotomy ought to have a rather wide range in lying-in hospitals and under circumstances that favor a good result, especially sufficient assistance and the possibility of having a reasonable degree of asepsis. In the flat pelvis I think we may expect an easy delivery when the conjugate measures at least three inches, and that it may yet be performed when the conjugate measures only two and three fourths inches. To go below this is hazardous, unless the child is abnormally small.

The great gain obtained in the lateral directions make symphyseotomy particularly valuable for us on account of the preponderance of generally contracted pelves in New York and Boston, and perhaps other parts of the United States. As to the upper limit for symphyseotomy, it ought, in my opinion, to be placed in a flat pelvis at a true conjugate of three and one-half inches, and in a generally contracted even at four inches.

Symphyseotomy may render good service under other circumstances than a narrow pelvis, such as pelvic tumor, occipitoposterior position, impacted mentoposterior face presentations, ear presentations, in eclampsia, etc.

In studying foreign authors on the indications for symphyseotomy in narrow pelves, it should be borne in mind that the average weight of new-born children is considerably greater in America than in Europe. Lusk found the average of two hundred cases in Bellevue Hospital to be 7⅔ pounds, while Tarnier gives it as 3,174 grammes = 7 pounds, Spiegelberg as 3,174 grammes = $6\frac{9}{10}$ pounds, and Playfair at only 6½ pounds. We can, therefore, not descend so low as European accoucheurs do, and must place the upper limit for symphyseotomy higher.

Craniotomy on the living child is a repulsive operation that has met with just condemnation from many sides. As long as the alternative was only Cæsarean section, I did not hesitate to sacrifice the child in order to save the mother, but since in symphyseotomy we have got an operation almost without danger to the mother and with moderate danger to the child, I do not think any man should feel compelled to, or justified in, deliberately murdering the child, provided the necessary conditions for a successful symphyseotomy can be brought about.

Induction of premature labor entails only a maternal mortality of five per cent. against nearly thirteen in symphyseotomy. In skilful hands there is hardly any mortality for the mother in either of these operations, but then the infantile mortality is very high,[3] and many premature children die.[4] In cases in which the mother's life is to be preferred, which is the rule, and we see the patient in time, recourse may, therefore, be had to induction of premature labor; but in cases in which the mother is particularly anxious to have a child, symphyseotomy at term should be preferred.

In Cæsarean section the infantile mortality is only six, against twenty in symphyseotomy, but then the maternal mortality is twice as large in Cæsarean section, twenty-five against twelve and one-half per cent., and if we only take the most skilful operators, the mortality of symphyseotomy is practically none, against eight per cent. in Cæsarean section. One must, therefore, be a fanatic worshipper of the latter operation in order to think of performing it when the former is practicable. Besides, Cæsarean section is only indicated in aseptic cases.

Symphyseotomy competes even with Porro's operation, since it has been successfully performed after the patient had been in labor for days, and had been examined without antiseptic precautions. But Porro's operation has a maternal mortality of 37.78 per cent., and an infantile mortality of 22.40 per cent.[1] If the condition of the patient is not too bad, and there is no absolute indication for Cæsarean section, symphyseotomy should, therefore, be preferred.

Even difficult forceps and version operations ought to be replaced by symphyseotomy. If the true conjugate is three inches or more it may be well to try the forceps before performing symphyseotomy as recommended by Morisani,[2] but below that we only jeopardize the child's life, and perhaps the mother's too, by using the forceps.

I have a painful recollection of cases in Maternity Hospital of generally contracted pelves with the male type, in which with all my strength I extracted a dead child, its mother dying within a few days, so that I even resolved in similar ones to perform Cæsarean section, but now would substitute symphyseotomy. Furthermore, all those cases we read about of three strong men pulling at once or in succession on a pair of forceps ought to be relegated to the history of barbarian times.

As to version, we well know how difficult it is to get a living child through the pelvis, if there is any appreciable narrowness. If the conjugate is less than three and a quarter inches, both version and the high forceps operation entail much greater danger for the life of both mother and child, to which must yet he added the danger of the child becoming idiotic or epileptic. If the child is unusually large, symphyseotomy comes in as a life saving operation for both mother and child, even when the pelvis is normal.

This paper has already become so long that there is no time left for me to enter at length into the question of the *modus operandi*. I shall only recommend the Italian method as much the simpler one, which also has given better results than the French.

Instead of the chain-saw needed in rare cases, which is expensive and difficult to render aseptic, Gigli recommends rough steel wire.[3] It is not necessary to unite the ends of the pubic bones with silver wire (Schauta), or, to hammer steel pegs into them and draw them together with silver wire (Regnier),[4] or to have special apparatus to press on the trochanters, as proposed by Pinard, Kofer, Bidder, and Krassowski.[5] Rubber adhesive plaster carried round the pelvis, while the legs are kept straight, is sufficient for a good union. I think it is better to leave a rubber drainage-tube behind the symphysis for a few days. The extraction ought to be made while the knees are kept bent, and not, as advised by Leopold,[6] in the suspension position (Hängelage), which brings the ends of the pubic bones together. Four assistants are needed, and at least one of them ought to be an expert, as the child often is asphyctic, and there may be maternal hemorrhage demanding immediate attention.

Who shall Perform Symphyseotomy?—In laying down rules for the indications of symphyseotomy I have only treated the question from a purely scientific standpoint, as it ought to be, without taking into consideration what every practitioner may be capable of doing. When a man has a cataract, it ought to be taken out: whether a particular physician is competent to do so or not, that is a question between him and his patient. But just as everybody is not a fit person for extracting a cataract, thus a man may be an excellent physician and still not be the right man to have a symphyseotomy performed

by. Nobody should undertake this operation who is not an operative gynecologist or a general surgeon with obstetrical experience. In some cases very serious hemorrhage has to be dealt with, in others severe injuries of delicate and important organs demand immediate repair, and in most the child has to be artificially revived. This is, therefore, an operation which most general practitioners had better place in the hands of a fellow-practitioner with experience in that kind of work, just as he would send a patient afflicted with a cataract to an oculist.

Where should Symphyseotomy be Performed?—As it is next to impossible to perform an aseptic operation in most private dwellings, especially of the poor, who are much more likely to require symphyseotomy than the rich; as many and skilled assistants are needed; and as the after-treatment often is quite complicated; the chances for a good result with this, as with all major operations, are much better in a hospital than in private houses. Wherever it is possible, patients requiring symphyseotomy should be removed to a hospital, be it a lying-in hospital or another institution where abdominal operations are usually performed. Such a place in this city is St. Mark's Hospital, and I shall be happy to treat any case there you will place under my care. It is, in my opinion, no excuse for killing a child that the accoucheur is not prepared to perform symphyseotomy, as long as there is somebody else within reach whose services can be obtained, and who is able to substitute a life-saving for a destructive operation.

SURGERY OF THE STOMACH.

By W. J. MAYO, M.D.,

ROCHESTER, MINN.

SURGEON TO ST. MARY'S HOSPITAL, ROCHRSTER, MINN.; EX-PRESIDENT OF THE MINNESOTA STATE MEDICAL SOCIETY; MEMBER OF THE STATE BOARD OF HEALTH.

MR. PRESIDENT AND MEMBERS OF THE SOUTHERN MINNESOTA MEDICAL SOCIETY: The stomach is now amenable to surgical relief from a large number of conditions, which until recently have been supposed to be purely medical in character, and in many respects it offers unexpected opportunity for operative interference. In the first place, it is an organ more or less fixed within a certain definite part of the upper abdomen. In the second place, in a large majority of instances it can be irrigated and rendered fairly clean before operation. In the third place, by rectal alimentation it can be given rest afterward; and lastly, its thick muscular walls afford a good hold for suture, while its blood supply is of such nature as to give union after extensive resections, herein differing materially from the thin-walled, mesentery-nourished intestine with more or less constant vermicular action. I will not take up your time with the anatomy of the stomach, more than to mention that its cardiac extremity is the only fixed point, and that it is suspended, so to speak, in such a way as to vary its position whether contracted or dilated. In the former case, lying deep under the liver against the crura of the diaphragm, and in the latter occupying a prominent position in the hypogastrium. The lesser omentum, as containing the main blood-vessels, is of much surgical importance, as are also the relations of the mesocolon and other delicate structures in the neighborhood of the pylorus. As pointed out by Tillaux, the cartilage of the ninth rib forms an important guide to the lower border of the stomach. The diagnosis of gastric disease, as a rule, is not difficult. The stomach can be distended by ether, as recommended by Felitzet, or by the use of bicarbonate of soda and an acid, as practised by Jacobi. Usually, the introduction of a definite quantity of water will sufficiently mark its outline, and by forcing air into the colon per rectum, as practised by Senn, the relation of the stomach to the transverse colon can be mapped out. By such means, I was able to diagnose a pancreatic cyst definitely, the tumor being shown to be retroperitoneal and lying behind the gastrocolic omentum, the operation proving the diagnosis. (Case 1349, St. Mary's Hospital Records.)

The value of the examination of test meals and the amount of acid as affecting the diagnosis of cancer, is thoroughly laid down by Von Jaksch in his "Clinical Diagnosis," the presence of free hydrochloric acid being a factor in the diagnosis as against cancer and in favor of ulcer. The effect of the weight of tumors in displacing the stomach is ably shown by Osler in a series of papers, beginning in the *New York Medical Journal* of February 3, 1894. As preliminary to operation upon the stomach, irrigation is of great value where it can be practised, and, as pointed out by Kussmaul, much benefit may be derived from lavage where obstruction exists below, thus relieving the stomach of irritating material, removing the distention and interference with breathing, and putting the patient into better condition for operation. Shall the stomach be distended previous to operation, to facilitate finding it? I have personal reason to know, in at least two operations, that where the stomach is contracted from stricture of the œsophagus and the colon greatly dilated through rectal alimentation, the difficulty of finding the stomach may be great. In these cases the stomach was found by the sense of touch, for after a little experience the feel of its thick walls will not be forgotten. Previous distention may assist in finding the stomach, but it complicates the further manipulation and introduces an element of danger of wound contamination from escape of its dilating contents. I believe it had best be empty. The after-treatment of gastric operations is changing toward the earlier administration of food by the stomach, especially in exhausted patients, although rectal feeding is the rule during the first few days.

Before closing these general considerations, I wish to call attention to gastric distress produced by traction of adherent omentum. Billroth has written well upon this subject, especially in reference to the small buttons of omentum protruding through little gaps in the upper abdominal wall. Koenig reports some twenty cases operated upon. I have seen several cases of this description (863 and 1059, St. Mary's Hospital Surgical Record). The first, a boy of fifteen, with a small hernia of adherent omentum protruding through a little defect in the median line above the umbilicus. The second, a lady of fifty, with adherent omentum in a femoral hernia, both cases having no local symptoms at the site of protrusion, and both relieved by operation. I have also seen some cases of this form of omental adhesion with corresponding symptoms in connection with post-operative ventral herniæ. Wounds and injuries of the stomach are to be treated on surgical principles, and where evidences of perforative wounds are found operative repair is imperative. Rose speaks of persistent vomiting of blood as a reliable sign of gastric injury. In case there be injury to the head at the same time, however, the possibility of there having been blood swallowed from the upper passages should be borne in mind. Foreign bodies in the stomach are a not infrequent cause of danger and suffering, and gastrotomy for the purpose of removal has been greatly perfected. Richardson, of Boston, gives a careful analysis of reported cases, and makes many valuable modifications in the technique, when the foreign body lies in the lower œsophagus. Bull also reports excellent work in this direction. The value of a potato diet in the non-operative treatment of foreign bodies of the alimentary canal, should not be forgotten.

Fistulæ are, as a rule, the result of operative work, and rarely come from accidental or pathological causes. They vary much in the difficulty of repair on account of location, those adjacent to the bony framework being much more difficult of operation than those more remote. The great value of the provisional suture to prevent escape of stomach contents during manipulation, is at once apparent. Chronic dilatation of the stomach, when not due to organic lesion, may be caused by chronic gastric

catarrh with sagging of the fundus, rendering it difficult for the stomach to empty itself. Taylor, of Birmingham, has studied this condition carefully, and believes that it produces a kinking at the pylorus with prominence of the mucous fold, causing a bar-like obstruction to the emptying of the stomach. He practises operative dilatation of the pylorus with success. Bircher, followed by Weir, mechanically raises the fundus, and reduces its size by putting a longitudinal plait along its walls, turning a fold into its cavity. This operation is indicated in those cases where lavage for a length of time has failed to relieve the symptoms.

Ulcer.—In the diagnosis of ulcer, the age of the patient, the quantity of the vomit, the lack of emaciation, which in ulcer is more often a profound anæmia without great loss of flesh, the presence of free acid, and slow course of the disease, are all valuable symptoms of ulceration as against carcinoma. Operation may be demanded for acute perforation, provided it can be diagnosed in time. As can readily be perceived, the location of the perforation, whether on the anterior or posterior wall, will greatly influence the ease of repair. Ulcer of the stomach being most frequent on the posterior wall, occasionally a perforation may take place and the escaping material, on account of its mechanical surroundings, become encapsulated as a sub-diaphragmatic abscess. Weir points out the frequency of left pneumothorax due to the secondary results of perforative ulcer. A case of subdiaphragmatic abscess came under my care. (No. 1,537, St. Mary's Hospital Surgical Record.) A Scandinavian, fifty years of age, with history of chronic stomach trouble, became suddenly ill, developed pain, and later, cough and hiccough. A deep swelling became manifest in the sixth interspace just to the right of the sternum, for relief of which he entered the hospital. A deep incision was made and pus evacuated; but as a sinus formed and failed to heal, the cartilages of the sixth and seventh ribs and a large portion of the lower end of the sternum were resected. The sinus was followed through the diaphragm to the neighborhood of the lesser omentum, where a small cavity existed; this was packed with gauze and slow healing followed. The secondary results of ulcer, in producing contraction at the pylorus, may call for operation for obstruction, either the digital divulsion of Loreta, or better the Heineke-Mikulicz pyloroplasty. Weir reports a case of this character in which gastroenterostomy was performed, and in selected cases advocates its expediency.

Cancer of the Stomach.—The age of the patient, lack of free acid in the vomit, the emaciation, and the possible presence of peptones and albumin in the urine, aid in the diagnosis of cancer. Gussenbauer and Winniwarter give sixty per cent. as the proportion of pyloric cancer to the whole number. Bull, with statistics of thirteen hundred cases of stomach cancer, gives the proportion as above fifty per cent. in the pylorus. Butlin, in his classical work, says of these cases, that a very large number of cases of pyloric cancer die from obstruction before glandular infection or extensive adhesion takes place. Billroth, the great exponent of operative surgery of the stomach, says that cancer of the pylorus produces great muscular hypertrophy and death from obstruction in one-half of the cases, before adhesions or glandular infection supervene. It is probable, therefore, in the light of this knowledge, that pylorectomy and partial gastrectomy have a larger field than has been supposed, although Butlin, in a careful analysis of reported cases subjected to operation, takes a very gloomy view of the situation. For cancer involving the cardiac orifice, gastrostomy is advocated by Von Hacker for the purpose of feeding. Lauenstein has been impressed by certain unfortunate sequelæ of gastrostomy in these cases, such as constant leakage, involvement of the fistula, etc. With either the Witzel or Frank operation of gastrostomy this objection would not hold good, however. For cancer of the fundus, Bernays, of St. Louis, practises gastrotomy and curetting of the mass from within the stomach. He shows that in the majority of cases the growth of the cancer is toward its free cavity. The danger and difficulty of the operation exceed the benefit to be derived from it, in my opinion. In this connection an allusion to the remarkable disappearance or temporary checking of the growth of tumors after simple exploratory incision, would not be out of place. Tait first called attention to this phenomenon. J. W. White has gone extensively into this subject in regard to the curative value of operations of themselves, independent of their intention. The total disappearance of a cancer after simple abdominal incision must be very rare, but I have twice seen temporary checking of its progress after laparotomy. (Cases 368 and 571, St. Mary's Hospital Surgical Record.) In cancer of the stomach a varicose condition of the peritoneal veins overlying the growth is frequently observed on laparotomy, and is due to obstructed internal circulation leading to adhesions. In one hundred and twenty-four operations on the stomach and intestines, Billroth gives a mortality of fifty per cent.

Operations on the Stomach.—In stomach operations, the abdominal incision for most purposes will be the classical one of Fenger, parallel with the left costal cartilages, and, unless otherwise specified, is the one used, excepting for fistula and other conditions where there is no choice of locality. Gastrorraphy, due to the genius of Billroth, may be performed for wounds and injuries, the simple Lembert or a Czerny-Lembert suture being applied. For fistulæ, some special means of preventing escape of the stomach contents during operation must be used. The older method was to introduce a sponge with attached string, and hold this firmly against the opening. The provisional suture of the margins of the fistula is a much better practice, and in many cases, by trimming away the attached tissues afterward, can be left as a Czerny suture and the Lembert applied to roll it in; or the stomach being brought well out, the whole of the fistula may be cut out and the Czerny-Lembert suture applied. In 1891 Bircher invented his operation for simple dilatation of the stomach, by suturing a fold which projects into its lumen with a Lembert suture. Weir has practised this with marked relief.

Gastrotomy for Foreign Bodies.—Richardson, in 1886, recommended a large gastric incision and the introduction of the whole hand, if necessary, to remove bodies from the lower œsophagus. Much of our knowledge of foreign bodies is due to his labors. Bull recommends a small gastric incision, and with fingers introduced, invaginates the wall into the stomach cavity. In either case, several holding-sutures to manipulate the stomach with are better than the fingers, which may slip, or forceps, which may injure the vitality of the wound margins. Gastrotomy for the purpose of curetting cancerous growths has been performed by Bernays, but cannot be commended.

Gastrotomy for Dilatation.—In 1892 Loreta practised gastrotomy for the purpose of digital divulsion of the pylorus for obstruction. It can be performed for stenosis of either orifice of the stomach. J. W. Taylor has made gastrotomy several times for the purpose of digital dilatation of the pylorus, in cases of twisting at the neck of the stomach due to chronic dilatation, and reports successful cases. Heineke and Mikulicz, nearly simultaneously, performed pyloroplasty for cicatricial stenosis of the pylorus. As ordinarily performed, a gastrotomy is first made and a grooved director introduced through the stricture from the stomach, the contracted tissues are then divided by a longitudinal cut, and this incision is now united in a transverse direction by suture. This admirable operation has been performed by Senn and many other surgeons, with the best of results.

Gastrostomy for the purpose of feeding is indicated by any obstruction between the mouth and the stomach, if it cannot be relieved by less dangerous and more expedient methods. First performed by Sedillot in 1849, it has had a perilous existence, until in recent years the method known as Fenger's has usually been employed;

but its high mortality, the leakage, with its attendant loss of nutrition and irritation of the surrounding skin, made it but rarely resorted to. In preventing this leakage, Ferrier made the important suggestion that the gastric opening be made high up near the lesser curvature. Most operations up to this time were done in two sittings, the stomach being first sutured to the abdominal incision and the site of the future fistula marked by ligatures, to guide the opening after adhesion takes place. In a case of impermeable cicatricial œsophageal stricture, I was compelled to make a gastrostomy after this method for the purpose of feeding, and for retrograde dilatation and division after Abbe's string method. While the eventual recovery was good, the annoyance of the constant leakage was great. (Case 1,278, St. Mary's Hospital Surgical Record.)

Hahn modified the operation by making the opening in the stomach high up, and putting the fistula between the ribs for better mechanical closure. This is done by making an abdominal incision and locating the stomach, then a special short incision in the eighth intercostal space is made, and by passing forceps through this button-hole they can be applied to the proper place on the stomach wall by the fingers in the large incision, and the stomach fixed in the small opening, the abdominal incision being then closed. For retrograde dilatation of the œsophagus Von Hacker's method should be preferred, as, while it affords only a moderate degree of retention, it permits of excellent intra-gastric manipulation. The method consists of a perpendicular incision through the body of the rectus muscle, which gives somewhat of a sphincter action. Witzel's method is the best for temporary fistula, as it gives perfect closure against leakage. I have performed this operation once with the most perfect satisfaction. (Case 1,679, St. Mary's Hospital Surgical Record.) After the usual incision the stomach is drawn well out and a small cut made in its wall, through which a rubber tube the size of a lead-pencil is introduced one inch toward the fundus. With a Lembert suture the free walls of the stomach are drawn together over the tube, beginning one inch to the left and continuing to the right one and a half inch, forming a channel lined with peritoneum. The stomach is dropped back and sutured to the incision. The great advantages of this operation are that feeding can be commenced at once without any danger of leakage, and, on withdrawal of the tube, the peritoneal granulation lining the channel will heal permanently. This is of obvious advantage if the condition giving rise to the operation can be removed. I can heartily commend this operation from personal experience. Andrews, of Chicago, has modified this by free incision of the stomach and formation of a channel from the mucous membrane. This is done to avoid the use of a permanent tube, but has greater danger of infection and is difficult of performance. For permanent gastric fistula the method advocated by Frank is undoubtedly the best. In this operation a fold of the stomach one and a half inch long is drawn out and sutured to the parietal peritoneum at its base. The skin above the upper margin of the abdominal incision is undermined along the seventh rib to a point over the sixth rib, where an incision three-fourths of an inch in length is made. The stomach cone is now carried under the skin flap and the apex sutured to this button hole; the abdominal incision is then closed, giving a spout-like opening. This operation is a model one for the purpose of a permanent fistula. Great credit is due to Willy Meyer for the popularization of the Witzel and Frank operations in this country.

Resections of the Stomach.—With these operations the names of Billroth, Wölfler, and Czerny are inseparably connected, and it was their courageous work in the face of an appalling mortality which has made resection of the stomach a legitimate operation. Péan, in 1879, made the first pylorectomy, though unsuccessfully. The mortality of Billroth, the great exponent of pylorectomy, has been nearly fifty per cent., deaths being due largely to collapse, and a number to gangrene of the colon from injury to the meso-colon while separating the pylorus. This surgeon employs the transverse abdominal incision, resects the stomach in a V shape, using a close Czerny-Lembert suture in closing the gastric incision, and suturing the end of the duodenum into the lower angle of the stomach wound. The separation of the pylorus is very carefully done, and just sufficient of the greater and lesser omentum tied off to permit of operation. The greatest care of the meso-colon must be taken. The tendency of American and English surgeons, led by Bull, of New York, McCormick, Treves, and Greig Smith, of Great Britain, is to make the usual median abdominal incision, and after the pylorus is separated, to at once completely suture the stomach with the Czerny-Lembert suture. The pylorus is now cut away from the duodenum and the end of the latter sutured, gastro enterostomy being then performed. This carries the opening away from the dangerous suture line. Partial gastrectomy, as a rule, is a simpler operation, Maydl having once removed nearly one-half of the organ. Complete gastrectomy has been several times attempted, notably by Conner, of Cincinnati, but must fail on account of total destruction of the meso-colon. Ohage, of St. Paul, in the midst of a partial gastrectomy, was confronted by unsuspected difficulties which rendered removal impossible. The stomach was freely opened above, the malignant mass turned into its cavity, and the upper cut edge sutured to the wall below the growth. The patient not only lived, but for a space of two years has been practically well up to the present time. Gastro-enterostomy is indicated by obstruction of the pylorus, especially if this be malignant and not suited for pylorectomy. It was first performed by Wölfler in 1881, by suture, and up to the time of Senn's great innovation in the use of bone plates for anastomosis, the mortality was great—about fifty per cent. At the present time, performed by the aid of bone plates or the mechanical device of Murphy, it is a rapid and safe procedure. Postnikow has attempted to improve the suture operation by freely incising the structures of the stomach and gut to the mucous coat, which is ligated, and then suturing the corresponding parts together, in the expectation that adhesions will take place before sloughing of the mucous coat completes the fistula. In all of these operations, if the duodenum cannot be easily drawn to the stomach, a loop of the jejunum may be used and drawn around the omentum, which is pushed to the left rather than through its folds. The latter practice has in several instances caused death, from kinking of the intestine and obstruction.

Education and Cleanliness.—The Chicago school board has been discussing the question of cleanliness, and as a result, another innovation, the bath-tub, will be introduced into the curriculum of certain schools in that city. In several districts many scholars possess erroneous ideas regarding the proper degree of cleanliness, and henceforth those presenting an unhygienic appearance will receive a scrubbing. The boys will be immersed by the janitor, and the girls will take their ducking under the supervision of women who are employed as assistant janitors. The board deemed it essential that a child should know the value of soap and water, as well as the double rule of three or the theory of the tides. The plan to supply the schools with bath-tubs originated with Mrs. J. M. Flower, who recently retired from a three years' service as member of the board of education, and who is now a candidate for trustee of the State university. This procedure marks another step toward clinical teaching in the schools. Theoretical physiology has been taught children for years, but it has not kept them clean. Under the new *régime* pupils will be instructed in the practical application of this science by demonstrations in bathing, and proof of the superiority of this method of teaching the phenomena of the human body will be manifest on the surface.—*The Physician and Surgeon.*

A CONTRIBUTION TO THE STUDY OF THE CAUSE OF STRICTURE IN THE MALE URETHRA.

By CHARLES GETZ, M.D.,

BALTIMORE, MD.

The cause of stricture in the male urethra is a subject which, it seems to me, has not received the amount of attention its importance deserves in the majority of surgical text-books. Even in the special works upon the subject of stricture, while exhaustive descriptions of symptoms, diagnosis, and treatment are given, with clinical illustrations *ad infinitum*, still, when the authors come to consider the cause, they, with the single exception of Sir Henry Thompson, have passed briefly over this important field. From those authors who have devoted a few short paragraphs to the cause of stricture there have originated ideas and theories so contradictory, in some respects, that instead of throwing light upon the subject they rather confuse the same.

By some writers inflammation, especially gonorrhœal inflammation, is given credit for causing most cases of stricture. Others, again, differ, and in their efforts to reach a correct conclusion concerning this disputed point overstep the proper bounds by denying gonorrhœa a place as an etiological factor altogether. Thus John Hunter, one of the most profound surgical pathologists of his time, in describing the relation of gonorrhœa to the cause of stricture, says, "I doubt very much if it commonly or even ever arises from this cause."[1] Against this opinion we may array the words of Sir Astley Cooper, who says, "If asked what was the cause of stricture, I should say in ninety-nine cases out of every hundred it was the result of gonorrhœa."[2] The writings of Hunter show that he believed almost exclusively in a congenital or anatomical cause for stricture, while the words of Cooper prove that he considered the condition an acquired one in nearly every instance. Both of these famous old surgeons were right, to a certain extent, in their convictions, but as is the case with most vexed questions, the truth lies between the two extremes; and in the course of my remarks I will endeavor to prove that in the majority of cases both a congenital defect and an acquired pathological condition are essential to the formation of close organic stricture.

Sir Henry Thompson, in his book on stricture, third edition, page 120, give a table of cases, 220 in number, in which the antecedent or supposed causes were as follows: Gonorrhœal inflammation in 164 cases; injury to perineum in 28 cases; cicatrization of chancre in 3 cases; cicatrization following phagedena in 1 case; congenital, including cases in which the urethra may have been small from malformation, and those in which marked irritability of the urinary organs existed from childhood, accompanied by an unusually small stream, 6 cases; poisoning by nitrate of potash, lithotrity, masturbation, of each 1 case; inflammatory stricture, including temporary stricture and retention from a sudden acute inflammation, usually caused by some excess, and disappearing by resolution, 8 cases; spasmodic stricture caused by irritation about the rectum, 2 cases; spasmodic stricture, no cause assignable, 2 cases; spasmodic stricture caused by undue acidity or alkalinity of the urine, 3 cases.

This table has been extensively quoted by other modern writers upon genito-urinary surgery and about represents the prevailing belief, as regards cause and effect and the proportionate percentage of each, up to the present time, with possibly two exceptions, namely, the congenital variety and those attributable to masturbation.

The former (congenital stricture), thanks to our modern exact methods of urethral exploration, are more and more frequently recognized. The latter (masturbators' stricture), which from one case in two hundred and twenty as quoted from Thompson's table has increased (though I cannot accept the fact) proportionately to thirteen out of every one hundred cases, according to Dr. Samuel W. Gross.[1]

Before entering fully upon the discourse of the subject I will preface my remarks with the admission that I accept every one of the causes of organic urethral stricture quoted from Thompson's table as having an important part to play in their formation, but with the exception of the traumatic variety and those following the cicatrization of venereal ulcers, I claim that all the other stated causes act secondary to pre-existing anatomical defects.

The chief source of error, so it appears to me, is that most writers, in describing the lesion, seem to regard the urethra as a tract anatomically perfect in structure and physiologically normal in function until its owner is unfortunate enough to acquire some form of urethritis, then, after a variable period of time, the urethra, having fretted under a lingering gleet, is examined, and if found contracted at one or more points a diagnosis is recorded of stricture—due to the variety of urethritis from which the patient has suffered.

How many physicians, when confronted by a case of stricture which seemingly may have originated as described in the preceding paragraph, will pause to consider how much the urethritis has had to do with the cause of the stricture? How can gonorrhœa, for example, make such serious inroads upon the integrity of the parts? The explanation, based upon anatomical grounds, is simple. It is because all urethræ are not perfect in structure. An overwhelming proportion have extensive congenital defects of such a nature as to favor the perpetuation of inflammation and its sequelæ once it has been established. The urethra is not an exception to other parts, but is as often the seat of irregular development and malformation as is the nasal septum, the hard or soft palate, the upper lip, and other structures in the mesial line of the body which are formed by fusion of opposite surfaces.

From the researches of the embryologist we know that during the early period of fœtal development the genital furrow exists as an open tract, and that between the third and fourth months the free edges of this tract coalesce or fuse together, leaving a crevice which constitutes the spongy portion of the urethra. Now it is coincident with this period and process of fœtal development that the first departure from perfect anatomy occurs. The edges of the genital furrow may unite irregularly, the normal limits may be exceeded at one or more points, so that instead of a free tract capable of expanding into an even open canal when required, we have bands and narrowings more or less abrupt along this tract which interfere with this free action. These congenital bands, if not prominent enough in early life to cause trouble, still are capable, even from natural laws, of acquiring greater prominence, while if seconded by pathological conditions they become formidable obstructions. These congenital bands, or, as we may very properly call them, embryonic strictures, may be divided into two classes according to the character of the tissue of which they are chiefly formed.

The first and most common variety consists of folds or puckerings of the urethral mucous membrane, but, unlike the natural folds, they reduce the limits of expansion at those parts of the urethra where they are situated. They are permanent and cannot be obliterated by any method of dilatation or condition of the penis. I say condition of the penis, because Otis,[2] in describing the folds so frequently met with at the peno scrotal angle, refers to a case where the folds disappeared during an erection of the organ. Folds of that conditional character are not included in this class. The true mucous fold is a permanent structure, and no matter whether the penis be flaccid or erect can always be demonstrated by the bulbous bougie. This variety of congenital narrow-

[1] Gross on Disorders of the Male Sexual Organs, 1st ed., p. 25.
[2] Otis, on Stricture of the Male Urethra, 2d ed., p 212.

ing is described by some writers as an adhesion of the mucous surfaces. Englisch[1] found forty six such examples in the urethral canals of new-born infants.

The second class of congenital narrowings differs from the first in having, in addition to the mucous fold, a tough, fibrous connective-tissue base, over which the mucous membrane is sometimes freely movable, though it may be adherent. This variety varies much in width and thickness, and sometimes the fibrous tissue is as tough as tendon. This class is described by some writers as cicatricial. Englisch also mentions having found thirty-nine examples of this variety in the urethral canals of new-born infants. These congenital urethral bands are very frequently met with in the adult, but because they are so constant in their occurrence we are not justified in considering them physiological in the full sense of the word.

The rule first proposed by Dr. F. N. Otis, in regard to a fixed relative proportion between the circumference of the flaccid penis and the internal urethral calibre, is a most reliable working guide, and though, as previously stated, most urethral canals have slight departures from this high normal standard, not sufficient in many instances to interfere materially with the function of the parts, still their frequent existence does not remove them from the domain of congenital imperfections. I am satisfied, from a large number of personal observations, that the nearer the urethra approaches the relative proportions as described by Otis, the more perfect are its functions performed; while if pathological conditions are acquired, the symptoms are milder and more promptly recovered from. It is an easy matter to demonstrate the existence of these congenital defects, but having done so, a more difficult problem arises, namely, when to class them in the category of true strictures. This was, and still is, a much-mooted question among the leading genito urinary surgeons, and has given rise to some of the most heated discussions of any topic within the realm of surgery.

Otis,[2] for example, is responsible for the following assertion: "If into a urethra, the normal calibre of which is equal to a circumference of 30 mm. of the French scale, only a 29 F. bulbous bougie will pass without detecting obstruction, then the urethra is not 'about right.' It is strictured to the extent of one millimetre in circumference, and never can be a healthy urethra while that stricture remains."

Keys,[3] on the other hand, takes a very different, conservative view concerning these congenital narrowings, and because they are not of pathological origin depreciates their importance almost as much as Otis magnifies the same. He says: "I have raised my voice for what it may be worth, in protest against the views of the new school in urethral pathology, which seems to claim that every natural undulation in the tissues of the pendulous urethra is a stricture fit for cutting; and that all the ills of the genito-urinary passages may be accounted for by the existence of these undulations, and, usually, made to disappear when the latter are cut."

Finally, Berkeley Hill,[4] in a few masterly lines, seems to strike the happy medium, and is very conclusive upon the question at issue.

He says: "If the balance between the natural expulsive force of the bladder and the friction along the urethra is disturbed, the bladder is irritated, the kidneys are affected, and the beginning of the long chain of events which terminates not infrequently in death is made."

The vesico-urethral balance to which Hill refers is a far more important factor in normal micturition than is generally supposed. That nature often fails to make a perfect urethra does not admit of a doubt, nor is there any doubt but that nature, as often, develops an unusually powerful detrusor muscle, therefore, the expulsive force of the bladder may be so great as to irritate moderate congenital narrowings in one case, where, in another, with even greater urethral defects, but less powerful detrusor, there may be no discomfort whatever. If this were not the case more persons having these congenital narrowings would be complaining of serious symptoms than we find in actual practice. Thus we have to consider, hand in hand together, both the anatomical defects and the symptoms of disturbed vesico-urethral balance in order to decide when a congenital narrowing is to be classed as a true stricture. A narrowing is always a stricture, anatomically speaking, but not so clinically, unless it be attended by symptoms.

Congenital stricture, in proportion to its extent, often gives rise to troublesome symptoms in early life. Vesical irritability, nocturnal incontinence, dribbling of urine, priapism, and precocious sexual habits, are in many instances due to this cause. Similar symptoms to the above have been noticed time and time again by some of the leading genito urinary surgeons, but, strange to say, none have ventured an explanation.

Sir Henry Thompson, in his book on stricture (3d edition, page 127), says: "There appears to be a tendency, strongly marked in some individuals, to irritability of the urinary organs, displayed first in early life, of which no precise explanation can be given, but which has sometimes been observed to precede the formation of stricture in adult age. The subjects of it suffer as children from obstinate incontinence of urine, particularly during sleep." Again he remarks: "If such individuals acquire a gonorrhœa, the attendant symptoms are more than usually severe and distressing, and permanent stricture is likely to follow. This state may be spoken of as one of congenital irritability of the urinary organs, but I have no solution of it at present to offer."

To my mind I do not think it possible for a more graphic picture to be drawn of the symptoms and effects of congenital stricture than is embraced in Thompson's account of what he terms, "congenital irritability." It is the key to the whole situation. If there exists this irritability there must be a cause for it, and, as the learned author very truly remarks, it (the irritability) "has sometimes been observed to precede the formation of stricture in adult age," what more convincing proof do we want than that congenital stricture existed in these cases from the beginning, and that the irritability is but an effect of their presence?

If in a case presenting such symptoms the prepuce is non-adherent, and the bladder is free from calculus or disease, depend upon it the clew to the trouble will be found in the urethra.

In my experience with the treatment of urethral troubles I have many times had related to me histories similar to the above-quoted description from Thompson, by patients whose memory and veracity were perfectly trustworthy. The following case will serve to illustrate:

Mr. C——, aged twenty-five, consulted me, in March 1881, on account of a most distressing irritability of his bladder. The symptoms had been especially marked since his nineteenth year. He stated that nocturnal incontinence had been a source of annoyance to him when a child, and that priapism was very persistent, at the same period of his existence, without excitation or known cause. About the period of puberty he began to experience severe cutting pain every time he passed his water. The pain was felt immediately within the meatus and only as the first rush of urine impinged upon that point —after commencing the act the balance of urine could be voided without trouble. This symptom persisted for many months, then gradually became less acute, but he was ever afterward bothered by disagreeable sensations within the urethra and other parts of his genitals. A feeling of fulness would persist in the urethra after urinating, followed by dribbling some minutes later. Severe neuralgic pains were for a long time felt in the gluteal region and over the hypogastrium. His urine was normal in character, but no system of medicine had ever

given him relief or blunted his ever-pressing desire to urinate. Thinking that his trouble might be due to some urethral abnormality, I examined the parts with bulbous bougies and an expanding meatoscope. The result of which examination was the discovery of a simple mucous fold, one third of an inch from the meatus, reducing the calibre of the canal at this point to 23 F. Lower down, at the peno-scrotal angle, were three distinct bands reducing the calibre of the canal at this point to 27 F. His normal calibre at all other points was 30 F. I cut the anterior contraction up to 32 F., and dilated daily with full-sized sounds until healing was complete. The result was immediate and surprising.

Before the cutting this patient was incessantly teased by an ardent desire to urinate. Thirty-six hours after, he retained his water ten consecutive hours without the slightest inconvenience, and then only urinated out of curiosity to know (as he expressed it) if his kidneys were fulfilling their function. Years have now elapsed and he remains perfectly comfortable. There never has been the slightest return of his old symptoms.

From the history of this case it will be seen that unusual irritability of the urinary organs existed from childhood, as in the description given by Thompson, also that all the symptoms were aggravated in adult life. An examination, however, according to the method of Otis, proved the existence of congenital stricture in my case (the patient never having had gonorrhœa), and though the narrowing only reduced the extent of urethral expansion 6 mm., still, this congenital narrowing was the sole cause of the existence and persistence of the symptoms, as was proved by a radical cure of the trouble upon restoration of the canal to its full calibre.

When these congenital narrowings are not prominent enough in early life to cause trouble, and the periods of infancy and childhood are passed in comfort, still, the maturing youth may fall heir to many distressing symptoms as he merges into puberty. This peculiarity can be accounted for, I think, as follows: When the genitals are undergoing rapid development in early adult life, those congenital defects which were in existence, but not of sufficient prominence to cause trouble, at this time acquire greater prominence through failure of the defective areas to enlarge in proportion with the normal parts, so that a canal which before puberty may have been sufficient for the requirements of nature now becomes too defective to perform its functions without disturbing the vesico-urethral balance.

As was stated at the beginning of this paper, John Hunter[1] recognized a congenital cause as the starting-point of stricture. He says: "Strictures are common to most passages of the human body," "They sometimes happen in the urethra where no venereal disease has ever been."

This opinion of Hunter, it is needless to say, has been severely criticised. To use the words of Sir Henry Thompson, "the great pathologist . . . stands almost alone in this opinion." If so, let it be to his credit. For Hunter more than a century ago, without the assistance of ball probes, bulbous bougies, or the urethrometer, but guided by his wonderful perceptive genius alone, arrived at about the same general conclusion which some at the present day consider new. His opinion has outlived him and affords us the most satisfactory clew to the cause of stricture. Bryant, in his "Practice of Surgery," page 518, says, in summing up his statistics of stricture cases, that out of 646 cases in only 273 was the lesion preceded by venereal disease, 43 were of the traumatic variety, leaving 330 in which no definite cause could be assigned. He concludes as follows: "That although gonorrhœa often precedes a stricture, that at least half the cases are found in subjects who have not suffered from such a disease."

Having occupied the attention of my readers long enough with the foregoing observations upon the relative frequency of congenital stricture, let us next proceed to study how these congenital defects are influenced by pathological processes, and how they form the nuclei, so to speak, of those close organic strictures which have hitherto been generally considered as entirely of acquired pathological origin.

In speaking of the relation of gonorrhœa to stricture Otis[1] says: "I recognize the fact that it is most often brought to our notice through the occurrence of and persistence of this disease, and that all pre-existing strictures, or thickenings, or irritations of the urethral mucous membrane are increased and intensified by it."

With this opinion I perfectly agree. It has occurred in my experience, and I think the same is universal, that cases of gonorrhœa will not always yield to any form of constitutional or local treatment. In spite of all care it may linger on indefinitely, nay, symptoms of stricture manifest themselves during the early period of the disease. Now with the knowledge we possess in regard to the formation and nature of cicatricial tissue is it at all likely that we should have such prompt effects resulting from an attack of gonorrhœa in a canal previously free from congenital defect? Furthermore, from a system of treatment, once the most popular (I refer to gradual dilatation), we derive most positive proof that congenital strictures do exist before and are the nuclei of those which are supposed to have resulted entirely from gonorrhœa. Any surgeon who has had much experience in the management of urethral cases has certainly come across strictures which respond finely to the method of gradual dilatation until a certain limit is reached, but beyond which it is impossible to progress without the strictured parts becoming irritable under the method of treatment. This class of strictures are mentioned by Van Buren and Keys in their work on "Genito-urinary Diseases," page 157, but no explanation is given for their exceptional peculiarity.

From the convictions that I have arrived at, after a careful study of the congenital urethral narrowing when intensified by inflammation, the cause of this irritability seems apparent, and I will venture an explanation for what it may be worth. When a stricture is treated by the method of gradual dilatation, the mechanical action of pressure, together with the stimulus given to the circulation in the affected parts, promotes the absorption of the acquired inflammatory tissue, which will go on under the gentle use of the sound until the original or congenital narrowing is reached, but the tissue of the congenital contraction, unlike the acquired inflammatory tissue, being unyielding and incapable of absorption, resents the attempts of art to enlarge by dilatation structures which nature had in the first instance failed to make of greater calibre.

Sometimes the gleety discharge and other troublesome symptoms disappear when the urethra has been dilated up to its point of limitation, but you cannot depend upon it, for when a congenital stricture has once been infiltrated by gonorrhœal inflammation it becomes a treacherous spot, prone at any time to light up trouble from the slightest provocation.

As a rule these congenital narrowings are sensitive to a degree far exceeding the other portions of the urethra. They easily fret and become irritable, even from contact with an exploring instrument. This irritability is quickly called into play by inflammation affecting the urethral mucous membrane, and as it happens that gonorrhœa is the most common form of acquired inflammation the urethra is subjected to, it necessarily becomes the chief intensifying cause of congenital stricture. Under the irritating influence of the gonorrhœal inflammation these congenital strictures are thrown into a spasmodic state of contraction and retain a certain amount of the acrid discharge within the canal instead of permitting an easy escape of the same—simulating small pus pockets at one or more points along the urethra.

The more abrupt the congenital contraction the more acute, generally, will be the symptoms, and from an in-

[1] Ricord and Hunter on Venereal Disease, p. 151.

[1] Stricture of the Male Urethra, 2d edition, p. 171.

flammation which was at first confined to the mucous membrane we have the morbid process, at these defective points, extending into the deeper structures and not infrequently involving the erectile meshes of the corpus spongiosum. Therefore, as a result of gonorrhœal inflammation, the tissues composing these congenital narrowings, and the parts immediately behind them, are more unfavorably acted upon than the other portions of the urethral tract. Bathed in pus and scalded by urine, the healthy epithelium is destroyed at these points and its place supplied by patches of granulation tissue; connective tissue corpuscles infiltrate the parts, and as the latter proliferate and condense, the calibre of the urethra is lessened, and we have formed those dense inodular strictures, the bugbear of urethral surgery.

If the urethra is well developed from end to end—free from prominent congenital narrowings, approaching the highest normal type, as described by Otis, I believe we can safely say that if such a urethra should become affected by gonorrhœa the attack would prove mild and in due time leave the parts unscathed by the ordeal through which they have passed.

Next in importance to gonorrhœa, if not equally as important as a cause for aggravating these congenital strictures, is pathological urine.

The urethra in repose is a collapsed tube which only becomes a canal in reality during the physiological acts of micturition and emission of semen.

When these acts are completed by a normal urethra the combined action of its muscles, together with the wave of blood which passes along the meshes of the corpus spongiosum should extrude every drop of fluid and leave the urethra free from all traces of moisture except its normal secretion. If, however, there should exist congenital narrowings anywhere between the bulbomembranous junction and the meatus of sufficient prominence to cause undue friction during the acts of micturition this perfect functioning of the parts cannot occur. The narrow points will be rendered unduly irritable by the forcible impact of the column of urine, and through the resulting contraction of the urethral muscular fibres interfere very materially with the extrusion of the last drops of urine. A few drops of urine will be retained back of the irritable urethral narrowing, where, acting in the way of a foreign body, it causes any amount of uneasiness until it is expelled. Nothing is more common than to hear persons, in whom this condition exists, complain of a sense of fulness in the urethra after urinating. They are apt to imagine the act was incompletely performed, and most likely will make another attempt shortly after in order to ease themselves; but if so, they only displace the retained drops in the urethra by a little more urine from the bladder, which leaves them in the same uncomfortable plight as before. Sometimes the drops of urine are retained quite a while before they dribble away, or, as is frequently the case, the patient, in making a quick muscular movement, as in rising from a chair or stooping to pick some object from the floor, forces the retained urine from his urethra, with immediate relief.

When effects like these are noted from the action of healthy urine upon the narrow defective points in the urethra, it is easy to understand how much more trouble is likely to ensue from a pathological secretion, such, for instance, as the urine of a gouty or rheumatic subject, that of the habitual dyspeptic, or urine containing inflammatory products, the result of disease in the upper urinary tracks.

These abnormal secretions are very damaging to a urethra previously crippled in conformation, and are just as sure to lead to the formation of close organic stricture as is a gleet resulting from gonorrhœa.

The irritation resulting from pathological urine is a slow-acting cause, and, therefore, all the more dangerous, for from the insidious nature of the symptoms neither patient nor physician is apt to have his attention directed to the forming stricture until it has assumed formidable proportions. On account of the slow development of this form of stricture we are most likely to encounter them in persons of middle age and advanced life; and I am of the opinion that if a careful investigation is given to that vast percentage of stricture cases which occur in men who never have had venereal disease, a satisfactory clew to this cause will be found under this heading.

Last in order, as a cause for intensifying congenital stricture, is masturbation. While it is a fact that this unnatural habit is entitled to a place among the recognized causes of urethral stricture, still, from the histories of most of the recorded cases, I am far from convinced that it is as potent a cause as some writers seem to think. It is easy to understand that by the persistent practice of masturbation a congested state of the prostatic sinus is induced which finally develops into a catarrhal inflammation—a condition of affairs attended by a muco-purulent discharge, a prostatic gleet in fact, which, like the gleet following gonorrhœa, is irritating and capable of intensifying pre-existing congenital defects. But without inflammation and a discharge first being excited, I fail to see how the habit of masturbation can cause stricture.

Yet how many cases of stricture due to this cause have of late years been reported! Many that are said to be due to this habit must, from the appended histories of the cases, have preceded the practised vice. In fact nearly all are nothing more or less than prominent congenital strictures. Because these strictures happen to exist in the urethral tracts of patients from whom a confession of the habit of masturbation has been forced, they have wrongfully been attributed to this cause entirely.

From among the tabulated cases of urethral stricture by Otis,[1] I find that out of a list of 234 patients, in 24 cases the cause is attributed to masturbation. I have not included any among the number who have a record of both gonorrhœa and masturbation. Now in 22 of these cases there is no history of an existing or pre-existing discharge. Also in 22 cases the contracted areas were situated in the anterior and middle portions of the urethra—not beyond three and one-half inches, just where we most frequently encounter the greatest number of cogenital narrowings. In the remaining two cases the contracted areas were situated at a depth of four inches and beyond. All were typical examples of stricture of large calibre, but from the histories of at least twenty-two of these cases I am forced to believe that the same contracted areas would have been found even if the patients had not been addicted to masturbation.

In not a few instances I have had patients who were suffering from the effects of congenital stricture, and who were not given to masturbation, describe their symptoms as follows: They would complain of an itching or tingling sensation within the urethra, and especially about that part enclosed within the glans penis; sometimes sensations not unlike an impending orgasm would be experienced, but without being attended by erection or erotic fancy. The strictures in these cases were situated a short distance from the meatus, and with their removal the irritations vanished.

Had these patients been addicted to masturbation how natural it would have been, backed by modern theory, to have ascribed both the stricture and reflex irritation to that habit?

Of course it must be admitted that like symptoms can be produced in some patients by the reflex irritations proceeding from a congested prostatic sinus induced by masturbation or excessive venery; but to attribute all these congenital narrowings in people who do masturbate to a habit which in most cases has had nothing to do with their existence, is as ridiculous as it is unfounded. Again, reasoning from a hypothetical stand-point, if sensations of the above nature were to be experienced by persons of little self-control, is it not more than likely that they might yield to these morbid feelings and acquire the habit of masturbation? No one will dispute the fact that patients who suffer from vesical calcu-

[1] Stricture of the Male Urethra, 2d ed., pp. 136 and 324-350.

lus or adherent prepuce may acquire this habit from the irritability of the genitals, superinduced by their infirmities. Why not, then, from the reflex irritations due to congenital stricture?

From all the information that I have been able to collect upon this topic, it seems to me that stricture of the urethra is more to be blamed for causing masturbation than masturbation is to be blamed for causing stricture.

If, then, we take these congenital urethral narrowings as the proper basis from which most cases of stricture arise, and consider them in association with inflammation, we will find that, with the exception of the traumatic variety and those rather uncommon cases resulting from the cicatrization of venereal ulcers, nearly every case may be classified under one or the other of the four following divisions:

1. Congenital stricture (simple), including all anatomical narrowings which are prominent enough to interfere with the normal vesico-urethral balance.
2. Congenital stricture, aggravated by gonorrhœa.
3. Congenital stricture, aggravated by pathological urine.
4. Congenital stricture, aggravated by masturbation.

In concluding my remarks I am fully aware that I have not presented much that is strictly original, more able observers having grasped the leading features long before, but I have tried to reduce the subject to something like a system in the order of cause and effect, and if my words have any weight in this respect, I shall not have labored in vain.

312 North Carey Street.

A PLEA FOR MORE RATIONAL MEDICATION.[1]

By W. P. OVERHOLSER, M.D.,

HARRISONVILLE, MO.

A RETROSPECTIVE glance at the practice of medicine of the nineteenth century presents to our view marked changes in many of the theories of our science, and great revolutions in the practices of our art. Our advancement has been particularly marked by steps of progression and retrogression, by a construction and reconstruction of views, by a continual building up and tearing down of medical beliefs and opinions. In fact this tendency has been so evident, that the intellectual effort of the medical world of the past and present seems to have been, and continues to be, characterized by a propensity to frame hypotheses and manufacture theories to meet and explain the manifold phenomena of animal life in health and disease.

From the beginning of the history of medicine, when in the Grecian temple of Esculapius medical information was first recorded, and the first steps taken to reduce the art to a science, by registering on durable tablets of marble disease and its supposed cures, down through the hoary ages of the past on through the latest centuries, and even to the very threshold of the present time, empiricism has largely characterized our work, and experimentation in disease continues even with increased ardor, with but few positive remedial results.

The recent laboratory and microscopical researches in disease, and experimental work in normal and abnormal processes of the body, have contributed volume after volume to the literature of medicine; but notwithstanding the light these researches have given us, as to the origin, diagnosis, and course of many diseases, science has as yet failed, except in but a few instances, to prescribe for us rules, laws, and remedies which, when applied in certain conditions, will give us positive, satisfactory results. Correct theories or doctrines of any science must coincide with philosophical truth, and be confirmed by experiment and observation.

A system of practice of medicine rational in its basis, scientific in its measures, and eminently successful in its results, would be a system different indeed from the one we so much boast of to day. Absolute facts in medicine are comparatively few compared with its unstable hypothetical teachings. It is true that many of our generalizations have stood the test of future experience and have therefore been retained, serving as they do to give something more than empirical direction to intellectual effort; but sometimes, and alas! this is too frequently the case in medicine, the airy castle of theory is found too light to withstand the onset of progressive experience, and the structure of but yesterday is the ruin of to-day.[1]

Is it not true that the conscientious physician of the present who endeavors to gather from every resource at his command more light and knowledge of the mysterious phenomena of disease, is often confused by the various theories as to its origin, multitudinous remedies for its treatment, and ofttimes contradictory clinical experience as to its progress and termination? We speak not disparagingly of our science, nor do we seek to condemn the work of those of our profession whose untiring efforts and profound research have scattered light and knowledge in many directions. We are proud that we live in a period of the history of medicine when every means of research is used to fathom deeply into the mysterious workings of nature; yet in this age of advancement, as we look back over our field of work and find scattered all along the line of action the ruined remains of what we once thought to be scientific truth, but which have since proven to be fallacies and inconsistencies, we feel more forcibly impressed with the importance of testing in the crucible of truth the great mass and bulk of medical experience and medical teachings that are heaped upon us to-day, and accepting only the atom of gold that may be found among the dross.

It is a fact to be deplored that we find in medicine beliefs, theories, and practices that wear the guise of learning, that appear scholastic in their teachings and scientific in their measures, that are of no practical benefit whatever to us as practitioners. Let me ask what has become of many of the measures and remedies that not a few of our profession, but a short time ago hailed with wild enthusiasm and accepted with the utmost confidence in their efficacy. They need but a mention: Koch's tuberculin, Kleb's tuberculocidin, Brown-Séquard's elixir of life, and others of no better nature; what are they to day? Are they not simply humiliating memorials of the credulity and infatuation of the physicians who commended and prescribed them? Who can tell that many of the boasted remedies of to-day will not, like their predecessors, fall into disrepute, and in their turn serve only as monuments in the history of medicine to mark our mistakes and ever expose our faulty conceptions of proper medication.

We have no lack to day of medical literature, no lack of medical theories as to the proper treatment of diseases, no lack of medical remedies suggested. The very shelves of our bookcases groan with the weight of medical lore, and our text-books on therapeutics prescribe for us an untold number of remedies for the various ailments of the human body. In fact, our science is becoming so unwieldy, and contains so much that is unnecessary and impracticable, that the medical student of the present is compelled to wade through the misty labyrinths of this accumulated mass of existing doctrines to find a little practical truth.

We do not wish to unjustly criticise the teachings of honorable men of our profession whose superior talent, moral worth, and dignified bearing have immortalized their names in the history of medicine. We will ever bow in humble submission to, and hold in high veneration, the devotees of our science who seek to give us substantial truth, sound inductive philosophy, that will stand the test of practical experience and ever be re-

[1] Read before the Hodgen Medical Society at Harrisonville, Mo., October 4, 1894.

[1] Dr. J. Leonard Corning, Medical Register, Philadelphia, Pa., vol. iii.

tained as immutable principles of eternal truth; but in the present status of our medical science we do not feel like offering an apology for entering a plea for a more rational system of medication.

Scientific medication must harmonize with physiological laws, and thus facilitate nature to throw off disease. Wherever a diseased process is going on, nature is striving to overcome it. Wherever there is a deformity or impaired use of any part or organ of the body, nature tries to compensate for it. The contraction of the muscles with flexed thigh in hip-joint troubles is not the disease, but nature's effort to protect the joint by fixation. The hypertrophied and throbbing heart is nature's method of compensating for an imperfect valve. An abnormal elevated temperature of the body is one of the chemical results of her method of eradicating a poison from her tissues. The adhesions surrounding a Fallopian tube, or the vermicular appendix, is her inflammatory barrier to prevent the escape of septic matter into the peritoneal cavity; and so on, through the whole category of diseases, we will find that if we view their symptomatic phenomena from a proper standpoint, they are conservative processes and nature's best methods toward effecting a cure.

To study closely her own efforts in restoring abnormal conditions of the body to health, will ofttimes give us more light and guidance as to the proper management of disease than that given us by the ineffectual speculations of scientists, many of whom simply write books for a reputation, and by their plausible theories and logical deductions so well disguised in the garb of learning, receive the applause of the medical world for the so-called latest and most rational methods of scientific therapeutics. Dr. Aulde, of Philadelphia, Pa., says: "There are a considerable number of the medical profession who now claim to practise what is termed rational medicine as contra-distinguished from empirical medicine; but when the question is asked as to the precise influence which remedial agents have upon nerve-cells and protoplasm, no one can be found competent to answer."

Of recent years so much attention has been turned to the study of bacteriology, so elaborate has been the work in this direction, that there now seems to be a general consensus of belief in the bacterial origin of all infectious diseases.

Bacteriologists tell us that all communicable maladies, such as can be imparted from plant to plant, from animal to animal, from animal to human being, from one man to another, are due to micro-organisms. The infinite variety and multitude of micro-organisms—the part they play in the phenomena of fermentation and putrefaction, and in the general break-up of organic life—the incessant struggles of the living organisms against the microbes, has furnished a large field for investigation by our bacteriologists, and the measures which antagonize their action and destroy them in living tissue, seem now to be the greatest problem of the present age. This has given origin to what is called bacteriological therapeutics—a science that is to give us measures, medicinal and hygienic, that will prevent the multiplication of these infective agents in the human body and thus eradicate disease by antagonizing their action and preventing the baneful effects of their secretions and excretions (ptomaines, toxines, and toxalbumins) upon the normal cellular action of living tissue.

If the origin and course of all infectious diseases be found to be due to the presence of some form of bacteria, and bacteriological therapeutics can furnish us with germicides that are available and safe, a system of parasiticide medication that will successfully prevent the development and multiplication of the microbe in the body, then indeed might we boast at least of one branch of scientific therapeutics. But let me ask how many here to-day can testify, by practical experience, to the value of any medicinal agent that has thus far been given us, that will destroy in the body the Eberth bacillus of typhoid fever, the Klebs Loeffler bacillus of diphtheria, the streptococcus of erysipelas, the diplococcus of pneumonia, or even Koch's bacillus of tuberculosis.

Is it not a fact that bacteriological therapeutics has thus far proven to be much more beautiful in theory than useful in practice? The modern idea of scientific medication we believe is slowly drifting away from so much speculative investigation with bactericide agents, and that "the rational treatment of disease will be based more upon a knowledge of the effects which medicinal substances produce upon the function of the cell." [1]

A study of nature's own efforts in coping with disease ought to lead us to observe, and in a measure understand, the methods she adopts in effecting her own cures. The term *vis medicatrix naturæ* is familiar to us all, and frequently spoken of as the power by which nature cures disease; but the factors concerned in this process, and the true secret of her success along this line, are yet imperfectly understood. We believe, however, there is now somewhat of a lull in the enthusiastic labors of the bacteriological therapeutists, and that we find ourselves gradually drifting back to investigate more carefully the function of the cell in maintaining its integrity, resisting disease, and restoring normal cellular life in an unhealthy condition of her tissues.

A fundamental principle about which pathology and physiology are not any more at variance, is that man, as well as any other animal, and also vegetative organisms, is a reiteration of structure; however complete in its organization be the construction of a body, every single part and all of it can be traced to a radical, an ultimate element of living tissue—an entity—a cell—a little mass of protoplasm which eats, grows, accomplishes work, and then dies. The radical entity of which man is composed shows a repetition of the phases of his accomplished being. It is in continuous motion, its life being kept up by processes analogous to those of the complete organism. In this physiological radical of man, and in all other organisms, is exhibited the function of disintegration and reintegration of tissue—a continuous change of matter constructive and destructive, a ceaseless metamorphosis of cellular structures with accumulation and liberation of life-forces. It is physiological cell-function, with laws governing its action just as laws preside over the existence and health of the developed organism. All curing action, whether by nature herself or artificially by the medical practitioner, is bound to be within the limits of histolysis or histogenesis of the cellular elements of the body. A point we wish to notice in the practice of our work, is that our medicinal agents are administered to the developed organism for their effect upon a particular organ of the body, or for their effect observed upon the organism as a whole, without a knowledge of their effect upon the organized units — the individual cellular structures of which it is composed—which are the only ultimate living factors in the production of lesions of disease, the only ultimate living agents in eradication of the same, and the only living factors of the animal economy that can restore abnormal conditions to health. All forms of disease come from some modification of normal cell-function. All diseases that are cured by nature or medicine must be accomplished through the function of the cell.

Disease due to microbic infection is simply a perversion of the physiological cell-function, an effort of nature to destroy and eliminate the foreign elements from her structures. It is a conflict between the subject who is smitten and the particular micro organism which multiplies at his expense, appropriating his air, water, and pabulum, disintegrating his tissues, poisoning him by its secretions or by the decomposition which accompanies its development. Exacerbations of disease and crises are occasioned by particular efforts of nature to overcome the obstacles which she meets on her war-path. It is a phagocytic reaction of the organism to an irritant (Metschnikoff). Cells are phagocytes, hungry to devour any toxine or microbe that may find entrance into the

[1] Dr. Aulde.

blood. The physiological, chemical action of the cell, by these irritant poisons is changed to a pathological, chemical one. Nature seeks to cope with her intruders by instituting measures that are incompatible with their existence. If she fails, her failure is due to a lack of power to resume in normal proportion her work of disintegration and reintegration of tissue with the normal evolution of life-forces. Here I believe is the starting-point of scientific therapeutics. The morphological results of cell-function in health and disease, I believe, are the basis upon which must be founded all medical means of treating disease by rational and scientific methods.

When our science gives us a pathological chemistry of the cell, with the physio-pathological effect of medicine within the sphere of tissue metabolism—a cellular therapy, we may then hope for a substantial basis upon which to found our teachings of a system of rational medicine; and until then, as Bigelow has said, "Therapeutics will continue to be a sad mixture of stale antiquity with spurious enthusiasms, in new-fashioned crazes—the theories of but yesterday becoming the superstitions of to-morrow, and the practices based upon such theories the shuttle-cock of each doctor's battledore."

"Students of other sciences are not content with simple ideas, or even facts, but are intent upon discovering law. With unwearying energy they systemize their facts, generalize, and rearrange, and whenever a law is discovered it is hailed as a precious boon to many a glorious messenger of light. In the domain of medicine the energies of our students seem differently employed. The field is swarming with adventurers who seek only the discovery of new material, and here and there, as one sees a fact which in the light of his fancy appears to glitter, he seizes upon it with avidity and preserves it as a precious gem for a short time, when his fickle fancy casts it away to search for something new. And so they go on increasing the disarray and adding to the heap of rubbish that is fast accumulating on the field of medicine, ever seeking, never finding, searching for specifics and panaceas, deluded by mirages, but unwilling to profit by experience.

"Have we not enough of speculative medicine, enough of empirical practice, enough of ineffectual efforts to combat microbic diseases, by internal parasiticide medication? Let us halt for a time and rearrange our material, discard what is worthless, put in order what is valuable and reduce it to a rule. Our palates have been tickled long enough with the endless variety, but our stomachs are worrying for something substantial."[1]

As earnest and conscientious practitioners, let us ever hold fast to that which is good, and until our science can give us something better, let us not forget to ever turn and listen to the voice of nature and seek to heed more closely her admonitions in disease; for many of her symptomatic phenomena are but indexes pointing out to us her mysterious ways of cure. Let us be content to be her humble assistants and not aspire to be her chief, for nature's skill is higher than our own, and to understand fully her methods of dealing with human maladies would be true knowledge indeed. When rational medicine is the practice, we believe there will be more cautionary guidance and less active interference in the measures nature institutes for the cure of her ailments.

In conclusion, to get at the basic truths underlying a rational practice; to invigorate the field of medicine with a new life; to discover law for facts; to lay a foundation broad and strong upon which to build the superstructure of our science; we beg leave to enter a plea for a more thorough investigation into the pathological chemistry of the protoplasmic entities of man, ever bearing in mind, as physicians, that practical medicine to be really in fact, as well as in name, scientific medicine, must be based upon therapeutics of the cell.

THE NON-OPERATIVE TREATMENT OF UTERINE DISEASES.—EXPLANATORY.

By P. J. McCOURT, M.D.,
NEW YORK.

In a previous paper upon this subject (Medical Record of May 13, 1893) I endeavored to describe so clearly the various procedures of the method of treatment, that the attentive reader might follow me without serious error; but that endeavor has failed of its object. Subsequent to the publication of the article, applicants for further information were very numerous; yet the queries propounded were usually brief, and were all answered by letter. Now that many have, in a measure, prepared themselves to apply the treatment and have met with obstacles, the extent of the answers called for renders reply by letter impossible. Anxious to see the method intelligently tested, and, if found worthy, generally adopted, I wish to give such details to the profession as will enable them to apply the treatment as successfully as I have done.

1. The preparation of the sponge should present no difficulty. A fine "Reef" sponge is best for use, and the exact proportion of hydrochloric acid to water is not constant. It should vary with the amount of calcareous matter in the sponge; but about one-half pound to the gallon will usually suffice. Of the potassium permanganate, cold water will dissolve the amount required in a few minutes. The bleaching fluid may consist of such solution of sodium hyposulphite (the sulphite has recently been found preferable) as cold water will make in about thirty minutes, 1 litre, and HCl 200 c.c. (200 to 1,000).

2. Cotton, wool, linteum, etc., cannot be substituted for the sponge-dressing; nor can the sponge be employed as an excipient for glycerin, since the latter will render the sponge nearly as hard and rough as sand-paper.

3. The sponge-dressing cannot be accurately adjusted to the parts through the speculum. The vaginal walls are best separated by the first and second fingers of the left hand, while the dressing is carried to its position and adjusted by the index-finger of the right hand.

4. When not corroded by the secretions, the sponge may be reapplied several times to the same patient, after being cleansed each time in the bleaching fluid.

5. Neither septicæmia, nor any appreciable approach to it (except in the breaking down of myomata), nor any serious inconvenience to the patient, has ever yet resulted from the application of these dressings, when properly placed and medicated.

6. At the beginning of a course of treatment the dosage should be very light, and the patient may be treated three times each week, rarely more frequently, for a month, or until such time as improvement is apparent; then twice, and finally once a week. There is danger, or at least waste of time, in overdoing the applications advocated in this treatment. If the patient be treated once or twice a day, as has been advised by one of my former students in this journal, peritonitis may result.

7. In treating cases of hypertrophied uteri, as the size of the organ diminishes the size of the sponge should be relatively increased, otherwise progress may cease, or the conditions may even take a retrograde course.

8. None of the materials used in this treatment can be supplied by me.

9. It is imperative, for the reasons assigned in my former paper, that the tinctures be made saturated, and from the fresh root or plant. The employment of other preparations for this purpose will be certain to defeat our object, and may injure the patient. The pharmacist should be able to make these tinctures in season, and to have them prepared where the plants grow.

10. The metric system employed has proven an obstacle to many of my readers. It is only necessary to remember that the litre contains the weight of 1,000 grammes, or the measure of 1,000 cubic centimetres. Hence, 3 grammes to 1 litre means simply three parts

to 1,000; 6 5 grammes to 1 litre means 6½ parts to 1,000; and so on throughout.

11. I am asked to specify the conditions in which variation of local temperature has been observed; and it is evident that this observation has been received with some doubt. Disproportionate elevation of intra uterine temperature has been found chiefly in connection with local hyperæmia; and the temperature has been found subnormal in some cases of induration, malnutrition, hydræmia, and other forms of defective hæmatosis. Surely these observations are not less credible than others of unequal axillary temperature, editorially noted in this journal, February 27, 1892, p. 240.

12. To vary the dosage on the sponge-dressing "by the fixed rules for individual cases," I meant that we may give a larger dose to a woman of strong, coarse, rigid fibre, than could be borne by one of fine, delicate structure—one who, in modern nomenclature, is a "sensitif," or what we so lately and erroneously called a "nervous temperament."

13. A careless reader—so familiar to all writers—tells me, while asking what others do in substance, "You condemn the use of iron, yet call it a valuable agent, and acknowledge that you prescribe it yourself. What are your indications for it?" I condemned no practice or practitioner, and merely took exception to the prevailing massive dosage of the metal, which repeated crucial tests with unvarying results had taught me to be both unnecessary and toxic. If the ears are pale and waxy, especially when viewed by transmitted light, iron is indicated. A person whose ears are red will rarely need iron. The drug may also give brilliant results in many cases when there is a deep, circumscribed redness of the face during pain or excitement, although in repose the face may be pale or yellow.

14. Evidence is curtly demanded as to "how the chemistry of the body can change ingested iron into the tannate?" I did not so represent the change, but the law of chemical affinity is not suspended within the body. Several articles of food—notably tea, coffee, etc.—contain tannin. This tannic acid will unite with iron on meeting it in the stomach, intestine, or elsewhere, to form the insoluble tannate of iron. The tannate thus formed will unite with animal tissues, living or dead, and remain permanently fixed in the body. It is unfortunate for many that none of these facts are given in our text books on chemistry. A number of the drugs named in the paper will, when indicated, dissolve this tannate of iron and eliminate it from the body.

15. A ready solvent of the viscid secretion of chronic cervical endometritis is not yet satisfactorily determined. A few drugs of undoubted value in this condition are now being tested. The best of these appears to be jacaranda gualandi, of Brazil; but I cannot yet commit myself to assert of any drug that it is a true remedy. It is still deemed best to remove the tenacious secretion by the mechanical means recommended in the paper, or by the curette, when the indicated remedies named will complete the cure.

16. In the treatment of uterine fibroids I have as yet nothing definite to add. When such tumors can be readily removed by operative means, this course is recommended. Where obstacles prevent, or danger threatens from operation, the sponge-dressing may be resorted to with a fair degree of confidence. In twenty-six cases thus far completed I have met with only two failures.

17. In treating erosions of the os uteri, etc., when the sponge-dressing adheres to the eroded surface, and its removal is followed by the discharge of arterial blood, it is evidence that a wrong drug has been used, and a re-examination of the patient will reveal the remedy to be employed. A very weak solution of silver nitrate, applied by the hair-pencil before the proper dressing, affords marked relief in such cases.

18. When stenosis of the os or cervix uteri presents, the first indication is to soften the cervical tissues, which are almost constantly indurated in such conditions, and then to open the cervical canal. Until the latter object is accomplished, further treatment may only waste time and irritate the organs involved. But once the cervix is dilated, and so maintained, the remedy is immediately distributed, not merely to the endometrium, but to the entire system, and free drainage will soon be established. It has been frequently observed, however, especially in young women, that stenosis and flexions yield spontaneously to the treatment without instrumental aid.

19. Pain or inflammation has rarely followed dilatation of the cervical canal, even when the patient had not been fully prepared for the operation, or when she had had a history of peritonitis. The dressing, charged with the sanguinaria co., combined when necessary with any other suitable remedy, will usually subdue pain and tenderness in a few minutes, after which the patient may ride or walk home with safety and comfort.

20. It is gratifying that so many of my correspondents seek adequate means for correcting excessive and deficient menstruation. The great majority of women who suffer from uterine diseases, lose by far too much blood each month; and but few other conditions can so rapidly make them prematurely old. I regard the normal menstrual period (some few cases of general plethora excepted) as being three, or at most four, days each lunar month; and that limit is usually established by a judicious course of the sponge treatment, whatever the menstrual history of the patient may have been. Abnormal menstrual flow may usually be corrected by a careful selection of the remedies named in my previous paper, guided by a study and appreciation of the characteristic secretions. If these fail—if we must treat the symptom instead of the patient—a valuable general remedy for menorrhagia may be found in savine, 1 to 12 of water. In scanty menstruation conium and pulsatilla are of equal efficacy.

22. The badinage lavished upon me for my "extravagant faith in medicine," would fill a small volume. This shower of spice may be gracefully accepted, since it disproves nothing, while I have proven my positions. But it is wise to bear in mind that our patients possess and adhere to a living faith in medicine, whether we do or not. They also have faith in us; and it is our duty to make that faith as well founded and abiding as possible. With this as well as higher objects in view, I have delved in many mines—have sought far and near for drugs of alleged value, and have studied in all systems worthy of the name. In nearly all I have been able to cull gems from the mass of detritus. The results of my search have been given without reserve to the profession, who can best judge of their value. I ask that those who have tested or who may test my method in practice, will report results in the columns of the MEDICAL RECORD.

To many members of the profession, in this and other countries, my grateful acknowledgments are due, alike for their welcome criticism and for their generous words of approval and encouragement. A reprint copy of the original paper will be sent on request to those who have not seen it.

233 WEST TWENTY-THIRD STREET.

Oliver Wendell Holmes as a Microscopist.—Forty-one years ago, Dr. Holmes, who was eighty-five years old on August 29, 1894, taught Dr. E. Cutter how to use the microscope with direct illumination. He had an arrangement of his own—a six-inch black disk fastened to the tube and graduated so that turning the disk would act as a fine adjustment. Dr. Cutter says that Dr. Holmes worked a good deal with the microscope in those days, and that the intellectual drill derived therefrom may have been used in literature. Is not the technical use of the microscope in college as good a discipline as the study of Greek? Surely the cyclops of the Odyssey would be better understood by one who has studied a living cyclops taken from a hydrant and shown under the microscope.—*The American Monthly Microscopical Journal.*

Progress of Medical Science.

Pylorectomy with Gastro-Duodenostomy Posterior.—Professor Kocher gives his method of excising the pylorus. (*University Medical Magazine.*) The incision is made in the median line, and is 10 to 15 ctm. long. The umbilicus is excised and all bleeding stopped. The tumor having been withdrawn as much as possible, small openings are made through the greater and lesser omentums, through these clamps are adjusted. The attachments of the omentum are then loosened from the growth and the latter enveloped in gauze. All bleeding is carefully stopped. A clamp, resembling an ordinary hemostatic forcep, is placed on the duodenum and an incision made between it and one applied on the stomach. He does not fear sloughing from pressure. The mucous coat which protrudes from the cut section is carefully cleansed with bichloride, 1 to 1,000. The stomach is then compressed by the fingers of an assistant, and clamps placed next the growth, an incision being made between them the growth is removed and the cut stomach cleansed and sutured shut with a continuous suture. This is then invaginated and another continuous Lembert suture placed above. The posterior wall of the duodenum is then approximated to the posterior wall of the stomach one-half or three-quarters of a centimetre behind the closed end, and the two are sewed together with a continuous sero-serous suture. The forceps being removed from the duodenum, all bleeding is stopped and its interior carefully cleansed. An incision is then to be made into the posterior wall of the stomach and the free edge of the duodenum sewed to it by a suture, either embracing all the coats or else two layers applied—one musculo-serous and the other mucous. The sero-serous layer of suture first applied is then continued all around. The cut end of the duodenum is thus fixed directly into an incision in the posterior wall of the stomach. Of six cases so operated on, one only died, and it on the twentieth day. Asepsis is insisted on, the lines of sutures being touched with gauze wet with sublimate solution. No washing of the abdominal cavity is to be employed. The continuous suture only is to be used. It is unnecessary to guard the forceps used to clamp the cut ends with rubber, because the pressure does no harm.

The Mechanical Treatment of Chronic Constipation.—Dr. F. Le Marinel believes that the mechanical treatment should be the treatment of choice in a large number of forms of chronic constipation. The manœuvres of massage comprise three forms—frictions, pressures, and percussions. In addition, various active and passive movements are undergone—flexion, extension, abduction, adduction, pronation, supination, rotation, and circumduction. The effects of medical gymnastics are studied as regards the circulation, respiration, animal heat, chemical phenomena, the muscles, bones and articulations, and the local results. The effect of massage upon the absorption, muscular system, nervous system, circulation, and local temperature are fully recorded. (*The American Journal of the Medical Sciences.*) The technique of various authors is fully described and illustrated. The various forms of constipation which are likely to be benefited are—(1) from anæsthesia of mucous membrane; (2) from muscular paralysis; (3) from induration of the stools, and (4) from mechanical obstacle. The contra-indications are—(1) acute inflammation of intestines, peritoneum, peri intestinal cellular tissue, or of intra-abdominal veins; (2) ulcerations (round, tuberculous) of stomach or intestines; (3) tumors of the alimentary canal (sarcomata, carcinomata, polypi); (4) voluminous fæcal masses of stony hardness. An interesting comparison is given of the value of diet, habit, purgatives, hydrotherapy, injections, electricity, various medicinal methods, with that described by the author, the general conclusion being that of all these methods only one can be compared to the mechanical, and that one is electricity. But when one considers the question from the standpoint of success, massage shows figures which are not surpassed by electricity. So far as facility of application, massage is superior in that it does not require any apparatus, and can be applied equally well at the house of the patient as of the physician. Further, massage is better borne than electricity, and particularly by children. A series of 147 cases is reported, the treatment being that advocated in the paper. The care shown in the report, the apparent accuracy of diagnosis, the fulness of detail, give an especial value to the clinical histories. In the cases cited, those of the synoptical table, and eleven in detail, 158 in all, radical cure was obtained in about ninety per cent. The final conclusions are: 1. Mechanical treatment takes rank among those therapeutic agents whose action is most energetic upon the circulation, the respiration, and general nutrition. 2. It can modify the abdominal circulation, and cause certain foreign congestions, notably those which are met with in abdominal plethora, to disappear. 3. Under its action the muscles acquire an increase in volume and strength. 4. It is the best curative agent in constipation dependent upon muscular paresis or paralysis, if it is not of central nervous origin. 5. It is the best curative agent for constipation dependent upon diminished sensitiveness, or anæsthesia of the mucous membrane when it is due to local causes. 6. Finally, it is formally contra indicated when constipation is due to acute inflammatory lesions or to tumors.

The Treatment of the Fever of Phthisis.—Dr. Savigny distinguishes three forms in this disease: 1, The initial or continued; 2, the hectic or concomitant; 3, the septic. In the last form the purely symptomatic treatment is powerless. The administration of the new antipyretics is not favorable, for all of them diminish the energy of the heart, only influencing the fever as a symptom, if indeed they have any notable effect, and they are only used in rapid tuberculosis, and when humanity demands only that the patient shall be made more comfortable. Hochhalt, after much research, has come back again to arsenic, but with the exception of recent initial apical catarrhs it has no influence upon the course of the disease. Hectic fever is manifestly influenced by this remedy, but it has no action upon the initial fever and upon the rapid forms of phthisis. Fowler's solution is recommended, in commencing doses of one to two drops, and increasing, day by day, to five or six; rarely more, for ten drops is quite likely to produce symptoms of poisoning. Other beneficial effects besides the lowering of temperature are the suppression of night sweats and an increase of appetite and body weight. The continued fever offers considerable resistance to the treatment by arsenic, for this fever is a manifestation of caseation, and is an expression of the clinical form of *phthisis florida*. By building up the system one can best combat the tendency to caseation. In these cases the condition of the heart and circulation is important; Brehmer and Dettweiler recommend the prolonged application of ice-bags; others use alcohol. Kühle and Liebermeister advise digitalis, which however, should be used with caution; but more advantageously the ten per cent. tincture of coronilla, in ten to twenty-drop doses, can be employed. In cases of initial fever without grave lesion of tissue, in association with fifteen grains of quinine, Hochhalt has seen this fever transformed into the intermittent type, where arsenical treatment is useful. In apyretic phthisis creosote is used; if at the outset it is not well borne by the stomach, it can be administered in cocoa-butter suppositories—with steady increase of all doses; in commencing with large doses there is danger of exciting the fever. In general the antipyretic treatment consists less in reliance upon the antifebrile remedies, properly so called, which have only a slight and transitory effect, as in the use of remedies which act directly upon diseased pulmonary tissue, than upon arsenic, the cardiac tonics, and nutrition by every means which can stimulate it.—*American Journal of the Medical Sciences.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 10, 1894.

THE NEW TREATMENT FOR DIPHTHERIA.

WHENEVER a new remedy is suggested for a prevalent and formidable disease it is quite necessary to exercise a becoming conservatism regarding facts which bear on the possibility of a brilliant discovery. The history of all similar cures proves that the initiative reports are not always borne out by subsequent results, and that nothing more is gained by a discussion of relative merits of other remedies than the ventilation of a new theory and the final mortification of its ultimate rejection.

On the other hand it must not be argued that students of therapeutics should be backward in seizing upon every plausible means to an end, or should neglect opportunities for the careful study of such data as may be presented with a proper spirit for deliberate judgment. Even in view of these apparent drawbacks we cannot resist the temptation of looking upon the antitoxin treatment of diphtheria as promising better than any that has heretofore been presented to the profession. Making due allowance for the remarkable percentage of cures, even in malignant cases, we can safely assume that if one-half of what is said of the antidotal power of the serum is true, we have made a most wonderful advance in the therapeutics of a most formidable and fatal malady. There is, indeed, enough encouragement in the astonishing results abroad to warrant an extended trial in this country.

The articles by Professor Baginsky, of Berlin, and Dr. Louis Fischer, of New York, in a recent issue of the MEDICAL RECORD, were calculated to arouse a new interest in the subject by calling attention to some remarkable results. The mortality of diphtheria in Berlin during the three years preceding the trial of antitoxin ranged from 32.5 per cent. to 41.7 per cent. Baginsky broke this record in one hundred and ninety-two cases by reducing the death-rate to fourteen per cent., while in eighty-two additional cases, making in all two hundred and seventy-four, the average mortality was 15.3 per cent. More recent statistics give in sixty-three cases a fatality of 5.5 per cent. In France, Professor Roux lowered the death-rate from 51.71 per cent. to 24.33 per cent. Viewed as plain facts the showing is certainly very remarkable.

The theory of the action of the antitoxin serum from a bacteriological standpoint at least is quite tenable, while clinically there are no obvious objections to its plausibility. It is in brief the transferrence of acquired immunity in an animal to a similar condition in the human subject. The natural resistance to the disease, the vital energies which are aroused to overcome the enemy, are sufficiently reinforced by the immune serum to turn the balance in favor of a cure. In a like manner the antitoxin is claimed to act in a protective way for such as may be exposed to the disease by a preliminary injection of immunizing serum, thus anticipating the evil effects of the disease by neutralizing its septic tendencies. So far the encouraging reports coming from Berlin and Paris are quite convincing, and, unless contradicted by more extended experience, warrant the brightest hopes for the future. There is certainly a singular agreement regarding the reduction of mortality as observed by different experimenters, which gives a truer scientific complexion to the facts than could be gained from partial sources or through biased channels. There is, then, every plausible reason why the antitoxin treatment should be thoroughly tested in this country. The great trouble at the start will be the scarcity of the remedy and the difficulty of obtaining it. This difficulty should be overcome as speedily as possible by extending its manufacture and in establishing necessary laboratories in different parts of the country. Thus far the only antitoxin that has been used in this country has come from abroad, and is now in such limited quantity as to be practically useless for purposes of extended experimentation. It is to be hoped, however, that ultimately the supply will meet the demand, and that opportunities may be afforded for such tests of the efficacy of this new remedy as seem to be warranted under existing circumstances.

LAUS GAMBRINO.

IT is rare that one finds a physician nowadays who gives that unqualified praise of beer, as compared with other alcoholic liquors, which was heard a few years ago. The tendency is rather to teach that "total" abstinence is best, and that beer is not much better than other forms of intoxicating drinks. The view once hopefully entertained, that beer was the best and safest beverage, and that its introduction into America would lead to an abandonment of spirits and to less drunkenness and alcoholism, is not now generally held. We read with some interest, therefore, an article in praise of beer by Dr. Lambert Ott, in *The Medical News*. The article is based on fifteen years' observation among beer drinkers. The class that Dr. Ott has studied is composed mostly of laborers and employees in breweries, the men being mostly Germans, but with a sprinkling of Irish and Americans. Some of these had drank from one to two gallons of beer daily for fifteen years without any obvious disturbance of the bodily functions.

Dr. Ott seems to think that beer-drinking has a distinct ethical value, for he says: "The German brewer is by nature an honest, industrious, and good-natured individual, fond of his home and family, and in every way a congenial person; even the Irish and American brewer partakes of those kind and congenial elements so common to the German brewer, leading one to believe that the constant association and use of beer as a beverage begets a distinctive type of humanity, possessing natures kind and pleasing. Often have I observed young men, of slight build, with no inherited predisposition to

obesity, after a year or two in a brewery acquire a sunny disposition and an accumulation of fat, the attenuated and introspective dyspeptic being transformed into the happy and fat brewer."

The blood of beer drinkers shows an increased proportion of red blood-cells and a diminution of white corpuscles. Excessive beer drinking leads to a condition of mental torpor, which soon disappears, however, when the cause is removed.

According to Dr. Ott, beer does not retard, but assists, digestion. However, in the summer time, when large amounts are poured into the stomach, a subacute gastritis may develop. Diseases of the heart and lungs seem uninfluenced by large potations of beer. Cirrhotic kidney and hob-nailed liver are never, he says, found in the beer drinker; neither does beer alone ever produce delirium tremens.

Altogether the beer habit, when not accompanied with other bad habits or the use of whiskey, is a healthful one.

Here, however, is the weak point in Dr. Ott's argument. The beer drinker is very liable to take other drinks after a while, and then bad results follow. The observations made upon a class of men who indulge in hard manual labor, cannot be applied to the community in general. It is the experience of most physicians that in this country, beer drinking, except in great moderation, leads to gastric troubles, and to gouty, rheumatic, and renal disorders.

DOCTORS WHO GIVE AND RECEIVE "COMMISSIONS."

What shall be done with that peculiarly contemptible species of huckster, which, protected by medical diplomas, sends gullible people only to those "consultants" and "specialists" who pay them an underhanded commission for their favors? That the thing is done admits of no doubt. But how to bring about exposure, and brand the medical trader and commission pedler as he deserves to be branded is a problem still requiring solution.

The *Philadelphia Polyclinic* is much exercised over this state of affairs, but has no practical reform suggestions to offer. According to this journal: "The *Tri-State Medical Journal* published a letter from a physician to a prominent consulting surgeon, asking what percentage he would pay for cases referred to him in consultation. Ophthalmic surgeons have all had experience with such offers from opticians, and Orthopedic surgeons from truss and brace makers. More than one hundred years ago it was declared reprehensible for a physician to enter into collusion with druggists and receive a percentage on the price of prescriptions compounded, and the declaration would hardly have been made if the practice had not existed. That it continues, and from time to time assumes new forms, we must also reluctantly admit. We will not here occupy space in arguing against the practice of the physician accepting a fee from a patient with the understanding that he is to give the best advice which his knowledge and experience enables him to offer, and then accepting a percentage or fee from somebody else in consideration of giving that advice a special direction. To any one who really has the slightest doubt as to the immoral and unethical nature of such a transaction, we would suggest this simple test. Would he be willing to do it openly and with the knowledge of the patient? Let the doctor who is captivated by the offer in question state frankly to his patient, 'I think you had better go to —— —— Sanitarium, the company pay me $100 for giving you this advice;' or, 'You must go to Mr. So and So to get your glasses, who will give me 33⅓ per cent. of the price you pay him for them, for sending you there;' or, 'You must consult Dr. Medicus, who gives me $5 for every patient I send to him.' The doctor who makes such an explanation to his patients, we believe has a perfect right to accept the stock or the percentage or the share of the fee. The doctor who accepts such compensation in secrecy, without any explanation to the patient of the nature of the influences under which the advice is given, belongs in the same class with the bunco steerer and the man that cheats at cards. The grocer who puts sand in his sugar, or the jockey that files his horse's teeth, are honorable in comparison."

Our Philadelphia contemporary calls upon the profession to put a stop to bribery within the ranks of a noble calling. Perhaps its pathetic outcry will be heeded. And then, again, perhaps it will not. The hardened sinner is generally too pachydermatous to be affected by "press notices." His moral sense resides in his pocketbook. To make him suffer, his emoluments must be reduced to the vanishing point. If all physicians would resolutely refuse association of any and every kind with the "commission doctors," the genus would soon become extinct. If Philadelphia will only lead, New York will gladly follow.

CIRCUMCISION.

Dr. Alexander L. Hodgdon, in the *Medico-Surgical Bulletin*, lays down some reasons why, in his opinion, all male infants should be circumcised. Aside from the stock arguments on this subject, we find nothing to support Dr. Hodgdon's position, except the statement that there are in the community two estimable classes among which the operation is done, viz., the Jews and the "physician class." Quoting Dr. Remondino, he says: "In the United States, France, and England, there is a class which also observe circumcision as a hygienic precaution, where from my personal observation I have found that circumcision is thoroughly practised in every male member of many of the families of the class—this being the physician class. In general conversation with physicians on this subject it has really been surprising to see the large number who have had themselves circumcised either through the advice of some college professor while attending lectures, or as a result of their own subsequent convictions when engaged in actual practice."

It will no doubt be somewhat of a surprise to our readers to learn that they belong to a circumcised, if not a chosen, class. We doubt if the facts at all support the assertions of the writers we have just quoted. In most cases the foreskin adjusts itself to conditions of perfect cleanliness at the time of puberty, if not before. Physicians are not so senseless as to unnecessarily mutilate themselves and their families. Circumcision is a relic of barbarous and semicivilized times, before soap and water and sanitation had been preached. It no doubt served a useful purpose among the nomadic tribes of

tropical countries. But in these days physicians should cease to preach or impose upon their patients an unnecessary and irrational mutilation.

The rite which in these modern times might be substituted for the early religious ceremony of circumcision would, according to some, be resection of the spermatic cord of the vicious and defective classes, so that they should cease to propagate their kind. Spermatorectomy will probably triumph over and replace circumcision, if anything does.

THE PREVENTION AND CURE OF SNAKE-BITES.

The early exploitation of a medical discovery in a popular magazine does not afford the best evidence that it is new and valuable. If, however, the discoveries of Dr. Calmette are not yet proven to the satisfaction of the scientific world, the confidence of the doctor in what he will be able to do is genuine and beyond the need of demonstration.

Dr. Calmette believes that by the help of his therapeutic serum the most venomous serpents will be rendered as harmless as doves. This substance will, he thinks, be kept in all the drug stores of India, Africa, and America, and will be carried in the pockets of all travellers and sportsmen who are exposed to the bites of serpents. The new antidote has been prepared and Dr. Calmette's investigations carried out at the Pasteur Institute. And the method employed is much the same as that used in obtaining the immunizing serum of diphtheria.

It is known that venomous serpents are not susceptible to the bites of their fellows, but that non-venomous serpents have not this immunity.

This furnishes some evidence that there is such a thing as being protected against snake poison. In order to induce the condition artificially, rabbits and guinea-pigs are chloroformed and then bitten by the cobra or viper, or are inoculated directly with the venom. The blood of the animals is then taken and its serum used as a protective against bites or inoculations of other animals. It is asserted that whereas the cobra bite usually kills the rabbit in one or two hours, if properly protected the animal skips around in as lively a manner as ever, no matter how severe the bite.

Dr. Calmette finds that besides his therapeutic serum there are two other substances which protect against serpent poison, viz., the chloride of gold and the chloride of lime, the last being much the better. He has not had an opportunity to try the chloride treatment on man, but his directions for such trial are these: "The chloride of lime should be free from absorbed water, and, when used, should in all cases be freshly taken from a hermetically sealed bottle. One part of it by weight should be dissolved in eleven parts of boiling water, and the solution should never be made until it is about to be used, as I have found that the therapeutic power diminishes by keeping. This should be injected subcutaneously with a trephine [*sic*] all about the wound, and also under the skin. From twenty to thirty cubic centimetres of the solution will suffice to save the life of a man bitten, it being administered in doses of five cubic centimetres each."

As to the immunizing serum, he finds that, generally speaking, about five cubic centimetres are necessary to make the animal proof against one milligramme of pure venom. He also finds that he can use three distinct specifics in vaccinating a rabbit, and by all analogy, a man, against the bite of the most poisonous snake, or as an antidote after they have been bitten. These are, first, the serum from an envenomed animal by itself; secondly, this serum mixed with chloride of gold or the hypochlorite of sodium or of lime; and, thirdly, either of these chemicals, or, preferably, chloride of lime, used by itself without serum.

Dr. Calmette has not experimented with rattlesnake poison, but he finds that the same antidote is good for all the other venoms he has tried, and he feels confident that it will answer for the rattler.

News of the Week.

Honor to a New York Surgeon.—Dr. Arpad G. Gerster has received from the Emperor of Austria and King of Hungary the high distinction of the Knight's Cross of the Order of Francis Joseph in grateful recognition of his valuable philanthropic labors in founding the Hungarian Emigrant Aid Association of this city. This is the first instance in which an American citizen has received this honor who has not held office under the Austrian government. It is eminently fitting also that a member of our profession should be thus closely associated with such noble work, and that he should be so worthily rewarded.

The Southern Surgical and Gynecological Association.—The seventh annual meeting will be held in the Artillery Hall, Charleston, S. C., on November 13, 14, and 15, 1894. Members of the medical profession are cordially invited to attend.

Chicago Gynecological Society.—At the sixteenth annual meeting of the Chicago Gynecological Society, held October 19, 1894, the following officers were elected to serve the ensuing year: *President*, Dr. Franklin H. Martin; *First Vice-President*, Dr. A. J. Foster; *Second Vice-President*, Dr. J. C. Hoag; *Secretary*, Dr. H. P. Newman; and *Editor*, Dr. T. J. Watkins. The retiring president, Dr. Fernand Henrotin, delivered an interesting annual address, after which the society adjourned to the annual banquet. Dr. John B. Hamilton, J. B. Murphy, Health Commissioner Arthur Reynolds, Alexander H. Ferguson and others were guests of the Society.

Dr. Pliny Earle's Bequest to Leicester, Mass.—The town of Leicester, Mass., has received $6,000 under the will of the late Dr. Pliny Earle, for the erection of a building for the public library of the town.

An Accident to Doctor Wiglesworth.—Dr. J. Wiglesworth, superintendent of the Rainhill Asylum, Prescott, Lancashire, England, was stabbed in the neck by a patient, who had obtained a sharpened staple; the internal carotid was severed, necessitating ligation of the common carotid artery.

Want no Physiology.—The Christian Scientists of Burlington, Ia., have petitioned the school board to excuse their children from attendance when physiology is taught. The petitioners declare that there is no material

body, and object to having their children taught to believe that there is anything so much in evidence as a stomach or a liver.—*Times and Register.*

Outbreaks of Small-pox.—A considerable outbreak of small-pox has occurred in Manchester, Mich., and neighboring towns, and is causing some alarm. Several cases of small-pox have occurred in Washington, D. C., recently. They have been traced to a case occurring in the family of an employee of the pension department.

Dr. Roux Decorated.—Dr. Roux has received from President Casimir-Perier the congratulations of the Government and the Cross of Commander of the Legion of Honor, in recognition of his work upon the serum treatment of diphtheria.

Foot-ball Casualties.—*The Lancet* of October 20th chronicles three deaths and four fractures as the result of the previous week's sport.

A Physician to be Trustee of the Boston Public Library.—Dr. Henry P. Bowditch has been appointed by the Mayor to be a trustee of the Boston Public Library.

The Antitoxin Treatment of Diphtheria in Vienna.—At the meeting of German naturalists and physicians held in Vienna last month, one of the most attractive subjects discussed was that of the papers of Professor Behring and Ehrlich on "Serum Therapeutics," and on the "Use of Behring's Antitoxin in the Treatment of Diphtheria." But neither paper brought any new facts before the meeting, and the most interesting communication concerning this question was made by Dr. Wassermann, of Berlin. He was endeavoring to obtain information on the question of idiosyncrasy as regards proclivity to or immunity from an infectious disease. For this purpose he withdrew a quantity of blood from persons who remained healthy though surrounded by persons suffering from diphtheria, and studied the effect of this blood on the diphtheria bacillus and its toxins. He found that the blood of such healthy persons destroyed the toxin of diphtheria, and neutralized tenfold its bulk of the toxin. In eight persons aged over forty years, he found in seven the same antitoxic property of the blood, while the percentage of younger persons possessing such antitoxic blood was lower, and reached only fifty per cent. of the children examined between four and fifteen years of age.—*Lancet.*

Professor Ludwig Mauthner, of Vienna, died suddenly of heart failure. He had just been appointed Professor of Ophthalmology in the Vienna University.

We Wonder if it be True.—*The Medical News* of Philadelphia remarks that the first statue ever raised to a medical man was erected in Brooklyn on October 20th, to commemorate the memory of Dr. J. Marion Sims. This bit of information will probably surprise Brooklyn physicians, as none of them seem to have heard of it.

Dudley Sharpe Reynolds, Jr., M.D., son of Dr. Dudley S. Reynolds, of Louisville; born at Louisville, February 20, 1873, died from the accidental discharge of a pistol, at Collinsville, Ill., October 22, 1894.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1895, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1895. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within it the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1894 has been awarded to Dr. G. E. de Schweinitz, of Philadelphia, for his essay entitled "Toxic Amblyopias." CHARLES W. DULLES, *Secretary.*

Another Post-Graduate School.—It will doubtless be news to many New Yorkers to learn that there is a third post-graduate school in this city. It is called the Metropolitan Post-Graduate School, and is homœopathic.

Obituary.

WILLIAM GOODELL, M.D., LL.D.,

PHILADELPHIA, PA.

DR. WILLIAM GOODELL, the eminent gynecologist, who had been in failing health for the last two years, died at his residence in Philadelphia, on October 27th, aged sixty-five years. Dr. Goodell was the son of the Rev. William Goodell, D.D., of Holden, Mass., and was born on the island of Malta, while his parents were journeying to Turkey, where his father was engaged in missionary work.

In 1849 he entered Williams College, Massachusetts. Graduating three years later, he came to Philadelphia and continued his studies at the Jefferson Medical College, and received his diploma in 1854. The same year Dr. Goodell rejoined his father in Constantinople, and there entered upon the practice of his profession. In 1857 he married, at Smyrna, Asia Minor, Caroline, daughter of the late Judge Thomas S. Bell, of West Chester, Pa., who survives him. In 1861 he returned to America on account of the unsettled condition of political affairs in Turkey, and locating in West Chester, there commenced practising medicine in this country.

In 1865, on his appointment as Physician-in-Charge of the Preston Retreat, at Twentieth and Hamilton Streets, he came to reside permanently in Philadelphia, and continued to hold this appointment until his health began to fail.

Soon after coming to Philadelphia he restricted his practice to obstetrics and diseases of women, on the subject of which he was a prolific contributor to this and other medical journals, and was also the author of "Lessons in Gynecology."

In 1870 he was appointed Lecturer on Obstetrics and Diseases of Women at the University of Pennsylvania, and in 1874 Clinical Professor of the University in the Diseases of Women and Children. He was also Honorary Professor of Gynecology of the University, a member of the American Medical Association, and the Gynecological Society; also of the State and county medical associations. He was a Fellow of the College of Physicians, and a member for many years of the American Philosophical and American Pathological Societies, and a correspondent of the Boston Gynecological Society, of the London Obstetrical Society, and of the Imperial Medical Society of Constantinople.

Reviews and Notices of Books.

A Practical Treatise on Orthopedic Surgery. By James K. Young, M.D. Philadelphia: Lea Brothers & Co. 1894.

In his preface, the author states that he has endeavored to provide students and practitioners with a guide to Orthopedic Surgery in accordance with the most approved knowledge of the present day. A noticeable feature of the work is the absence of long descriptions of operative measures for the relief of deformities congenital or acquired, or the result of inflammatory joint or spinal disease. The author wisely emphasizes the mechanical treatment of the various conditions, leaving an extensive description of operative measures to works on general surgery, in whose province they rightly belong. He devotes considerable space to the pathology of the different affections considered, and has brought this part of the work up to the most recent views. Want of space renders a detailed criticism impossible, but the author has given a fair and complete résumé of the different ideas in vogue at present regarding the etiology, pathology, symptoms, and treatment of the different conditions now assigned to the specialist in orthopedic surgery.

The work is a beautiful example of typographical art, and is abundantly illustrated. Dr. Young's work gives evidence of careful and conscientious research, and is a valuable addition to the literature of orthopedic surgery.

La Lèpre. Observations et Expériences Personnelles. Par le Docteur Jules Goldshmidt. Paris: Société d'Éditions Scientifiques. 1894.

What makes this little brochure so attractive that one is not apt to lay it down until the fifty pages have been carefully read, and the ten full-page phototype illustrations studied, is the impression left upon every paragraph, we might almost say, that the author is giving not only his personal experience, but a personal experience which is worth giving.

Leprosy has prevailed in the island of Madeira almost since its discovery, or for some four centuries. During the past twenty-six years of this time the author has lived there, and has made the most of his time and advantages for studying the disease in its many bearings, if we can judge by the result before us.

Clinical Medicine. A Manual for the Use of Students and Junior Practitioners. By Judson S. Bury, M.D. Lond., F.R.C.P. London: Charles Griffin & Company, Limited. Philadelphia: J. B. Lippincott Company. 1894.

This book comprises twelve chapters, covering all the more recent methods of diagnosis. It is quite novel to find the vast changes in books of this kind within the last few years. The skin, cutaneous eruptions, diseases of the nails, are certainly interesting. The examination of the blood is certainly as useful to-day as an aid to diagnosis as any other special symptom. The chapters on the chemical and microscopical examination of the urine have been most carefully prepared; so, for example, Esbach's method of estimating albumin shows it to be up to date. This book reminds us very much of that most admirable book by Seifert Miller, published in Germany. The illustrations are excellent, and the book is not only admirably adapted for the position of manual, but may even claim to be exactly what every physician should know to-day. It contains 468 pages, and is neatly printed.

Diseases of the Nose and Throat. By F. De Havilland Hall, M.D., F.R.C.P. Lond. With 2 Colored Plates and 59 Illustrations. Philadelphia: P. Blakiston, Son & Co. 1894.

This book is divided into three parts. Part I. treats of diseases of the nose, accessory sinuses, and naso-pharynx. Part II. treats of diseases of the pharynx. Part III. treats of diseases of the larynx. It has been written from a medical rather than a complete surgical standpoint. It fulfils its purpose, for it is written plainly and gives all that the ordinary practitioner requires for immediate reference. The book is profusely illustrated, and is well worth reading.

Some chapters, especially those on the specific infectious diseases affecting the throat, *e.g.*, scarlatina and diphtheria, although very carefully written, still show that all modern therapeutics has not been included. So, for example, antitoxine is not even mentioned as a therapeutic measure in 1894, although it has been extolled since 1891. However, the book merits the confidence of the profession.

The Senile Heart. Its Symptoms, Sequelæ, and Treatment. By George William Balfour, M.D. St. Andrews, LL.D. Edin., F.R.C.P.Eng., F.R.S. Eng. Consulting Physician to the Royal Infirmary, to the Royal Hospital for Sick Children, and to the Royal Public Dispensary, Edinburgh; Consulting Physician to Leith Hospital; formerly Physician to Chalmers Hospital, Edinburgh, etc.; Member of the University Court of St. Andrews. New York and London: Macmillan & Co. 1894.

This is a very clearly expressed and readable treatise upon a subject of great interest and importance, which has perhaps hitherto not received the careful study it deserves. We are gradually learning that old age is not the hopeless and helpless condition that some used to regard it, but that it is just as deserving of study as is any other period of man's life, and the rewards of its study are as great or greater. We cannot cure old age any more than we can cure infancy, but we can often, by our art, change what would otherwise be a period of torment and suffering into one of peaceful content. To this end is the teaching of Dr. Balfour's book, and no one can arise from a perusal of it without feeling that he is in better position than before to assuage the distressing ills to which some of our dear aged ones may be subject. We can heartily commend the work as a valuable contribution to the literature of old age.

The Students' Dictionary of Medicine and the Allied Sciences. Comprising the Pronunciation, Derivation, and Full Explanation of Medical Terms, together with Much Collateral Descriptive Matter, Numerous Tables, etc. By Alexander Duane, M.D., Assistant Surgeon to the New York Ophthalmic and Aural Institute; Reviser of Medical Terms for Webster's International Dictionary. Philadelphia: Lea Brothers & Co. 1893.

The rapid growth of medical terminology, especially in the departments of bacteriology, pharmacology, and therapeutics, makes the possession of a reliable technical dictionary an absolute necessity for student and practitioner alike. Dr. Alexander Duane, who is well known as a medical writer of wide experience, and who has had special training as the reviser of medical terms for Webster's International Dictionary, has issued such a work, which proves to be a model of conciseness, convenience, and thoroughness. Obsolete words have been discarded, and the book is brought accurately to date by extended research among current medical journals and recent monographs. The definitions of diseases include a brief synopsis of their etiology, symptoms, and treatment; the anatomical and physiological terms are accompanied by outlines of the essential features of structure and function, and each drug is described, with its reputed action, therapeutic uses, and pharmacopœial preparations.

Although contained within the limits of a handy volume of 650 pages, many of the definitions possess encyclopædic value. Useful anatomical and other data are tabulated with originality and precision. Under the word Artery, for example, is found a table covering eight pages, presenting the origin, lateral and terminal branches,

and their distribution, of each vessel. Twenty tabular pages are allotted to the origin, direction, and insertion of the muscles, with their action and nerve-supply; while thirty-two more are given to the "Table of Bacteria and Fungi," with their origin, morphological characters, proper temperature for culture, properties, etc., as well as a complete list of all bacteriological diseases. The latter is the most comprehensive and serviceable table of the kind yet issued. The system of pronunciation is simple, and the spelling is in accordance with the best usage rather than analogy. Derivations from foreign tongues are given, those from the Greek being in English text for the benefit of readers unfamiliar with the original. The typography and arrangement of the book are highly commendable.

The author is to be congratulated upon the production of a work combining such practical utility with a fund of most extensive research.

1. Directions for Laboratory Work in Bacteriology, etc. By Frederick S. Novy, Sc.D., M.D.; Junior Professor of Hygiene and Physiological Chemistry. Pp. 309. Ann Arbor, Mich.: George Wahr.

2. Laboratory Manual of Elementary Physiology and Urine Analysis. By John H. Long, M.D., Sc.D., Professor of Chemistry, etc., Northwestern University. With numerous illustrations. Pp. 366. Chicago: E. H. Colegrove & Co.

If there be "no royal road to learning," the seeker after medical knowledge to-day at least may choose a princely road. The books, whose title-pages are given above, illustrate that the American medical teacher is rapidly approaching perfection in method and style. Both books present the subject-matter in a clear, comprehensible manner, guiding the student gradually and pleasantly through the intricacies of the primary work, which are usually so discouraging. Neither work claims originality, the authors in both instances frankly stating that they have drawn from the best sources, and arranged the matter for their purposes. The paper and type are good; those of the first book excellent.

1. Professor Novy's work opens with clear directions for preparation of nutrient gelatin, potato culture, describing the microscope and method of examination of bacteria, hanging drops, staining of bacteria, examination of colonies. A description of various bacteria follows, giving their origin, form, motility, sporulation, growth, oxygen requirements, temperature, behavior to gelatin, aërogenesis, and pathogenesis.

The bacteriological examination of water, soil, and air is briefly described. Pathogenic bacteria, methods of infection, post-mortem examinations, sputum examinations, and agar plate cultures, are followed by a full and mostly clear exposition of the technique of direct microscopical examination of streak preparations made from organs and tissues of infected animals. Methods of testing disinfectants occupy the closing pages of the book. The plan of interleaving the latter with blank pages for drawings which the student is expected to make, is to be commended.

2. Professor Long's little book is an outgrowth of the course given to the second-year students. He claims that two years should be given to this subject in all medical colleges. This is really done in some of the New York and other colleges.

The first portion of the book is devoted to simple experiments in elementary chemical physiology, describing and illustrating the apparatus and technique, chapters on carbohydrates, fats, proteids, the blood, bone constituents, saliva, gastric juice, bile; on milk, beef extracts, flour, water, and air, briefly enter into tests and general experimental studies.

The second part deals with urinary analysis. This is especially valuable to the medical practitioner, inasmuch as it is the most recent exposition of the subject, and contains a valuable appendix of test-solutions and tables.

A System of Genito-urinary Diseases, Syphilology, and Dermatology. By Various Authors. Edited by Prince A. Morrow, A.M., M.D., Clinical Professor of Genito-urinary Diseases; formerly Lecturer on Dermatology in the University of the City of New York; Surgeon to Charity Hospital, etc. With illustrations. Vol. III., Dermatology. New York: D. Appleton & Co. 1894.

The third and last volume of this composite product of American work in the field of Dermatology and Syphilology, surpasses in some respects the preceding volumes, which have already received favorable notice in these columns. The list of contributors includes most of the familiar names in matters dermatological, extending alphabetically from Allen to Zeisler, and geographically included within a line drawn from Montreal to New Orleans by the way of Chicago.

If the work consisted in a series of monographs by these authors, written by them to parade each his own pet hobby, it would perhaps make interesting reading for those specially engaged in treating skin diseases; but it would be of little real value to the physician at large. As it is, the editor has selected, with apparent excellent judgment, the man for each particular chapter who was best suited to give a clear, correct, and at times necessarily concise, account of all that is known upon the subject. In this way a practical treatise, for the most part comprehensive enough for a reference compendium, has been produced which most creditably reflects our present knowledge of skin diseases, and while a true exponent of American dermatology of to-day, does not in any way neglect those diseases peculiar to other parts of the world. As the editor tells us in his prefatorial remarks, some forty diseases have been here described which only a few years ago were not to be found in text-books as distinct clinical entities. Especial commendation is due the illustrations, which we must say are, as a rule, decidedly superior to those of the other volumes. There are twenty-seven colored plates, twenty-five half-tones, and over a hundred figures in the text. Some of the new process pictures are very life-like. The editorial work and Dr. Morrow's own article on Leprosy, deserve praise. The publishers have left little to be desired, but we think they might have put on a better binding. We predict for the work a large sale on its merits.

The Horse. Its Varieties and Management in Health and Disease. Revised and enlarged by George Armatage, M.R.C.V.S.; formerly lecturer in the Albert and Glasgow Veterinary Colleges; Author of "The Horse Doctor," "The Cattle Doctor," etc. London and New York: Frederick Warne & Co 1893.

This little work is written in a simple style and contains, aside from the descriptions of disease and therapeutic advice, a rather full chapter on horse-management, hints on purchasing, shoeing, breeding, breaking, etc. Such a large proportion of medical men are of necessity horse owners, that a work devoted to their faithful friends cannot fail to interest.

The book before us will not be found sufficiently scientific for the physician who knows anything at all of the subject, and he will feel, in reading a considerable part of the instructions, that they were written for Englishmen. Still an occasional hint of value can be picked up.

Text-book of Anatomy and Physiology for Nurses. Compiled by Diana Clifford Kimber, Graduate of Bellevue Training School; Assistant Superintendent of New York City Training School, etc. Pp. 268. New York: Macmillan & Co. 1894.

The author informs us that the scheme of this book has been practically worked out in class teaching. She correctly surmises that she has devoted too much space to minute structural anatomy, which courses he defends by her experience in teaching. She claims that nurses

thus taught would be led step by step to a correct grasp of the subject, and would thus be trained to think. We apprehend, however, that the average nurse will fail to reach the author's ideal. Her style clearly indicates that she has well measured the capacity and demands of those for whom it is intended. The mechanical execution of the book is creditable to the publishers.

Transactions of the Medical Society of the State of New York for the Year 1894. Published by the Society. 1894.

Among the most interesting of the contents of this volume of transactions are the discussions—abnormal surgery, diphtheria, and menstruation. There are also a number of single papers that are well worthy of preservation in permanent form.

Clinical Department.

THE USE OF ANTITOXIN IN DIPHTHERIA FOLLOWING SCARLET FEVER.

By W. S. GLEASON, M.D.,

NEWBURGH, N. Y.

At this time, when, as a profession, we are awaiting with interest the effect of the use of antitoxin upon the human subject, I feel that the following results should not go unrecorded:

On the morning of October 5th I was called to see John ——, aged eight, a robust boy, son of vigorous parents. I found upon examination well-marked evidences of scarlet fever; temperature, 104° F.; pulse, 140; upon my evening call, temperature, 105° F.; pulse, 144. The temperature, unless reduced by antipyretics, ranged between 104° and 105° F., with but slight variation between the morning and evening observation.

On the second day of the disease a fibrinous exudate made its appearance on both tonsils and pharynx, with intense tonsillar enlargement, and in spite of thorough pharyngeal disinfection there was great difficulty in swallowing. Gradually the appearance of the exudate changed its appearance, and upon the seventh day from the time of my first call I felt that I had a true diphtheria engrafted upon the scarlatina angina. Starr brings out the fact in his "American Text-book of Diseases of Children." As we have not the means to make cultures in our city, I was not able to verify the presence of the Klebs Loeffler bacilli. The temperature, if unrestricted, remained at 104⅘° F.; pulse, 150; glands of the neck enlarged, and an excoriating nasal discharge was present.

At three o'clock in the afternoon of October 12th I made my first injection of Aronson's serum, using twenty minims, followed by a second injection of forty minims in six hours. With close observation I could not appreciate the least reaction as an immediate result of the injection. Twenty-four hours from the last injection the temperature dropped to 99° F., with a corresponding amelioration of the symptoms. There was an evening rise of temperature to 103° F., but from that time, October 12th, to this date, October 23d, the patient has steadily convalesced, with no decided fluctuation of pulse or temperature. I combatted the scarlatinal conditions with carbolized inunctions to the body, lime-water, and peroxide of hydrogen sprays for throat; and a judicious use of quinine and phenacetine as antipyretics. The diphtheritic manifestations were met with the same spray for throat, and bichloride irrigations, 1 to 1,000, for both throat and nares. Internally, full doses of mecuric bichloride. For forty-eight hours preceding the use of the serum, the heart flagged and required careful stimulation. The fact that within twenty-four hours after the use of the serum such a remarkable change took place proved to me conclusively that the absorption of septic material ceased at once, and produced a reaction not found in such intense conditions.

EXTRA-UTERINE PREGNANCY.

By WILLARD McCHESNEY, M.D.,

JANESVILLE, WIS.

In the following case of extra-uterine pregnancy with retained fœtus, no reference will be made to the literature on the subject, as the investigator can readily refer to it. The case appended presents points sufficiently interesting to merit its publication.

Mrs. Eugene B——, aged forty-two, a resident of Texas, became pregnant, or at least so pronounced by her family physician, in the early spring, 1889. The usual symptoms present in such cases were not lacking,—there was cessation of menstruation, nausea, tenderness of the breasts, enlargement of the abdomen, motion, etc. The husband, from whom the history was obtained, did not know whether fœtal heart sounds had been demonstrated. Mrs. B—— says abdomen continued increasing in size until she had passed the full period of gestation. At the expiration of her period labor did not come on, and for two months following there was a period of complete quiescence. At the commencement of the eleventh month she had pains, quite severe, and the pains were accompanied by a discharge from the genitals of a serosanguinolent character. The pain and discharge continued for nearly three months and gradually ceased. During this time the abdominal enlargement decreased in size, and at the end of the fourteenth month nothing remained but a firm tumor occupying the right iliac fossa. At about this time menstruation was re-established and the patient considered herself in fair health, as there was no inconvenience from the tumor. Shortly after this a consultation was held to decide whether an attempt should be made to remove the tumor by operation. The husband is not clear as to the conclusions arrived at at this time, but the consulting surgeon advised no operative interference. Mrs. B—— informed me that the tumor changed in size, but in view of what was subsequently determined, thinks she was in error.

From dates given above until March, 1894, the health of patient was very good, but during the early days of March she was taken with quite a severe chill, followed by fever; in a few days she had chills coming on irregularly, associated with fever, diarrhœa, and quite severe sweats. There was also some muscular pain somewhat resembling the pain of muscular rheumatism. There was a rapid waste of tissue and strength, and the services of a rectal specialist were called into requisition for the purpose of relieving the patient of a very bad case of hæmorrhoids, the operation to be done without the use of knife, cautery, or ligature (parenthetically, we have no hesitation in saying that they were not used). Regardless of the rectal operation, emaciation was rapidly progressive, diarrhœa continued, and was held in check only slightly by opiates administered by rectal injections and by mouth, and a northern trip was advised, trusting that the change might be beneficial. The trip north was uneventful, and the patient did not suffer materially from the effects of her journey. Shortly after her arrival, however, she became considerably prostrated, and Dr. Q. O. Sutherland, of Janesville, who was called in to see the case, diagnosed it as one of extra-uterine pregnancy, and advised immediate removal to his private hospital, hoping to get her in condition to undergo an operation. A strong effort to build her up proved of no avail, and she died quite suddenly September 20th.

Mr. B—— kindly permitted an autopsy, which was held the following morning. On opening the abdomen the bowels were found to be singularly free from adhesions, and it was at once seen that the right Fallopian tube was the seat of the difficulty. On its posterior surface the tube was adherent throughout to the pelvic peritoneum and the bowel; the anterior surface was free from adhesions. On opening into the tube we found the badly decomposed remains of a fœtus, showing a growth of about seven months. After thoroughly cleansing the foul-smelling cavity, it was found that a free opening existed

between the fœtal sac and bowel, and that the tissues in the vicinity of the bowel were necrotic. It was evident that an operation, to be successful, should have been performed several months previously.

In reviewing the case several points present themselves for our consideration. The principal one to consider is, naturally, the one which questions the ability to have made an early diagnosis. In looking over the case as it presented itself at the hospital, and reviewing its history, it seems hardly possible to have erred in making a diagnosis.

1. We have a clear history of pregnancy in so far as that fact could be determined, and it might have been possible to have detected the fœtal heart-sound, a positive sign.

2. Pains occurring at the eleventh month, with a discharge, decrease in size of the abdomen, and a firm tumor left.

3. The very evident signs of septic infection which first appeared about March 1st, with the previous history, should have been a prominent factor in establishing the diagnosis of extra-uterine pregnancy and decomposition of fœtal remains.

In conclusion, the chances were strongly in favor of recovery had a diagnosis been made sufficiently early to allow an operation, either by laparotomy, or, as suggested by Dr. Sutherland, opening directly into the sac from the vaginal vault, and if cavity was septic, treating it as an ordinary abscess cavity.

LEAD-POISONING AND THE MORPHINE HABIT—REPORT OF A CASE.

By R. ABRAHAMS, M.D.,

VISITING PHYSICIAN TO MOUNT SINAI HOSPITAL, OUTDOOR DEPARTMENT.

Besides the unusual mode of acquiring the morphine habit, and the strange association with it, that of profound lead-intoxication, the history of the case that I am to report contains an additional item which may well interest the physician, his inevitable ally, the druggist, and possibly the public, if it reached their ear.

I presume it is the experience of almost every practitioner to find, at one time or another, his prescriptions repeatedly renewed without his advice or consent, written or oral—whether the prescription orders morphine or rhubarb, cautious use or ordinary care. My object, however, is not to discuss the abnormal relation between the physician and apothecary that such a practice involves, but rather to point out the serious trouble that it may lead to, and there is not a better illustrative case than the following one.

Mrs. K——, aged forty, mother of ten children, the last one still-born, has been in poor health for the last few years; pale, emaciated, and complaining of neuralgic pains at different points of the body; appetite very poor; never felt hungry for meals; bowels moved very irregularly, and colicky pains in the abdomen were of frequent occurrence. On a Friday in the month of July, the day being moderately warm, she was suddenly seized with severe cramps in the abdomen and the legs, incessant vomiting and diarrhœa. Physicians were hastily summoned, a diagnosis of cholera morbus agreed upon, and treatment accordingly instituted. The next morning, as there was no improvement in the patient's condition, I was asked to see her, and the following is what I found: Vomiting and diarrhœa every half-hour; both dejecta were copious, one green, and the other blackish and malodorous; the extremities cold; the face extremely pale, pinched, drawn in, and covered with a cold, clammy perspiration. The abdomen was hard and retracted, very tender around the umbilicus. The tongue was thickly coated and moist; the breath peculiarly offensive. The pulse, much to my surprise, was full and regular, and the rectal temperature a small fraction above the normal. The patient continually moved her hand toward the abdomen. Now, this condition of apparent collapse, with a good pulse and a normal temperature, were, in my mind, hardly compatible with an attack of cholera morbus. The clinical picture rather suggested some form of profound intoxication, which I at once set about to find out. On a second examination of the patient I discovered, much to my satisfaction, a blue line along the gums.

This was a key that unlocked the mystery, and although the source of the lead supply was unknown, the diagnosis, however, was tolerably certain. Later in the day, the patient's husband volunteered the following information: Eight years ago his wife was troubled with hæmorrhoids, for which the physician in attendance prescribed "something." His wife got well, but the curative agent pleased her so much that she continued to take it to that day. He was totally ignorant of the contents of the "box," but he was positive that a failure to supply her with it rendered her unspeakably wretched. By and by, exercising her womanly prudence, she laid aside a good stock of her favorite drug for a rainy day, as it were. She never experienced any difficulty in obtaining it, for she had a copy of her original prescription in about half a dozen shops, where she could get it on the presentation of the old label. In the course of time she became subject to frequent attacks of colic, which, however, always yielded to an extra dose of her medicine.

While narrating this unvarnished tale, he called my attention to a supply of "pain-killers" under her pillow, to which she liberally helped herself during the present illness, but with very little benefit. Now, this favorite panacea was in the shape of a suppository, which, on inquiry, I found to contain a third of a grain of morphine and one-half a grain of acetate of lead. This piece of etiological enlightenment left no doubt as to the real nature of her condition. It is hard to estimate the quantity of lead the patient consumed during the eight years; for, at times, she told me her colic was so acute and the desire for relief so intense that she filled her rectum with suppositories to its utmost capacity, while in the absence of pain she took the suppositories simply to supply her craving for the alkaloid, as the habit was perfectly established. Thus one drug spurred her on to take the other. The poor victim knew that she could not be without the suppository; yet her ignorance of its composition was only exceeded by her passion for it.

The moral and interest of this peculiar case will be enhanced by one more, rather amusing, feature of it. My patient was regarded by many a neighboring woman with pious admiration. Many a pain she relieved, and for all I know, many a woman, through her agency, is now suffering from the effects of lead-poisoning and the morphine habit.

From a pathological standpoint, this case strikes me as being a unique one, for, excepting the anæmia, the emaciation, the colic, the alternate constipation and diarrhœa, the neuralgic pains, and the "lead line," while sufficient to establish a diagnosis of lead-poisoning, none however of the great and marked nervous symptoms were present. In a case of such long standing, one would naturally expect to see some form of paralysis. Although the arterial system showed commencing atheroma and the urine contained slight evidences of renal disturbance, yet the nervous system showed nothing to indicate any lesion whatever.

Whatever form of plumbism this case may be regarded, its chief interest, perhaps, lies in its combined features, and their mode of acquirement.

158 Clinton Street, New York City.

Bogus Degrees in England.—The trade in degrees from non-existent American universities has recently revived in England. These degrees give no rights, but their purchasers have the satisfaction of adding a few more letters after their names. The price charged for an M.D. or LL.D. is £30, and for any other degree wished for, £25.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, October 25, 1894.

MALCOLM MCLEAN, M.D., CHAIRMAN.

Tubal Pregnancy—Rupture, Operation, Death.—DR. CHARLES E. NAMMACK presented a specimen of tubal pregnancy in which rupture had taken place about the forty-third day; slight symptoms of collapse, pain, and hemorrhage manifested themselves; he advised an operation. Three consulting surgeons objected, believing that the hemorrhage was limited by the folds of the broad ligament, but the next morning the patient went into collapse from recurrence of concealed hemorrhage, and then no difference of opinion existed with regard to the propriety of operating. It was too late, however, for the patient did not fully rally, and died fifty-two hours after removal of the blood-clots and ovum per laparotomy. Dr. Nammack said his object in presenting the specimen was to impress the danger of letting extra-tubal pregnancy continue, especially after the first signs of rupture, on the supposition that the pregnancy was extra-peritoneal and that the hemorrhage would be limited. In the many cases operated upon by Dr. Joseph Price not one had been encountered in which the pregnancy was extra-peritoneal. Yet it was the custom of general practitioners, he believed, to rely upon their ability to say whether the hemorrhage was extra peritoneal or intra-peritoneal; if the former, to wait, and in waiting take the great risks of recurrent hemorrhage, peritonitis, septicæmia, and subsequent trouble from a damaged tube.

DR. BOLDT named one justification for temporarily postponing the operation, namely, shock attending the rupture.

DR. J. R. GOFFE thought Dr. Nammack need not go outside of New York to get confirmation of the view that a prompt operation was demanded in cases of ectopic gestation. The most prominent gynecologists in this city had advocated and practised prompt interference for years, among them being Dr. Janvrin, who had taken this position as many as ten years ago.

Point of Origin of an Ovarian Tumor.—Dr. J. R. Goffe presented the sac of an ovarian cyst, on one side of which, for a distance of eight or nine inches, the fimbriated extremity of the Fallopian tube could be seen spread out like a veil. Evidently the small cyst which was the commencement of the tumor had lain directly under the fimbriated extremity of the tube. Part of the other ovary had also undergone cystic degeneration; two-thirds of it were removed; the edges were turned in so that no raw surface would be exposed to form adhesions. The patient was doing well.

Sarcomatous Degeneration of Uterine Fibroids.—Dr. Goffe also presented a uterus with multiple sub-peritoneal fibroids and sarcoma. This and two other cases seen by him recently showed the importance of operating early for uterine fibroids causing symptoms if one would spare the patient malignant disease.

The Chairman, DR. MCLEAN, said he had removed an ovarian tumor weighing over forty pounds, three or four years ago, and finding the fimbriated extremity of the tube spread largely over it, he dissected it off and dropped it back with the rest of the tube. Two years later he had occasion to reopen the abdomen of this patient for another disease, and it was interesting to note that the tube was healthy and had diminished to its normal size.

New Pelvimeter.—DR. HERMAN L. COLLYER presented a new pelvimeter, the blades of which could be taken apart and placed parallel with each other when not in use; which registered in both the English and metric systems; which would give pelvic diameters up to fourteen inches, and which cost but two dollars, or a third to a fifth as much as any other instrument in the market. Cheapness was extremely important in an instrument which every general practitioner should keep, and yet one which he was not likely to use more than a few times during a life practice.

DR. MARX mentioned a case in which the calipers presented by Dr. Collyer measured the external diameters of a very large pelvis, which others at his command had failed to do.

Fœtal Abnormality.—DR. E. A. TUCKER exhibited photographs of a child with a left foot and leg connected apparently by osseous as well as fleshy union with the upper dorsal spine. The foot was perfectly formed, and one could make out what seemed to be leg, knee, and thigh. It was sensitive to touch.

The mother, Irish, twenty-eight years old, addicted to drink, mother of three other children which were born normally, was brought to the hospital for pain in the left side caused by a kick from her husband. The os was somewhat dilated, but real labor did not come on until six days later. The woman was very positive that the abnormality was due to the kick by the husband's left foot, and was in the nature of a punishment for the act. Of course, Dr. Tucker said this notion was absurd, since such a growth must have started long before six days prior to full term, and doubtless had its origin in a blasted ovule which became attached to this fœtus.

When during the labor Dr. Tucker felt the foot between the shoulders, he remarked to those present that there probably would be dislocation of the leg, and was much surprised later when two other feet dropped out. Had the case been a breech presentation, this foot might have caught and caused trouble; or if a shoulder had presented first, there would have been great difficulty in making full diagnosis.

When the waters broke, a small, irregular, soft, whitish mass came away, which Dr. Tucker thought at first was vernix, but on section was found to contain two cysts, and was composed of cells, but the exact nature of the structure was a mystery to Dr. Prudden, Dr. Freeborn, and others who had examined it. There was a small, scar-like protuberance on the heel of the third foot, and the mass was believed to have been attached there.

Extirpation of the Uterus and Adnexa in Pelvic Suppuration and Post-Puerperal Septicæmia.—DR. H. J. BOLDT read a paper with this title. Pelvic suppuration might leave multiple abscesses, it might leave double pyosalpinx, it might leave a mass of inflammatory material enclosing pus—a variety of conditions in which successful treatment often involved operative interference of grave nature. In quite a considerable percentage of the cases in which the uterine appendages had been removed trouble had still persisted, due to the fact that the uterus, the origin of the primary, or seat of the secondary, trouble, had been allowed to remain. The author was led to ask the question, is the uterus of utility to a person with bilateral disease of the tubes and ovaries to such degree that they have to be removed? The answer, he said, must be in the negative. Some operators who entertained this view made it the excuse for always removing the uterus when they opened the abdomen and found double tubo-ovarian disease. But Dr. Boldt had opposed such a course for the reason that often disease in the uterus could be corrected, that abdominal hysterectomy complicated removal of the appendages, and that if it should finally prove necessary to remove the uterus, it could be more safely done through the vagina, and would be unattended by risk of hernia, which was considerable in all abdominal operations. In comparing vaginal with supra-vaginal hysterectomy, the author claimed that the former was not attended by greater risk of subsequent intestinal obstruction, that there was greater traumatism and consequent shock from handling the intestines in the abdominal method, also much greater liability to spread infection, and, as said before, liability to ventral hernia in spite of all precautions.

The author, being an advocate of conservative surgery, advised the abdominal route wherever there was a possibility of being able to save the whole or a part of an ovary. But where it was possible to make a positive diagnosis, which called for removal of the uterus as well as of the adnexa, he advocated the vaginal method, and claimed that by it one could reach the uterus, the appendages, and other diseased structures. An important advantage of the vaginal route was that it gave natural drainage (by gravity), and also that it enabled the patient to return home in a much shorter time. In suppurative cases clamps had usually to be employed instead of sutures, but they could be removed in twenty-four hours, and during that time favored drainage.

Regarding the mortality of the vaginal operation, Dr. Boldt had lost one patient (almost a hopeless case to begin with) out of seven operated upon; 542 in literature gave a mortality of 4 32 per cent., at least 295 of them having been suppurative. He had serious doubts whether one could collect 500 cases of abdominal hysterectomy with a smaller mortality than seven per cent.

In acute general puerperal septicæmia he had washed out the abdomen in four cases, and they died, had removed the uterus in four, and they, too, had died, yet he regarded it as more logical to hope for a favorable termination from vaginal hysterectomy and removal of the tubes than from removal of the tubes alone where the uterus was the original site of infection.

Dr. Von Ramdohr thought that in cases of multiple pelvic abscess in which it had been determined to remove the uterus, the abdominal route should be selected, since some of the foci of infection might escape notice through the vagina. In puerperal cases, also, it was necessary to open the abdomen in order to find all collections of pus.

Dr. Grandin said that if the paper was intended as a plea for removal of septic appendages, he agreed with the writer; but if it was intended as a plea for removal of such appendages through the vagina rather than through the abdomen, he disagreed with him. He believed in seeing as well as feeling what one was about, and it was for this reason that he was opposed to returning to the old method of treating these cases through the vagina, even with the addition of removing the uterus. Extirpation of the cancerous uterus through the vagina might be simple in the hands of an expert, but vaginal hysterectomy in disease of the appendages, with all the possible complications, such as adhesion to the vermiform appendix, etc., might be anything but simple. The danger of hernia in abdominal operations was greatest where up-drainage was practised, but such drainage had been abandoned in favor of passing gauze down through the vagina.

In acute general puerperal peritonitis he had not found the infection limited to the uterus, and consequently it would not have been sufficient only to remove that organ either by the vaginal or abdominal method. There were multiple abscesses scattered throughout the abdomen, and it was by opening these, washing out, and draining under the liver, under the spleen—in other words, resorting to multiple drainage and cleansing, that a Western physician had succeeded in saving one patient.

Dr. Goffe had had under observation six or seven cases operated upon by the method advocated by Dr. Boldt—the Belgian method—and the impression which he had received was that it was a very blind, a very bloody, and unattractive procedure. The abdominal operation was clearer; it enabled one to see what he was doing and should do, and left the way open for either conservative or radical operation, according to the more exact diagnosis made possible by touch and sight.

Dr. W. E. Porter could not agree with the author, particularly in septic disease of the appendages, believing that, in the very cases in which the vaginal method had been advocated, there were the strongest contraindications to its employment. In tubal disease it was impossible, owing to the frequency of extensive adhesions and complications, to make an exact diagnosis and operate with safety without abdominal section. In puerperal cases the simplest operation, one least attended by shock, would give the best results.

Dr. Robert H. Wylie found it difficult to discuss the paper because, he said, it dealt with so many other subjects than those indicated in the title. So far as the mortality rate was concerned in the list of cases of vaginal hysterectomy given by Dr. Boldt, the result had been excellent, but it was not yet possible to speak positively of the remote results, particularly of the occurrence of hernia. It was a long time before we learned of the frequency of ventral hernia following laparotomy, for operators were too much concerned with other points to pay much heed to this accident. Might it not be so with regard to hernia into the vagina following vaginal hysterectomy? In puerperal septicæmia he could not see how the author could distinguish between cases in which the infection was limited to the uterus, and justified removal of that organ through the vagina and cases in which it had passed to the peritoneum, which it might do directly instead of through the tubes. He would, therefore, open the abdomen and then decide what should be done.

Dr. Boldt made some closing remarks. He thought it strange the gentlemen should advocate the abdominal operation when the vaginal had given so much better results, that is, in the cases in which alone he had advocated it.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, October 22, 1894.

Seneca D. Powell, M.D., President, in the Chair.

Officers.—Many of the candidates having withdrawn, there remained but two for president, two for first vice-president, eight for censors (five to be elected), and but one candidate for the other offices. Dr. Egbert H. Grandin was elected *President;* Dr. Richard Van Santvoord, *First Vice-President;* Dr. S. Henry Dessau, *Second Vice-President;* Dr. Charles H. Avery, *Secretary;* Dr. William E. Bullard, *Assistant Secretary;* Dr. John S. Warren, *Treasurer;* Drs. Seneca D. Powell, Charles L. Gibson, George T. Jackson, Edward D. Fisher, and Charles H. Knight, *Censors.*

Report of the Treasurer.—Dr. Warren read his report as treasurer, and it was found correct by the auditing committee. The receipts for the year had been $4,152; adding balance from last year and subtracting disbursements for this year, which amounted to $4,441, left a balance of $2,392.

Report of Committee on Hygiene.—Dr. W. A. Ewing, chairman of the committee, read the report. They had found that some of the dispensaries had acted on their advice and separated children with contagious diseases immediately on entering the dispensary, not allowing them to mix with others in the general waiting-room. Some of the larger dispensaries, however, had not yet adopted this most important regulation for the prevention of spread of disease.

The work of the Board of Health with regard to vaccination and report of contagious diseases among school children, and the management of diphtheria, was commended. Some of the dangers of spreading tuberculosis were mentioned, and it was suggested that in the lower tenements it would be much safer to do away with carpets than to leave them on the floor as dirty as they commonly were.

The Communion Cup, the Court Bible, and Syphilis.—The committee was pleased to report that some churches were dispensing with the single communion cup and were using one for each communicant, thereby avoiding one way of spreading syphilis. In this connection attention was also called to the danger of communicating syphilis by kissing the court Bible, and it was suggested that if this custom were continued the book ought to be covered with a thick layer of iodoform gauze.

The Disposal of Garbage.—The habit of the authorities of allowing ash-cans to stand until overflowing, and then of filling carts beyond their capacity and scattering the ashes and garbage in the streets, was condemned, and the recommendation was made to burn the garbage.

Report of Committee on Ethics.—Dr. W. M. Polk, chairman of the committee, made a verbal report, stating that few complaints had been brought before the committee and these had been settled by the delinquents making prompt amends. Regarding complaints against members for using the daily press in some form for advertising, the committee suggested that they be brought before the Society itself, with the hope that the greater publicity given the matter might have some restraining influence on delinquents of this character.

Dr. Joseph D. Bryant, chairman of the Committee on Prize Essays, stated that no essay had been received.

On Symphyseotomy, with Report of a New Case.—Dr. H. J. Garrigues read the paper. (See p. 577.)

Dr. Egbert H. Grandin was requested to open the discussion. Prior to the rejuvenation of symphyseotomy in 1890 he was exceedingly sceptical. But personal experience with it in two cases in which he had operated, and in three others in which he had assisted, had since proven to him that it was a distinct advance in the obstetric art. He did not believe the profession yet fully realized what symphysetomy meant. It meant that we were no longer called upon to take life in order to save life; to sacrifice the child by embryotomy in order to save the mother.

Too few operations had been done in this country to enable anyone to speak dogmatically upon the position which symphyseotomy was destined to take, for we must judge by what can be accomplished in America, not by what has been done in Europe. He believed, however, that the time was approaching when the general practitioner would have a practical knowledge of pelvimetry and of aseptic surgery, and that then many children would be saved by elective symphyseotomy. If the operation were done aseptically, before the woman and child had become exhausted, there should be no mortality for the mother, and he thought also none for the child.

Dr. H. C. Coe had peformed symphyseotomy three times, twice within the past six weeks, but did not feel quite so enthusiastic about it as the last speaker. Further experience was necessary to enable one to pass an intelligent or final opinion upon it. He had noticed a good deal of difficulty in extracting the head, and there had not been as much gain in the pelvic diameters as he had hoped there would be. With the conjugate under three inches he would perform Cæsarean section, but where it was between three inches and three and a half he thought symphyseotomy should be resorted to, provided the case were seen at the beginning of labor. All of his patients were seen early, pelvic contraction was recognized, everything was favorable, but such conditions were not likely to be present in cases seen in private practice. He had not yet made up his mind as to the best method of extracting the child. The cervix not having been fully dilated there was considerable delay of the head, and one child suffocated. It would seem, therefore, that the forceps might be indicated quite as often as version. Like Dr. Grandin, he expressed preference for the blunt-pointed bistoury over the Galviani knife. He did not believe in working in the dark, but would expose the full front of the symphysis and see what he was doing. The operation in this country was still *sub judice*.

Dr. Charles Jewett agreed with the author's conclusions on most points. Symphyseotomy, compared with Cæsarean section, labored under two disadvantages. The first was the difficulty of determining the size of the child's head and mother's pelvis, which it was not necessary to know in Cæsarean section; the second, related to the first, was the fact that if the pelvis were overestimated the operation would probably prove a failure. There was greater difficulty, too, in the after-care of a case of symphyseotomy than of Cæsarean section. In the former the bones had to be kept in apposition and the wound free from contamination with urine. He agreed with other speakers, that the operation was too recent in this country to justify sweeping statements. One who placed the lower limit of the conjugate diameter at three inches would probably find symphyseotomy a safe operation.

Dr. R. A. Murray thought symphyseotomy could be done safely in private houses as well as in hospitals, but we could not hope for the results which had been obtained abroad until, like there, it came to be performed by those who had had previous experience. He called attention to the increase in the oblique and transverse diameters as well as in the conjugate, which rendered the operation especially suitable for the generally contracted pelvis, which was the deformity oftenest found in this country. He also referred to the larger size of the newly born in this country, the average weight at the City Maternity Hospital being about seven pounds and a half, as against about six pounds in Italy. Of course the larger the child the larger must be the pelvis to justify symphyseotomy instead of Cæsarean section. Do not try to determine the size of the pelvis by one or two fingers; introduce the whole hand.

Dr. Garrigues made some closing remarks. Symphyseotomy had been recommended where the conjugate was only two inches and a fourth, but he thought three inches a safe lower limit in this country, and three and a half sufficiently high, for above that one should be able to extract by version or with forceps.

Correspondence.

APEX CATARRH OR TUBERCULOSIS.

To the Editor of the Medical Record.

Sir: In reply to the very kindly criticism of Dr. H. B. Moore, of Colorado Springs, concerning an article by myself in the issue of September 22d, allow me to call his attention to an article on "Apex Catarrh," in the issue of January 6, 1894. Also to a paper read by Dr. G. R. Butler, of Brooklyn, N. Y., before the Climatological Section of the Congress of American Physicians and Surgeons, in Washington, D. C., May 29, 1894. The title of this paper was "The Methods and Value of Exercise and Diet in the Prophylaxis of Pulmonary Phthisis." The name apex catarrh is said to be objectionable. The name is as unsatisfactory to me as to any one else. In the cases called apex catarrh all the mucous membranes of the body are more or less affected—the gastro-intestinal, as a rule, the most of all. It seems hardly wise to name the disease with reference to the localized bronchitis only. Thus far, however, no better name has been suggested. The term, "the pre-tubercular stage of tuberculosis," has been suggested. If all, or a large proportion of cases of apex catarrh, became tubercular, this term would exactly fill the requirements, but such is not the fact. The great majority of cases of apex catarrh recover within a few months, and only the exceptional case ever develops tuberculosis. On this account I have avoided any name calling attention to a possibility. While it is always possible that a given case may become a localized tuberculosis, most cases look back to their condition of depressed health as a time when they "were a little run down from overwork," "had a stomach trouble," etc.

The conditions of apex catarrh and tuberculosis run into each other. No one can decide when the tubercle bacilli gain a foothold in the tissues depressed in resistance and vitality by a catarrhal inflammation, and the case pass from a pre-tubercular into a tubercular condition. A decision can only be arrived at by watching the course of the disease. I early realized my inability to decide which case would take a bad course (become tubercular) and which one would recover within a few months. An apex catarrh does not arise from an acute

cold in the majority of cases. A small proportion of cases cannot well be explained on any other basis, and yet this question is one concerning which I have much to learn. A very large proportion of cases of apex catarrh present themselves to the physician when suffering from an acute cold, but careful inquiry generally elicits the fact that the patient did not feel well before taking the last cold.

As to the examination of the sputa in such cases. If the patient has no disease of the upper air-passages that occasions cough no sputa can be obtained. In the great majority of cases in which the sputa can be obtained no tubercle bacilli can be found. If they are present then the case is one of tuberculosis and transcends the limits of this discussion.

With the assistance of a competent bacteriologist I pursued this line of examinations for two years, until I satisfied myself that the tubercle bacilli were not to be found in cases of apex catarrh. The sputa was generally taken from well-marked cases. Because nothing was found in such cases I reason that they are not present in cases in which the physical signs are less well marked.

As to the case cited as having died of a "profuse hemorrhage," allow me to say the choice of this case was unfortunate. It is misleading, I confess. The point I especially wished to make is the importance of a chest examination in every case of disease of the ear or upper air-passages. The boy had a mastoid abscess. I suspected chest disease also, as I did not think that the local inflammation necessarily explained his constitutional condition. He had undoubtedly tuberculosis. The consultant was much older than myself, and because he wanted to do so he had ridiculed my ideas as to chest unsparingly. He suggested calomel and rhubarb because of the marked gastro-intestinal disturbance. I thought the chest ought to be examined and creosote given possibly. My suspicion was that he had an apex catarrh, whether it had advanced to a tuberculosis I did not know. Inadvertently the report of this case was not complete enough. I see many cases of apex catarrh. I see only a few cases of tuberculosis comparatively. My suspicions were in the line of the greatest possibility. I see probably a very different class of cases than occurs in Colorado Springs. As a specialist I see the very early cases of chest disease, whether the cases referred to are peculiar to Cleveland is a question. They are probably as frequent in other cities in the same latitude, and of the same elevation. I do not believe that cases of this sort develop in Colorado Springs. If they do, all reports as to the freedom of people living in that locality from disease of the chest is unreliable.

Dr. Moore sees a different class of cases from those I have attempted to describe. He sees the cases that become a localized tuberculosis, the cases that do not recover at home as rapidly as desired, and are sent to a higher altitude. In May, 1894, I looked up the record of the last fifty-four dispensary cases coming under my care, and found that of this number eighteen, had an apex catarrh. No one would believe that these cases had tuberculosis if I took that position. My professional friends have more often claimed that there was nothing at all the matter with the chest, that the patient had a primary disturbance of the stomach, etc. Dr. Moore thinks that I treat these cases too lightly. Clinically the only reasonable explanation of these cases is that they are catarrhal in character. The etiology of tuberculosis used to be very complicated. It seems to me now to be very simple. It is simply a question of "soil and seed." The tubercle bacilli are everywhere. Healthy tissues resist their growth. Tissues or cells weakened in vitality and resistance through inflammation permit of their growth and development.

A catarrhal inflammation attacks the epithelium lining the capillary bronchial tubes or air-cells at the apex of the lung. After a certain stage the tubercle bacilli are permitted to grow. Then we have a tuberculosis. Why the bacilli gain a foothold in such a small proportion of cases is probably explained by the fact that the catarrhal inflammation in the majority of cases close up before the vitality of the cells is greatly interfered with. I fully endorse the doctor's statement as to the frequency of tubercular cases and the frequency with which healed tubercular lesions are found on autopsy. I do not, however, feel very sanguine concerning cases of chest disease in which the tubercle bacilli are found. The great majority of such cases, as I have been hitherto permitted to follow them, have died of tuberculosis. Whether the presence of the tubercle bacilli in the sputa in fair numbers necessarily dooms a patient if he remain in Cleveland I shall not say. I have a very few cases on record who have apparently recovered.

The physical signs in an average case of apex catarrh on percussion are—no dulness, sometimes slight tenderness and slightly increased resistance; on auscultation transferrence of heart-sounds, rough breathing, slightly cog-wheeled breathing, slightly shortened inspiration, may be slight suppression of respiration, or may be transferrence of heart sounds only. I see many a case in which the physical signs are never more marked than this. If, after recovery from this disease the patient should meet death by accident or otherwise, and an autopsy could be made, does anyone believe that a pathologist could find any lesion remaining? I, for one, incline to think that its location even could not be determined. I do not believe such cases are tubercular. Neither do I believe that there is nothing the matter. I believe that the early detection and treatment of such conditions are of the utmost importance, and yet I am accused of minimizing the importance of early chest disease by giving it an innocent name. From Dr. Moore's remarks I infer that he either believes a patient to have a healthy chest or tuberculosis, and recognizes no intermediate stage. I believe that there is an intermediate stage, a pretubercular stage, that in the majority of cases can be diagnosed with the greatest ease. If I am wrong in my reasoning I shall thank any one who will point out to me the error of my way.

Very truly yours,

HOWARD S. STRAIGHT, M.D.

185 EUCLID AVENUE, CLEVELAND, O.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: By allowing a healthy discussion in the columns of your esteemed weekly regarding the question "Is Apex Catarrh Tuberculosis?" you will shed abundant light in minds that are still dark. It goes without saying that a correct understanding of the pathological process underlying the so called "apex catarrh," is of the utmost importance, not alone to the physician's reputation and success, but to his patient's future life and welfare. Study and observation have long made me a disciple of those who maintain that "apex catarrh" is of tubercular origin. And with a view to further strengthen my belief and conviction I have, with the splendid assistance of my friend, Dr. Philip Meirowitz, lately examined the sputa of a dozen patients, all of whom showed the so-called "apex catarrh." The patients were all taken from my clinic (Mt. Sinai Hospital Dispensary) with regard to no special selection whatsoever. In every single case tubercle bacilli were found. The number of them was never any too great, but, on the other hand, they were never entirely absent. In a few cases it was necessary to examine and re examine the same or different specimens in order to demonstrate the presence of bacilli. A little difficulty in attaining this end lies in the fact that in some cases there is no sputa to examine—the cough either being dry or the expectoration being extremely scanty. But this inconvenience is easily removed by resorting to some mild expectorant of one kind or another.

Now, in view of this and abundant higher authority, it seems to me that, if all those who agree with Dr. Howard S. Straight[1] in regarding "apex catarrh" as "a lo-

[1] MEDICAL RECORD, September 22, 1894.

calized capillary bronchitis," sufficiently invoked the microscope, they would certainly not be guilty of such gross pathological blasphemy. And it is exactly in this form of phthisis that the instrument is worth the investment. The difficulty of recognizing incipient phthisis is only exceeded by the importance of the recognition. The great majority of the patients with "apex catarrh," as a rule, do not bear as yet the various tubercular stigmata on their constitution. What brings them to the physician is an annoying cough or blood stained sputum. The cough is sometimes dry, sometimes moist, or attended with considerable expectoration. I have found the following physical signs in every case of tuberculosis of the apex, or "apex catarrh:" 1. Prolonged, harsh, but more frequently tubercular, expiration. 2. A more or less audible sibilant or sonorous râle. 3. Moist or a crepitant râle at the end of inspiration. The tubular breathing is invariably present, the other two come and go. I often heard the tubular breathing extending to some distance below the clavicle. The microscope, when appealed to, invariably confirmed the significance of this trinity of symptoms. At the early invasion of the apex, percussion is not worth trying, especially if the right apex is involved. Only a little while ago a member of my family consulted two physicians about a slight soreness in the chest. One prescribed for a subacute bronchitis, the other volunteered to relieve him of his turbinated bones. On seeing him I suggested a change of climate, for I made out an "apex catarrh." Two days later he was in bed with hæmoptysis—in three days he had nine pulmonary hemorrhages which exsanguinated him almost to the point of death.

Another instance of unrecognized phthisis of the apex: A girl, about eighteen years of age, came to my office with a history of a dry cough of long standing. A week before she consulted a doctor whose name is familiar to a considerable portion of the profession in this city. Her mother was told that the girl had only a slight catarrh of the throat which will pass off in a few days. But it didn't. On examination I found the three mentioned symptoms at her right apex, and somewhat extending a little below the clavicle. On informing the anxious parent that her child had a "touch of consumption" she immediately expressed a desire to consult a professor, a wish that I am always ready to gratify. I referred her to one of our most eminent diagnosticians in town, stating my diagnosis. The following was his usual cautious reply: "The girl evidently has a chronic broncho-pneumonia of the right upper lobe. Whether it is tubercular or not can be known by the examination of the sputum." The sputum has been since examined twice, and each specimen revealed bacilli, though in limited number. I could mention many more such cases of apex catarrh where the real tubercular nature of the catarrh was entirely overlooked. Especially is this statement true in cases of apex catarrh associated with disease of the upper air-passages, for then the impression takes root in the minds of the superficial observer that the same inflammatory process that characterizes the mucous membrane of the nose, pharynx, or larynx, exists in the apex. Dr. Straight states in his paper that with the improvement of the catarrh of the apex the affected upper passages improve. Certainly so! for it is more than an ordinary likelihood that the catarrh of the apex is responsible for the disturbance of the upper passages. The same gentleman states that he derived great benefit from creosote in all such cases. It seems to me that this beneficial effect of creosote on the disease in question should have made him think of tuberculosis. There is no other disease that is so favorably influenced by creosote as pulmonary tuberculosis—not one. This statement is doubly true with regard to incipient phthisis. One has only to see the wonderful improvement of all the symptoms in pthisical dispensary patients, a class of people mostly living in wretched surroundings, to be convinced of the specific action of creosote.

I have dwelt largely on this question, for I think its importance cannot be overrated. It is but proper that we should call things by their legitimate names—and there is a good deal in a name. In the great science of modern medicine a rose cannot smell as sweet by any other name.

R. ABRAHAMS, M.D.

156 CLINTON STREET, NEW YORK, October 22, 1894.

IS MALARIA A WATER-BORNE DISEASE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of September 15, 1894, Dr. W. H. Daly, of Pittsburg, in a long letter, most emphatically asserts that such is the case. He gives his personal experience in the Kankakee swamps, he quotes other medical men who think as he does, and now Dr. Norbury, of Jacksonville, Ill., in his letter of October 6, 1894, endorses Dr. Daly. Well, I venture to slightly disagree with the sweeping claim these gentlemen make that malaria is only contracted by drinking shallow well or surface water. This town has a water works and the water is considered good. Every care is taken to prevent contamination. It is generally used by all who live within the village limits.

Some months ago the western part of the town had a new sewer laid, the streets were opened up, and just as sure did they begin to dig malaria developed along the course of the ditch, while other parts of the town were free. The persons attacked were of all nationalities—Italians, Irish, Germans, Swedes, Negroes, and last but not least, native-born Americans. The water they used was that supplied by the Water Company, and so it went, as the street was opened in the immediate vicinity were the sick to be found. My own little boy, two years old, developed an acute attack. No sewer was laid near my house. He did not get it from or through any water, for what he drank was sterilized. It was not his milk, for that went through the same process. My neighbor dug up a lot back of my place that had not been disturbed for ages, and I firmly believe that turning up the soil caused my child to sicken, as the colored servant girl complained of the well known symptoms a day or two after.

In my practice it is a common occurrence to find nursing infants with well-marked malaria—little things that never drank a drop of water. I saw a woman, sixty-three years old, develop malaria, the old-fashioned kind as they say here, chills and high fever (105° F.), who never had it before in her life, and who has been living in the same house and using the same water for six years. I looked about for a cause, and found that a cellar was being dug next door. Two days afterward I was called to see another member of the same family. These people attributed their sickness to the turning up of the ground, and I certainly agree with them.

Dr. Daly's claim that we take in our malaria on the leaves of turnip-tops, greens, kale, spinach, cabbage, is very far-fetched, if not absurd. These vegetables are not used raw. They are boiled, and if lettuce is used uncooked, the majority of people smother it in vinegar.

I am an unfettered, and I hope an original, observer, although I do not agree with Dr. Daly, and I claim that malaria is not a water-borne disease *"pur et simple,"* and that those old dogmas and text-books are deserving of respect, and were not so far wrong after all. Quinine, et cetera, were useless in my child's case.

He was treated by Dr. Tifft, of this town. Change was recommended by the Doctor, and so we sent him to his mother's native place, Pittsburg, Pa., where he has made a complete recovery, and now drinks the water used there, which certainly is not uncontaminated, and, considering its source, should be fruitful in malaria. Still I believe Pittsburg has but very little of this disease.

As to Dr. Norbury's forty Swedes, why he himself says they were peculiarly susceptible, and from my experience I agree with him, and further, that newly

landed emigrants are specially liable to contract malaria even in New York City. That it may be and is conveyed by water, I admit; but that it is the only way that we can become affected my experience has led me to believe differently.

F. W. DALRYMPLE, M.D.

NEW ROCHELLE, N. Y., October 10, 1894.

THE MARRIAGE OF SYPHILITICS.

A REPLY, WITH EXPLANATIONS, TO THE QUERIES OF DR. BURNSIDE FOSTER IN THE MEDICAL RECORD FOR OCTOBER 6, 1894.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Hypothetical questions in medico legal cases are perhaps justifiable, and are frequently resorted to, but as a rule the answers given are so vague that the meaning is about as clear to the average hearer as a strong infusion of common earth in water.

The three questions propounded by Dr. Foster may not be in any sense hypothetical, but the majority of the readers of the MEDICAL RECORD who have had any experience in the management of cases of syphilis will bear me out in the statement that not one in fifty *can* answer question No. 3 at all, and I will give my reasons later on.

As regards query No. 1. To answer it: that he has seen *any* case at *any* period communicated by a patient under his care, would lead the readers to say that the physician had been derelict in his duty in not impressing so forcibly upon his patient the dangers he so constantly bears about upon his person that he (or she) will not endanger the health of others by exposure.

The first aim, the highest duty of every true physician, is, or at any rate should be, to protect the health of those who are placed, either directly or indirectly, in such a position as to be saved by him from any contagious disease. I believe, through the columns of another journal, in an original article already accepted, I shall show at an early day some arguments, based on a large experience and continuous observation, demanding protection to the innocent from one of the blighting curses of our nineteenth century.

Passing on for the present to query No. 2, and no one among the thousands of readers of the MEDICAL RECORD will appear who cannot, from either personal knowledge or good evidence, furnished in journals and medical textbooks, cite cases almost without limit, where syphilitic men and syphilitic women have been the parents of syphilitic children, either alive or still born, at full term, at all periods after the initial sore, limited only by the menopause in the female or senility in the male. In fact, almost every physician will tell you that it is the rule, almost as certain as that the "day follows the night," that syphilitic female or syphilitic male WILL procreate syphilitic progeny. Admitted that, under proper treatment of the mother during gestation, an *apparently* healthy child may be born; but wait the next generation and see what is the result, as is too often instanced all about us.

No. 3. Any physician, if allowed to cut query No. 3 off where the *query* proper ceases, will, and so every reader of the MEDICAL RECORD will, answer YES.

With the limiting conditions attached to the end of the query proper, as I said at the beginning of this paper, not one in fifty can answer at all. In the first place, our authorities state, and we have all been taught, that we should always say to every syphilitic case which comes under our care, "that TWO years must be devoted to the careful attention of the malady." How many of our readers can keep the case for even two years? How many have had any individual case "constantly under observation" during *four* years?

If any physician has influence enough over the dulled sensibilities and selfish natures of their syphilitic cases to keep them under constant observation for four years, he certainly should have force of nature sufficient to prevent the patient exposing the innocent to the danger of communication by contact, either with original lesion or secondary mucous manifestations; at any time *such* danger may be present, and to carry the influence still further he should not during that *four* years permit the possibility of the syphilitic patient becoming a parent.

To sum up on the queries, I will say: Whether under observation or not a syphilitic can communicate the disease at any time, while either the original lesion or any external or internal mucous lesion is present, in whatever stage and at whatever period; that they do not do so even more than they do, is due to the force with which the true physician impresses the patient with the necessity of absolute *non-contact*. A syphilitic man or a syphilitic woman can, and do, become the parents of syphilitic children at all periods after the initial sore, limited only by the period of ovulation in the woman and the natural results of age in the male.

Plenty of cases are obtainable where four, fourteen, or twenty-four years after the initial chancre, under any and I may say *all* treatments, that syphilitic men and syphilitic women have been the parent or parents of syphilitic children. And the few cases that can be brought forth where syphilitic men or syphilitic women have brought forth *healthy* children, no matter at what period the antisyphilitic treatment has been applied (before or during gestation) with the mother, are misleading, and are but a small percentage of births occurring in the families of parents who have ever suffered from syphilis. And if such, as before stated, *apparently* healthy children be watched to the period of their maturity, you will find weakened bodies, blunted intellects, early decay; and if they happen to be the parents of the third generation the child must come under the Bible declaration and bear the "sins of the parents." Hydrocephalus, basilmeningitis, *scrofula*, *marasm*, idiocy, and the many like *conditions*, are the harvest reaped from past generations. With a brief expression of my ideas in the matter of "the marriage of syphilitics," I will close.

No matter what the treatment, and no matter how *apparently cured*, syphilitics cannot procreate a fully vigorous, healthy, strong, and noble type of manhood. Where is the benefit to accrue to the nation that is populated with weak minded, feeble-bodied humanity? Breeders even of stock select but the BEST with which to increase their herds—why should man, the noblest work of God, do any less? What is the excuse for willingly *permitting* marriage of our syphilitic cases? It is our duty as guardians of the public welfare, and holding the position, as we do, of guardians of the public health, to advise all syphilitics *never* to marry, and use all possible means to prevent their marriage. There is but one argument that can be brought to bear in favor of *permitting* syphilitics to procreate, and that is "That some wealthy man or woman may have children as heirs to their estate." It were far better that the estate have no heir than that the heir must inherit such a physical body as such parentage bestows. Wealth and a weak body are a poor inheritance. Physical and mental strength inherited, and life is sweet.

Professor Richard A. F. Penrose once said to the students of the University of Pennsylvania, in a personal lecture for their welfare: "When the superintendent of a building wishes to rear a structure that shall be an honor to his name, he selects the best materials for its construction. From poisoned syphilitic bodies you cannot raise up sons and daughters that shall be an honor to yourself and a benefit to your race. For God's sake, young men, keep your *building material* first class."

It now becomes our duty to advise everyone the same, and also to prohibit, if possible, by strong arguments and the evidences around us "the marriage of syphilitics," and use every means in our possession to have the *building material* of our patients first-class.

FRANK E. MAINE, M.D.

AUBURN, N. Y., October 26, 1894.

The New York Academy of Medicine and the Constitutional Convention.—The following is the report of the Committee of the New York Academy of Medicine appointed to confer with the Constitutional Convention:

New York, October 6, 1894.

The President and Fellows of the New York Academy of Medicine.

Gentlemen: Your Special Committee appointed to confer with the Constitutional Convention respectfully submits the following report:

After several meetings the Committee decided to avoid all questions which could in any way be imputed to political bias or a desire to push the interests of the profession. Three problems were selected for discussion, and three recommendations made. All are of vital interest to the community. Your Committee appeared before the appropriate Committees of the Convention and recommended the following amendments to the Constitution of the State.

From Art. X., Sec. 1, strike the word "coroners." Into the same article and section introduce the words, "Medical examiners shall be appointed by such County authority as the Legislature shall direct."

We sought the abolishment of the coroner system on the following grounds:

(*a*) There should not be vested in one individual the functions of a scientist and of a judge; but the two should be kept separate and distinct.

(*b*) It is the sole purpose of an inquest to detect crime. That is a judicial function, and the determination of the question "Has a crime been committed and by whom?" rests in the interpretation of facts by judicial inquiry.

(*c*) It is the sole purpose of an examination to determine whether a death be due to violence. The examination should be made by a competent scientist, in order that facts may be obtained for interpretation by a judge.

(*d*) The examiner merely ascertains that the death is one of violence, the judge, that a crime has been committed. There should be no confusion of the two offices and no association in duties.

The confession of weakness in the present system lies in the appointment by coroners of "coroners' physicians." Thus a coroner with judicial powers appoints and controls him who shall furnish the coroner with the data requisite to his conclusions. A judge should be divorced from interest in the premises upon which he bases his opinions. The proposed amendment seeks the appointment of physicians only as examiners, and may be termed "class legislation." But already a "class" has control of examinations, inasmuch as these are held by "coroners' physicians." So, practically, no innovation was sought. The provision of a proper judiciary for acting upon the findings of the examiners we left to the Legislature.

(*e*) It is our belief that the coroner fails too often to detect crime, does not adequately protect the innocent because of that failure, and that the present system is open to abuse.

The Convention has agreed to submit to the people an amendment striking out of the Constitution all reference to coroners; but it refused to substitute any other system for the present abominable one. This will leave the law governing coroners upon the statute books. If the amendment is approved, the office of coroner merely ceases to be a constitutional office. Something will have been gained when the amendment is adopted.

The second recommendation by your Committee related to the Regents of the University. Amend Article IV. by the addition of a Section with these or similar words: "The Regents of the University shall consist of such persons as the Legislature shall direct. The Regents of the University shall have the sole power to grant licenses to practise medicine and surgery, and shall perform such other acts as the Legislature may direct. The Regents of the University hereafter appointed shall each serve ten years."

The Legislature has already conferred upon the Regents the sole power to grant these licenses. Therefore, here again, no innovation was sought. But this power has been placed in the hands of Regents appointed for life. Herein lies a possible abuse of power. We, therefore, asked that each subsequent appointee should serve but ten years. Inasmuch as reappointments could be made, efficient officers could be retained in office, and the limited tenure of office would preserve the people against the work of a mischievous clique in the Regents. No fault may now be found with the work of the Regents, but we must all confess the possibility of a bad element getting control. Should such a thing happen, death alone could put a stop to it. We would call your attention to the fact that the Regents are the only officers under the proposed Constitution who hold a life tenure of office.

For many years the medical profession has striven to elevate the standard of medical education in the State, and to have set some one standard of excellence to which all those seeking licenses shall attain. In these labors you have been conspicuous. Even though the Regents become constitutional officers, nothing will prevent thwarted incompetency and unsatisfied greed getting the existing beneficent and protecting law annulled. The profession must be as unceasingly alert as before, lest the Legislature be induced, unwittingly perphaps, to legislate unfavorably for the interests of the people. The interests of the community demand that a law so materially affecting the well-being of all be removed from the possibility of too frequent change in this vital feature. Unless their tenure of office be limited the incorporation of the Regents into the Constitution will be a menace to the best interests of medical education in the State, and for the reasons pointed out. Merely making them constitutional officers does not insure to them the permanent and sole right to grant medical licenses, and does not make them answerable to any authority for misconduct. It is altogether a bad amendment. We will have to fight for all we have gained in the past, and a new issue is introduced, in that we will be compelled to watch carefully lest evil men be made Regents.

Our last recommendation related to the great Department of Public Charities and Correction, of which so many of you are officers.

Amend Article X. to read:

Section 1.—"Sheriffs, Clerks of Counties, including the register and clerk of the city and county of New York, district attorneys, and in the counties of Kings and New York, one commissioner of prisons and one commissioner of charities shall be chosen by the electors of the respective counties, once in every three years, and as often as vacancies shall happen."

We submit a brief for our reason for requesting that the Department of Public Charities and Correction be made into two county offices:

1. The condition in the counties of New York and Kings does not exist elsewhere in the State, inasmuch as the cities of New York and Brooklyn are in themselves

the counties named. There is, therefore, no reason why those city offices should not be made county offices.

2. It is manifestly preferable that where a city is a county, in all important city and county offices the power of removal should lie with the Governor.

3. As the present commission is composed of a number of individuals, it is difficult to punish any one of the commission for incompetency, the responsibility being divided. The removing power is at the same time the appointing. The present system is cumbersome, and fails, in that more than one must consent to the performance of each single act, thus retarding the business of the department over which the commission presides. Or else power must be delegated to one commissioner in order that work may be efficiently and speedily performed. This latter, in fact, is the method these many-headed commissions adopt. If delegated power to one commissioner be sufficiently effective, why a plurality of factors?

4. The proposed addition to the Constitution deals with two great classes of the community: those who merit punishment at the people's hands, and those who are their wards. A certain system is requisite for the execution of punitive and correctionary laws, another for the gratification of the people's charitable impulses.

Prisoners require for their management a system far different from and a genius almost opposite to that essential to the proper conduct of hospitals and asylums. Inasmuch as the cities of Brooklyn and New York are the Counties of Kings and New York, and as a very large percentage of the population of the Counties of Kings and New York become inmates of their correctionary and charitable institutions during the year, the importance of embodying a suitable article in the Constitution relative to the commissioner of prisons and the commissioner of charities is apparent. As before said, these cities are unique in being counties. The management of these vast armies of criminals, paupers, insane, and sick, by one commission, with two distinct and dissimilar systems, is not consistent with the best results.

It is questionable if the numerous "Boards of Visitors," "Aid Societies," and "State Visiting Societies," etc., etc., could have originated, if satisfactory management marked these departments.

5. Not alone the State, but the country as well, has been shocked by the results of the recent investigation by the State Commission in Lunacy.

The fault lies in the entirely wrong association of two absolutely opposed systems under one commission.

6. The one great argument used by those who advocate this association is that two commissions would greatly increase the *per capita* cost of maintaining the sick and needy, inasmuch as much of the unskilled work about asylums and hospitals is done by criminals. This contingency could easily be met by a system of requisitions by one commissioner upon the other, a system now practically employed.

7. It is a matter of *common rumor*, as well as a demonstrated fact, that the present system is a failure.

We therefore request that these two commissions be made county offices under the Constitution, and thus removed from insecure and imperfect legislation in one most important particular.

This amendment was refused us. So many more important questions were before the Convention that the dominant party feared to load these down with others which might enlist enemies against their recommendations to the people. We suggest to you that in the future there be appointed each year a Committee whose duty it shall be to watch legislation, and to make to the Legislature such recommendations as you wish to become laws.

The fate of the proposed amendments none can foretell. Should those in which we are so interested be accepted by the people, we will still have to continue urging certain changes in the laws.

The regents should serve for such time as will protect us, while giving us the most efficient work. Sufficient medical examiners should be appointed by the proper county authority. There should also be one judge, well salaried, a man skilled in jurisprudence, whose sole function shall be to determine whether deaths are due to criminal violence. He would have to report to the district attorney's office. Such a man could do all the work now performed by the number of coroners. Some provision should be made for the regulation of the practice of midwifery. The injustice at present is in compelling an obstetrician to pass a certain examination before the regents, while a small fee confers almost equal rights upon a woman, without any inquiry as to fitness. If license to practise midwifery were conferred upon the competent only, we believe that the death rate would be lowered, and one very great cause for diseases of women appreciably removed.

We would also call to your attention the fact that by law a medical man is debarred from being president of the Board of Health, a most unjust discrimination against the very class of men from whom such officer should be chosen.

Your committee was courteously received and granted all hearings requested. Taking into consideration the dislike which the legislator has to the scientist meddling in law-making, we have been fairly successful. We desire to express to you our appreciation of the honor you have conferred upon us, and beg that wherein we have failed of complete success will be overlooked in the earnestness of our efforts. Respectfully,

WILLIAM R. PRYOR, M.D., *Secretary*.

The Action of Sunlight on Micro-organisms.—The following correspondence has been sent us for publication:

RAPIDS P. O., LA., October 15, 1894.

SURGEON GENERAL U. S. A.

DEAR SIR: I have discovered that the rays of the sun are a disinfectant and antiseptic. At 110° to 120° F. they will arrest decomposition and destroy microbes. I have directed them on old and new sores on man and beast, and in an incredibly short time a sun-bath will destroy corrupt matter and leave a bad sore in a healthy condition that will heal up in a short time. For instance, two bad boils on the same person, one treated with washes, poultices, etc., taking a month or more for perfect healing, the other in less than one hour's exposure to the sun's rays, cleansed and healthy and healing in a few days. These, with a number of other tests, lead me to the belief that it will become a successful treatment for sores, ulcers, etc., of recent and long standing, especially in hospital practice.

I have called the attention of our local physicians, who tell me the treatment is not known to the profession, to their knowledge. I am not a physician, but made the discovery in the course of butchering animals for market, the particulars of which and subsequent tests I will send if deemed of any importance; if proving to be, I want it given to the medical profession at large. Not knowing just how to reach them I concluded to write to the Medical Department, United States, which could make such tests as would prove its efficiency. Mine were made with the direct rays of the sun on days when the thermometer ranged 96° to 98° F. in the shade. I have given much thought as to how, in a northern latitude and cooler weather, the rays could be directed through a lens made for the purpose. Also have made the treatment on other ailments besides sores, and the results prove to me that it will become one more of nature's remedial agencies in curing and helping many ailments to which the human race is subject. This may be known already to the profession, but so far as I am concerned it is original, and came about as the result of some things to which my attention was called.

Hoping my motives may be understood in this communication, I am,

Yours respectfully,

JAMES T. DEZENDORF.

War Department, Surgeon-General's Office,
Washington, October 18, 1894.

Dear Sir: I have read your letter of October 15th with interest. Very numerous experiments have been made during the last few years with reference to the action of light upon various microbes, and it is well settled that the direct rays of the sun very promptly destroy the vitality of many disease-germs. Some observations have also been made with reference to the therapeutic use of sunlight, and it is certainly desirable, in view of the facts already known, that further clinical experiments should be made in this direction. Your own observations are of great interest, and the spirit in which you communicate them is highly commendable. If you authorize me to do so I will publish your letter, and my reply to it, in some medical journal.

Very truly yours,
George M. Sternberg,
Surgeon-General U. S. A.

Mr. James F. Dezendorf, Rapids Post Office, La.

A Model Surgical Clinic.—Scene, a spacious room. At a large table in the centre is seated the surgeon; his secretary is opposite, an enormous folio register open before him. A group of students is clustered about the table. Benches filled with waiting patients occupy the sides of the room. The secretary calls No. 120,736. A man aided by crutch and cane limps forward. The surgeon's examination into the biography and genealogy of the patient (four folio pages carefully written out by the secretary) being ended, the attendant removes the multiple wrappings of the right foot, exposing an inflamed great toe with ulceration upon one side of the nail. The surgeon gives it a hasty glance, and turning, addresses the students as follows: "Gentlemen, a few years ago a case of this kind—evidently an ingrowing nail—would have been at once submitted to local treatment, and, I admit, with fair prospects of obtaining a good result. But now that we have learned the general interdependence of the different organs of the body, we feel that a thoroughly scientific treatment demands the examination by specialists of these different organs, in order to detect any conditions likely to be etiological factors in the case. The attendant will therefore take him and a copy of his history to the different rooms in succession, and return here with their respective official reports."

(*Some Hours Later.*)

Surgeon (*loquitur*).—"Gentlemen, the patient has now returned to us, and I ask your attention while I read the reports of the various specialists."

Ophthalmological Department.—Case No. 120,736. This patient is myopic. As I recall a case where a similar visual defect was the cause of injury to the great toe in a person who "stubbed" it against the curbstone, I have ordered appropriate lenses to correct the difficulty, as a prophylactic against the recurrence of the disease. It is essential, however, that this treatment should be supplemented by wearing a loosely-fitting shoe.

Otological Department.—Case No. 120,736. I find no defect of audition. As the patient's trouble may have arisen from want of suitable support to the foot, I have thought it best to shorten the stapes leather two holes.

Rhinological Department.—Case No. 120,736. A case of nasal toe nail. Wishing to bring about a radical change in the parts, I have removed with the curette all adenoid growths, together with the adherent mucous membrane, from the cavities and packed them all with aseptic gauze—which should be removed if the patient wishes to sneeze.

Department Abdominal Surgery.—Case No. 120,736. Drs. A——, B——, and C——, in consultation. The history showing that the patient's mother during life lost a set of false teeth, Dr. A—— reasoning that "tooth and nail" are generally associated in action, is inclined to think the set may have been swallowed unconsciously and remained in the patient's stomach. Of course, he advises an operation.

Dr. B——, in view of the accepted belief that "Gallia est omnis divisa in partes tres," thinks it possible that one of them may have wandered down to the great toe, and advises an exploratory incision of the gall-bladder to ascertain if either part be missing. The "Gallic boot of love," cited by Dr. O. W. Holmes, seems to indicate a tendency of the gall to the foot.

Dr. C—— concurs entirely with both of these opinions, but on general grounds advises the removal of the appendix. The patient, however, avers that this has been already done, and that he has it in a bottle at home, which he will fetch if required. It is therefore deemed advisable to await further development.

Gynecological Department.—Case No. 120,736. Palpation reveals no abnormal condition of uterus or appendages. A medical student calling our attention to the fact that the patient wears pants and has well developed male generative organs, we doubt if this is a proper case for this department.

Department Genito-urinary Diseases.—Case No. 120,736. Organs apparently healthy. It, however, is not impossible that the patient may have had a stone (vesical) which was passed naturally and impinged upon and injured the great toe.

Department of Neuroses, etc.—Case No. 120,736. The result of a careful examination of this case indicates a deficient innervation of his lower extremities. Two well-marked areas of impaired sensibility or partial anæsthesia are located in the gluteal regions beneath the tuberosities of the ischia. His history not mentioning this, we questioned him as to how long the condition had existed. His replies were unsatisfactory—merely to this effect, that he had "sat so long upon those d——d hard benches that his —— got numb." A rubber cushion with two holes is recommended, and the case should be kept under observation.

"There, gentlemen," continued the surgeon, as he finished reading to them the reports, "you have the result of a careful scientific inquiry into this case. I shall now send the patient to the chiropodist around the corner, with instructions to have the toe cleansed and a piece of sheet lead inserted under the roughened edge of the nail. I counsel you all not to lose the opportunity of witnessing the operation. Good-morning, gentlemen!"—*Boston Medical and Surgical Journal.*

An Outbreak of Cholera.—The United States Consul at Sivas, Turkey, reports some interesting facts about the outbreak of cholera in that city. The city is about five thousand feet above sea-level, nevertheless the river which supplies the city with water became polluted with cholera dejections at a village about a mile above Sivas. The water which the people drink and use for all purposes about the house flows in open ditches, where the people also bathe and wash their soiled clothing and rugs. That which has served one family for its various needs flows with all its filth to another. Ultimately the water reaches the open sewers, or larger streams, which traverse the city and which receive all the excreta of the population. In these larger streams the people bathe, wash their clothes and kitchen utensils, the children wade and play. During the epidemic this went on as usual. This is just one of the myriad examples illustrating the spread of cholera by an infected water-supply; but note that, in spite of the fact that the whole population drank an infected water without boiling or other precaution, the consul reports that only twelve per cent. of the population contracted the disease, and only one quarter of these died. This indicates that a majority of the people were not susceptible to the infection.—*The Sanitary Inspector.*

Antidote to Snake-bite.—Dr. Mueller, of Australia, claims that strychnine is a certain antidote to serpent venom. The Indian Government has recently had a series of experiments conducted with a view to test its efficacy. The results thus far have not been entirely satisfactory, but the experiments are to be continued for two years more before a final judgment will be passed.

THE TREATMENT OF DIPHTHERIA WITH ANTITOXIN.[1]

BASED UPON A SERIES OF CASES TREATED AT WILLARD PARKER HOSPITAL WITH "ANTITOXIN SCHERING."

BY A. CAMPBELL WHITE, M.D.,

RESIDENT PHYSICIAN WILLARD PARKER HOSPITAL, NEW YORK.

HISTORY and experience tell us the most dreaded of all enemies of man are the infectious diseases. However benign the disease or mild the epidemic it always leaves some mark of devastation in its path; but one consoling feature of these so much feared diseases is the immunity granted by one attack against future invasion. This power of immunity seems to have been long recognized, for some centuries ago in India and China self inoculation was practised with virus obtained from the pustules of small-pox occurring in a mild epidemic; thus suffering a mild form of the disease protection was granted during future and more fatal epidemics. We have the authenticated report of Lady Montague, of England, as early as 1717, inoculating successfully her own son with small pox.

Although this practice was carried out to considerable extent for many years, it finally became very unpopular on account of its consequent dangers, many of those inoculated unfortunately developing the disease in its most fatal form. The first really practical application of this point of immunity was made by Jenner in 1798. We all know the history of his valuable discovery of vaccination against small pox, and how it has rendered that once most common and formidable scourge the least prevalent and least to be feared of all the infectious diseases.

From this time to the present most constant efforts have been made toward accomplishing similar results in the other infectious diseases, and the rapid advancement made in the field of bacteriology during recent years has rendered great assistance to a more intelligent and practical knowledge of this power of immunity.

Bacteriology was probably first successfully applied in this direction by Pasteur in the results obtained through his experiments upon immunization against certain animal diseases. He obtained immunity against anthrax and fowl cholera by the inoculation of weakened or attenuated bacilli. Still later we have the same method applied to hydrophobia, cholera, and diphtheria with more or less salutary results.

This entire work is based upon the principle that cultures of the most virulent bacilli can be made less and less virulent, until finally they are capable of producing only the mildest form of disease when injected into the living organism. But however carefully this process of attenuation has been carried out, however confident the experimenter may be that the virulence of the bacilli has been reduced to a minimum, there always must be some danger attending the inoculation of a human being with a medium containing the poison of perhaps the most fatal disease. To be successful some reaction must follow the injection. That this reaction may be greater and more pronounced than is desired or safe must always impress the operator and render the method less popular perhaps than is deserved.

[1] Read before the Pediatric Section of the New York Academy of Medicine, and contained in a report made to the Board of Health of New York City, November 7, 1894.

Recognizing this danger, others have labored in another direction, *i.e.*, to obtain the same power of immunity without using the disease poison itself. It has been found that the blood of animals rendered immune is capable, when inoculated in suspectible animals, of granting them the same immunity possessed by the animal from which the blood was obtained. This method is followed by no reaction. Whether the serum thus obtained acts directly upon the germ or its toxin, or whether it causes some reaction in the cellular tissues of the body rendering them proof against the germ or its toxin, is still a question of some dispute.

Buchner,[1] Tizzoni and Cattani[2] have carried out experiments on the antitoxin of diphtheria and tetanus which tend to show that the latter theory is the correct one. Still I believe this theory is not universally accepted. Whatever its action, this inoculation of the serum obtained from an artificially immunized animal is preferable to the attenuated bacilli method. The points in which the former differ from the latter make the serum method the safer and more practical of the two. The differences as described by Aronson[3] are—(1) the effect of the serum method takes place at once; (2) is accompanied by no reaction; (3) by increasing the amount of serum (antitoxin) protection against infection of any strength may be afforded.

This describes rather incompletely the two methods of bacterio therapy, and it is upon the second, or serum method, that the treatment of diphtheria with antitoxin is based; and to Behring, working in the Berlin Institute for contagious diseases, is due, more than to any other, its discovery and development. He found that not only could he grant immunity to an animal, but by giving larger doses of the serum of an immunized animal an attack of diphtheria already artificially developed could be modified or aborted. The method of obtaining this serum, as invented by Behring and modified by others, we will consider as briefly as possible.

First, a pure culture of diphtheria bacilli must be obtained. It has been found that the more virulent the bacilli, at least after some immunity has been established, the better the results which will follow. Aronson[4] claims that the strength and efficacy of his antitoxin depends chiefly upon this point, and describes an elaborate method by which the virulence of the bacillus can be made fifty to two hundred times stronger than fresh cultures from the most malignant cases. The extremely poisonous culture having been prepared, and its strength having been accurately determined, it is injected into the animal which is to furnish the serum, beginning with very small doses, which are gradually increased until the most powerful poison can be resisted by the animal. It requires many months to obtain such an immunity, and the constant liability to the loss of animals from an overdose of the toxine is very great. Animals are selected which have some susceptibility, but of course must not too readily succumb to the poison. The guinea-pig, dog, goat, sheep, cow, and horse have all been used. The horse, being less susceptible and furnishing more anti-toxin, is used by Aronson,[5] Roux, and Yersin,[6] and I believe more recently by Behring. The animal when

[5] Deutsche Medicinische Wochenschrift, No. 19, 1894.
[6] Annals de l'Institut Pasteur, No. 9, 1894.

it has developed a high degree of immunity is ready to furnish antitoxin. The blood is obtained from the larger veins in the body, the animal first having been put under the influence of morphine or an anæsthetic. The serum is separated from the blood, and in this serum is contained the antitoxin. It may be mentioned that efforts have been made with some success to still further isolate this antitoxin property or to obtain it in a more concentrated form.[1]

Of course the serum coming from different animals, or from the same animal at different times, necessarily varies in strength, and to be used therapeutically some idea of its antitoxin power must be obtained. Ehrlich[2] describes a method employed by Behring for ascertaining (relatively) the amount of antitoxin in the blood-serum. This same method, with perhaps some slight modification, is used by all others.[3] He first determines the strength of his test-poison, *i.e.*, how much of this poison is required to kill a guinea-pig of a given weight in thirty six to forty-eight hours. He then takes of the test poison ten times the necessary dose to kill the animal, and puts this amount in each one of several test-tubes, together with different amounts of the serum to be tested. Salt-water is added in sufficient quantities to make all of the same bulk. The contents of these tubes are injected into as many animals. The reaction following the different injections determines the power of the solution tested, *i.e.*, the quantity of blood serum necessary to neutralize the poison (save the animal) varies according to the degree of antitoxin it contains. The strength of the solution is expressed by giving the amount of serum required to save an animal of a given weight inoculated with a fixed poison, *e.g.*, if it requires 0.001 c.c. of the serum to neutralize sufficient poison to kill an animal weighing 300 gr., the strength of the serum is as 1,000 c.c. is to 300 gr., or 1 part of antitoxin to 300,000 parts of body-weight. This can be expressed by simply saying the serum is a 1 to 300,000 antitoxin solution. With the addition of a small amount of trikresol to preserve it against decomposition, the serum is ready for therapeutic purposes.

In appearance the solution of Behring and the "immunization solution" of Aronson are alike. They look like diluted blood-serum. But the strong solution of Aronson has the appearance and consistency of dirty milk.

I have now attempted to describe the bacterio-therapy of antitoxin, the process of its development, the methods for determining its dose, and its appearance; but before considering this remedy clinically I wish to call your attention to some of the more important clinical features of the disease we are to treat.

In considering the results of any treatment for diphtheria the age of the patients upon whom the trial is made is always of vital importance in ascertaining its value. Any one who has had extensive association with diphtheria, at least in this city, and more especially perhaps in hospital practice, must have been impressed with the low mortality among adults. Even those suffering the disease in its severest form generally get well. In one hundred and eighty-eight cases of diphtheria, over sixteen years of age, treated at the hospital the mortality was less than three per cent. The mortality in diphtheria of children between five and sixteen years, although much higher than in adults, is still surprisingly low for a disease commonly considered so fatal. At this hospital the past year the mortality among children of this age has been 13.6 per cent.; in 1893, twenty-two per cent.; and in 1892, 11.7 per cent.

Diphtheria, therefore, as far as mortality is concerned, is essentially a children's disease, and it is among children under five years of age the disease causes such appalling disaster. The mortality in five hundred and six children, under five years, treated in the hospital for the past two years, has been 42.7 per cent. Therefore any treatment for diphtheria should be directed against the disease as it occurs in young children in order to thoroughly test its efficacy.

It has always been noticed, and is mentioned in nearly every treatise on diphtheria, that the mortality is higher during certain months in the year, *e.g.*, the highest mortality in the hospital during the last year was in the months of February, December, and August, and the lowest in September, June, and July. The difference in mortality between September, the lowest month, and February, the highest, was twenty-six per cent.

That some epidemics of diphtheria are more severe than others hardly needs to be mentioned. That bacilli vary in virulence we have mentioned before, and this has been established beyond a doubt by the researches of Brieger and Frankel,[1] Roux and Yersin,[2] Aronson,[3] and others. So we see the severity of the epidemic and the difference in virulence of bacilli in different cases of the same epidemic must also be considered when discussing the value of any new treatment. Where diphtheria is the true cause of death, *i.e.*, where death is due to the toxin generated by the Klebs Loeffler bacillus, the patient generally dies at some time during the first ten days from toxic infection, extension of membrane into larynx and bronchi, or occasionally as early as this a patient apparently doing well will die from sudden heart failure or paralysis. In those patients who die later than the tenth day death is generally due to pneumonia or paralysis, rarely nephritis, while in some rare instances the septic condition will persist for some time after the membrane has disappeared, finally causing death. In 170 fatal cases coming under our observation the past year 135 occurred within five days after admission to the hospital, 17 within ten days, and 18 after the tenth day. Of the 18 cases 9 died of heart-failure or paralysis, 2 of septic infection, 1 of meningitis, and 6 of pneumonia, twenty days after admission. Excluding the 9 cases of heart-failure and the 2 of septic infection, all the cases in whom diphtheria toxin was the cause of death died within the first ten days after admission, or the first thirteen days of the disease (the average day of admission in these cases being the third day of their sickness). Ninety per cent. of the cases died within the first eight days of the disease. Thus, taking all these facts into consideration, a remedy for diphtheria which will prolong the life of the patient beyond the thirteenth day will carry him beyond almost all danger of death and can truly be called a specific.

In studying still further these cases which die from diphtheria toxin, we find the mortality almost entirely confined to those patients who have false membrane, not on the tonsils and pharynx only, but added to this diphtheria of the posterior nares or of the larynx. Those cases which do not have false membrane in the nose or larynx generally recover, and a specific remedy tried on them could give no reliable results.

The proper treatment of diphtheria undoubtedly lowers the mortality, and without proper treatment and attention we believe every case of diphtheria affecting the nose and throat and larynx would die. The mortality of all cases treated at the hospital during the past two years has been between twenty-eight and twenty-nine per cent., and the treatment pursued in these cases we cannot but believe has had more than a little influence in maintaining so low a percentage of deaths. The essentials of the treatment pursued in these cases are as follows: 1. Absolute rest in bed in recumbent position. 2. Fluid diet. 3. The room kept at an even and rather high temperature (75° to 80° F.). 4. Thorough, frequent, and complete washing of the nasal and throat cavities with a normal salt solution. 5. Tincture of the chloride of iron in large doses. 6. Stimulation and catharsis as indicated. In addition to this treatment we have depended almost entirely in the laryngeal cases upon

calomel sublimations and moist heat applied externally, with operative interference when necessary.

That this treatment faithfully carried out and intelligently performed will prevent, in the majority of cases, extension of membrane, and in all cases the development of laryngeal stenosis, is evidenced by the small number of patients who suffer extension of membrane after entrance, and the extremely rare event of a case of stenosis appearing after admission. I only know of three cases developing stenosis after entrance, and in every one there was an undoubted history of exposure to a draught from an open window. Nevertheless, in opposition to all our efforts with this method of treatment, for which we claim so much, there still confronts us a class of cases that furnishes a frightful mortality, and makes diphtheria the most fatal of all the infectious diseases with which we come in contact. The cases we refer to are always dangerous at any season of the year or in any epidemic, however mild that epidemic may be, and it is from this class of patients we have selected the cases for the antitoxin treatment.

The serum used in our cases is made by Aronson, and was kindly furnished to us by Schering & Glatz, the agents for Aronson's antitoxin in this country. This solution was several times stronger than that first and last sent over by Aronson, called the "immunization solution," which corresponds to Behring's "normal antitoxin." Diphtheria poison sufficient to kill control animals weighing from 300 to 400 gr. in thirty eight to forty-six hours is completely neutralized by .00025 c.c. to .00033 c.c. of the stronger or concentrated solution. The age of the patient, the duration of the disease, and the severity of the case, must all be taken into consideration in determining the dose to be given. The injections were made under all aseptic precaution, and in no case was there any sign of local inflammation following the injection. Instead of injecting the entire quantity in one place we selected several locations, the interscapular region and the buttocks.

The following table shows the general results obtained, the amount of antitoxin injected, and, as far as possible, describes the local condition of the different cases:

Day of Disease on which Patient first came under Treatment.	Number of Patients.	Average Age in Years.	Number of Cases in which Nares, Tonsils, and Pharynx were involved.	Number of Cases in which Tonsils or Pharynx were involved together with Larynx.	Number of Cases in which Tonsils, Pharynx, Nares, and Larynx were all involved.	Number of Injections of Antitoxin.	Average Amount of Antitoxin per Patient.	Rash following Injection.	Intubation.	Tracheotomy.	Albuminuria.	Paralysis.	Number of Deaths.	Mortality.

* One of these case was undoubtedly true scarlatina, and another was diagnosed as a doubtful case of measles. In the third case the rash disappeared in a few hours without further symptoms.

† Totals.

This tabulation shows 14 were laryngeal cases, with additional membrane on throat or nose. Five of the cases were operated upon; 4 intubated, and 1 tracheotomized. Of these 14 cases, 1 intubation case, three years old, died on the twenty-fourth day with lobar pneumonia. The bacilli were absent in this case seven days before death, and at one time we had considered the child recovered. The tracheotomy case, two years old, died on the thirty-fourth day with broncho-pneumonia. In this case there was a history of exposure to cold four days before death, and the bacilli had been absent some time. Two cases not operated upon died: One a girl, six years old (the only case treated over five years old), died from sudden heart-failure on the twelfth day. On this patient treatment was not begun until the fifth day, and at that time the child was in a terrible condition—skin moist and cold, color bad, stenosis quite well marked, membrane on tonsils, uvula, pharynx, and nares, diffuse swelling of glands in the neck, temperature a little below normal, and pulse, 114, and weak. Could hardly expect child to live twelve hours. Stimulants were given, irrigated once, and 12 c.c. of antitoxin injected in four places. Twelve hours later the improvement in general condition was marked; in fact, the rapid improvement in this case was more noticeable than in any of the others. The child continued doing remarkably well for six days, when we considered her practically out of danger. But on the following day the child suddenly went into syncope and died three hours later, stimulants and restoratives being of no avail. A slight paralysis of the soft palate was noticed the day before death, and the membrane at this time had entirely disappeared. We regret that a larger or repeated dose of antitoxin was not given in this case. The other death was from pneumonia, in a child two years old, all signs of membrane having disappeared twenty days before death.

Of the six cases which had no laryngeal complication, but which had membrane on tonsils and pharynx and in the posterior nares, only one died. This child, five years old, developed a bad scarlatina, and died fifteen days after beginning of his diphtheria and five days after beginning of his scarlatina. The membrane had disappeared on the tenth day, and the child at this time was in excellent condition. During the course of treatment large plugs of membrane were removed from the nose. The case received 20 c.c. of antitoxin, the largest amount given to any one patient.

Theoretically, the antitoxin could only have prevented one of these five deaths, the child who died with sudden diphtheritic paralysis of the heart on the twelfth day of the disease, for in none of the other four cases was death due to the diphtheria toxin. Then, excluding these four cases, we have one death in sixteen, or a mortality of 6.2 per cent. in cases, the average age being three years, selected on account of their severity. Including all deaths the laryngeal cases showed a mortality of 28.5 per cent. as opposed to the regular mortality of over 50 per cent., and the other cases give a mortality of 16.6 per cent.

The treatment with the antitoxin was begun in the latter part of July, having previously used the weaker solution on several cases, and extended through the following two months. Twenty cases were selected for treatment during this time, and every case was one in which a most unfavorable prognosis would have been given at time of injection, while in all other hospitals where the serum treatment has been applied all cases have been injected without regard to the age or condition of the patient. The latter method gives a larger number of cases, but is not so severe a test, unless the treatment extends over a long period of time. Good results obtained in this way can be claimed as due to the season of the year, or the mildness of the epidemic. Our cases differ in another important respect from most of those already reported, *i.e.*, the treatment consisted entirely of injections of antitoxin, with the exception of irrigating all cases once on admission, and two cases several times, for the purpose of removing membrane which completely plugged the nose. Of course stimulation was given when indicated.

The temperature of diphtheria is so variable, being sometimes low in the most severe cases and high in others, it is impossible to tell how much it is influenced by any treatment. In some of the cases the rise in temperature after the injection was marked, in others there was no decided change, while in still others there was considerable fall. This fall of temperature we notice in many cases soon after the entrance to the hospital, the temperature on admission probably being the so-called "ambulance fever." Streptococci, inflammation, and other complications also give a high temperature, and, of course, antitoxin could have no influence on these temperatures.

The effect upon the pulse is of much more importance. In nearly all cases nine hours after the injection the pulse was much improved in strength, volume, and frequency. The two following representations of the composite pulse and temperature curves of all cases will show what influence, if any, antitoxin had upon the temperature and pulse:

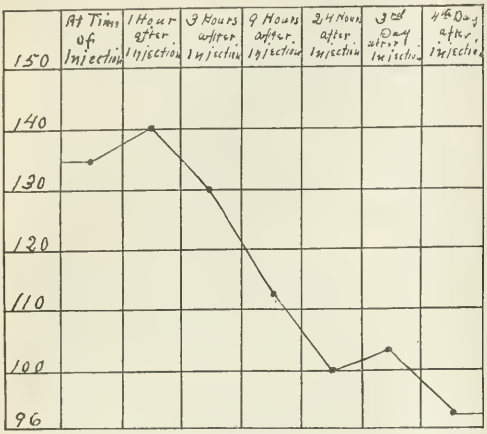

FIG. 1.—Composite Pulse Curve of the Twenty Cases.

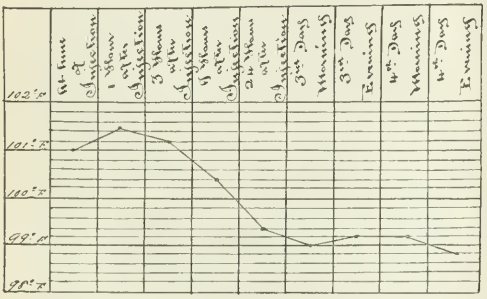

FIG. 2.—Composite Temperature Curve of the Twenty Cases.

The diphtheritic false membrane disappeared, on the average, on the ninth day of the disease. This is about the ordinary duration of membrane in most cases, but is probably a little early for cases so severe as these. The persistence of the Klebs-Loeffler bacilli, as would be expected, was not apparently influenced, the average time for disappearance of bacilli being the nineteenth day.

Antitoxin given early and in sufficient quantity, ought to prevent post diphtheritic paralysis, as it is now almost universally conceded that the paralyses of diphtheria are due to the toxines absorbed, and generally follow the more severe cases. Among the cases treated with antitoxin, four had post-diphtheritic paralysis. The paralysis was noticed on admission, the tenth, the eleventh, and the eighth days of the disease, treatment having been begun on the seventh, the fifth, the third, and fourth days of the disease respectively.

Albuminuria was present in three cases—in two cases on admission, and in the other case it appeared ten days after the injection. It lasted no more than three days in any case. No casts were found in the urine, and no unfavorable symptoms could be traced to the kidneys.

Diphtheritic or septic pneumonia occurred in no case, the pneumonia complications all coming on very late, as mentioned before. The pneumonia cases due to extension of membrane or infection from above, always begin in the early days of the disease and die within a few days.

Besides the twenty cases treated with the stronger solution, we have injected twelve other cases with Aronson's weaker antitoxin, called the "immunization serum." Some of these cases were quite mild, and received a small amount of the serum. They would probably have recovered in any case. Several of the bad cases received as much as 20 c.c. of the serum. On two patients tracheotomy was performed, one of whom died on the twenty-first day after the operation, the other making a good recovery. The age of the former was four years, of the latter thirteen months. Two cases were intubated; one died and the other recovered. Still another case died on the thirty-seventh day with pneumonia. All of these twelve cases were under five years of age, and give a mortality of twenty-five per cent. No death occurred until after the fifteenth day of the disease. There was not the marked change for the better in the general condition of the patient some twelve hours after injection, as was noticed in the cases treated with the stronger solution. We mention these cases to show the difference in strength between the two solutions, and to demonstrate, by giving larger doses of the "immunizing solution," that it can be used as a healing fluid.

In drawing conclusions from the results obtained with the treatment by diphtheria antitoxin, we must first be satisfied that it has at least some curative power, however slight or insignificant that influence may be. If we grant it has any appreciable influence when opposed to the toxin developed in a patient suffering with diphtheria, we must concede it is a specific for diphtheria; for the degree or amount of influence it exerts must, from the nature of the remedy, depend entirely on the strength of the serum and the care with which it is prepared.

Before deciding this question we may with benefit consider the results obtained by others, who have given antitoxin a fair trial. The following reports have, with two exceptions, come from the hospital of Berlin:

Korte,[1] through Vaswinckel, reports 60 unselected cases treated with antitoxin. Of these, 30 were severe cases, with fifty per cent. recoveries; 16 were quite severe cases, with eighty-one per cent. recoveries; 14 were light cases, with one hundred per cent. recoveries. Seventy per cent. of all cases recovered. Those cases having been excluded in which antitoxin could have had no effect, the total mortality was twenty per cent. Twenty cases were tracheotomized, with fifty-five per cent. mortality. The months previous to and following the treatment gave a mortality of 46.5 per cent. and in tracheotomies seventy-one per cent., or a total increase in recoveries under antitoxin of 26.5 per cent., and in tracheotomies a gain of sixteen per cent. He says no dangerous effects from the serum were observed; a few cases had some rash after the injection, and in a few cases albumin appeared in the urine.

Rinne,[2] through Schubert, reports 34 unselected cases, all of whom happened to be severe diphtheria in children, with a mortality of 17.9 per cent. The 6 patients who died were tracheotomy cases. Autopsies showed death to be due to septic pneumonia in 2 cases, mechanical plugging of small bronchi in 2 cases (so that tracheotomy did not afford relief), pronounced myocarditis and nephritis in 1 case, and the remaining case died after being discharged from hospital. The observer considers the serum an effective cure. The local symptoms improved rapidly, the effect upon general condition was more marked than any other (especially true of those cases with a very weak pulse) and a rash was noticed in several cases following injection. Much larger doses were used than experiments with animals would indicate.

Sonnamberg[3] reports 44 cases, with a mortality of

[1] Deutsche Med. Woch., No. 22, 1894.
[2] Ibid. Cases were treated at the Elizabeth Kranhenhaus, Berlin.
[3] Ibid., June 7, 1894. Cases treated at the Krankenhaus Moabit.

twenty-five per cent. Nine tracheotomies give a mortality of 37.8 per cent. Excluding 6 cases in whom antitoxin was not indicated, the mortality in all cases was 13 3 per cent. Improvement of general condition, rapid disappearance of membrane, and fall of temperature was noticed in most cases.

Strahlman[1] reports 48 unselected cases, with three deaths (two of sepsis and one tracheotomy), showing a mortality of 6.2 per cent. The immunization power was tried in 94 cases, and seemed to protect from five and a half weeks to ten weeks. He summarizes as follows: "The changes caused by injection were marked, the membrane disappeared quickly, temperature fell considerably, and general condition improved very perceptibly."

Roux, Yersin, Martin, and Chaillou[2] have studied clinically in l'Hôpital des Enfants Malades of Paris, and bacteriologically in the Pasteur Institute, over four hundred cases treated with their 1 to 50,000 antitoxin solution. They chose those months for the treatment in which diphtheria attains the highest mortality, and for comparison had the statistics of l'Hôpital Trousseau, where no serum was used, in the same city, covering the same period. The mortality for the four years previous to the treatment was 51.71 per cent. in 3,971 children. In 448 cases entering the hospital during the serum therapy the mortality was 24 5 per cent.; covering the same period the mortality among 520 cases at l'Hôpital Trousseau was sixty per cent. Therefore 27.21 per cent. represents the exact benefit obtained by the antitoxin treatment as compared with other years in the same hospital, and shows a difference of 35.5 per cent. in favor of the serum as compared with the regular treatment for diphtheria in another hospital during the same epidemic and in the same city. The mortality among pure anginas, without croup complicating, was twelve per cent., while during the same period at l'Hôpital Trousseau the mortality was thirty-two per cent., and previous to antitoxin in the same hospital it had been 33.94 per cent. The mortality in croup with serum treatment was forty-nine per cent.; at l'Hôpital Trousseau for the same time it was eighty-six per cent., and had previously been, at l'Hôpital des Enfants Malades, 73.17 per cent. Excluding some cases in which the Klebs-Loeffler bacilli could not be found, and others in which the serum treatment was not applied, the mortality among three hundred cases of true diphtheria treated with antitoxin was twenty-six per cent., or twenty-five per cent. better than any results obtained by former treatment for true diphtheria in the same hospital.

We find, then, of four hundred and eighty-six children (including operative cases) treated for true diphtheria by various observers, with different strengths of antitoxin solutions, one hundred and sixteen have died, or a mortality of 23.8 per cent. in a class of cases in which about fifty per cent. always die.

The first question—"Does antitoxin accomplish any appreciable good results in diphtheria?"—judging from our own twenty cases alone, can be answered decidedly in the affirmative. Otherwise we must believe is is sometimes possible to save over ninety per cent. of children suffering diphtheria in its severest forms with no other treatment than rest in bed. When we add to our own cases the results obtained by others, we cannot help but believe we have received in antitoxin not only a remedy that will grant immunity for a short period of time, but a specific that will, in every case, given early in the disease and in sufficient quantity, prevent death by the absorption of the toxine of diphtheria.

Long Life in Greece. — The German statistician, Bernhard Ornstein, has computed that Greece stands in the first rank among European countries in the number of centenarians. He attributes this to its climate.

ANTITOXIN IN DIPHTHERIA.

Second Paper, Being Extended Experience in this City and in Municipal Hospital of Philadelphia, with Some Practical Points in the Treatment of the Disease.

By LOUIS FISCHER, M.D.,

Instructor in Diseases of Children, New York Post-Graduate Medical School and Hospital; Physician in Charge of Messiah Home for Children; Attending Physician, Children's Department, German Poliklinik.

In the Medical Record of October 6th I published a report of a very successful case of diphtheria treated with Aronson's antitoxin. Since then I read an elaborate paper before the Post Graduate Clinical Society, October 13th, giving my results in many consultations, besides giving a brilliant outlook for the treatment of the septic, infectious like diphtheria. Moreover, the opportunity for testing the value of this agent arose in a hopeless case of puerperal septicæmia, and with astounding results. The details of this case will be published later on. It is safe, therefore, to assume that not only can antitoxin exert healing influence in toxins generated by the Klebs-Loeffler bacilli, but that they seem to modify, and possibly cure, other toxins generated in the human organism by germs distinct from those known to be the specific cause of diphtheria. Granted, then, that this is the case we can not only modify a severer type of the disease, but prevent complications which we all know to be the sole danger in diphtheria, besides cutting short the course of the disease and thus preventing serious damage to the heart and kidneys.

While no rule has as yet been definitely established as to what cases are and are not suitable for this new therapeutic agent, still extensive experience has already demonstrated certain positive facts. They are:

That diphtheria is not a self-limited disease, that it is always dangerous, and that if treatment is commenced early to guard against extension of same, we can sometimes avoid complications and save life.

We are, therefore, justified in applying antitoxin not only when we can already see the local manifestations of the disease, but when we have reason to suspect that a patient has been exposed and possibly infected. This will then bring me to the mildest kind of serum, and which has been called immunizing fluid.

This serum, made by Aronson, is clear, milkish-white, having a slight odor of trikresol, of which it contains 0.2 per cent. to preserve it and prevent decomposition of the albuminous ingredients.

If a child in a given family has diphtheria, it has been found that other children apparently healthy can, by receiving small injections of 2 c.c., be kept immune from diphtheria, and this immunity can be prolonged for several months.

In fact, Aronson found that when children treated in this way for prophylaxis, did contract the disease, the symptoms were so mild as to prove the fact that antitoxin had, in all probability, neutralized considerable of toxic matter in the human organism, and in this way most likely modified the course of the disease.

This immunity was not only lasting, but could be prolonged for some time by repeated injections, and thus the period of the immunity could be continued for many months.

The technique of the preparation of antitoxin is one requiring little or no skill, but owing to the great length of time required for rendering animals immune, this period sometimes extends over one year and more, hence the great difficulty in obtaining large quantities of serum.

Statistics in this city show from 1880–1887, for a period covering eight years, 5,923 cases, with 2,167 deaths, or an average of 42.62 per cent.

Nine years ago Henoch reported 319 cases with 208 deaths, in Berlin, or about 65.5 per cent. fatal. At Hospital Trousseau, in Paris, 1883, of 606 cases treated, 391 died, or 64.5 per cent.

So, taking three distinct parts of the world at about the same time, with most improved form of treatment, we have

Berlin mortality	65 5 per cent.
Paris	64.5 " "
New York	42.62 " "

Since then, the true bacteriological origin of the disease and our knowledge of antisepsis, tend to introduce a new course of treatment, although the old bichloride of mercury has stilln umerous adherents.

Comparing those statistics with the most modern, we find Katz reporting 128 cases of diphtheria, in a severe epidemic in the large Kaiser u. Kaiserin Friedrich Hospital in Berlin, with only 13.5 per cent. mortality.

When Professor Baginsky detailed the method of using the antitoxin treatment, he especially laid stress on the fact that this new remedy had influenced the statistics, and that the mortality fell from thirty-seven per cent. to thirteen and even eleven per cent. The result has never yet been equalled by the most improved form of treatment, and in our mildest epidemic.

How curious to note that under this new form of treatment all severe symptoms subsided in a few days, and rarely did an early case of diphtheria develop complications; and not in a single case was it necessary to relieve stenosis of the larynx by intubation or tracheotomy where the treatment was commenced early.

Even a complicating nephritis seemed to appear milder, showing a decided influence had been exerted by this new method.

Professor Roux, in Hôpital des Enfants Malades, in Paris, had 448 cases; of this number 109 died, a mortality of 24.33 per cent., contrasted with average mortality of four preceding years, when of 3,971 cases, 51.71 per cent. died.

A critical examination of the statistics for this year involved the drawing of a distinction between cases of true and false diphtheria. Of the 448 children admitted into the diphtheria portion, bacteriological examination showed that 128 cases were not infected wlth true diphtheria; further, 20 of the cases were already moribund when admitted. There remained, therefore, 300 cases which afforded a fair test of the efficacy of the treatment; they yielded 78 deaths, a mortality of twenty-six per cent., which must be contrasted with an earlier series of cases subject to the same eliminations, but treated by other methods, which gave a mortality of fifty per cent.

The rule in the hospital has been to give an injection of the serum immediately after admission of the child. The injection was not repeated if bacteriological examination showed that the case was not one of true diphtheria. In none of these cases was the injection followed by any unfavorable symptoms; it was not painful, and, if made with aseptic precautions, was not followed by any local disturbances. In cases of true diphtheria a second injection was given twenty-four hours after the first, and as a rule this was sufficient.

If the temperature remained elevated, a third injection even was given. As a rule a child received an amount of serum equivalent to one thousandth of its weight, but in a few cases the quantity reached one hundredth of the child's body-weight.

Under the antitoxin treatment, complications were observed in only a few cases, but in some paralysis supervened. Occasionally, during convalescence an urticarial eruption was observed, apparently due to the injections. The treatment appeared to diminish the liability to albuminuria.

A further classification was made of the cases of diphtheria by M. Roux. Taking first the cases in which the larynx was not involved, he said that in 120 of these the diphtheria bacillus was present alone; of these 9 died, a mortality of 7.5 per cent. But of these 9 children, 7 did not survive their admission into the hospital for twenty-four hours. Eliminating these, the mortality was only 1.66 per cent. Further, of the two remaining children who died, one was suffering from tuberculous peritonitis, the other from severe measles, so that it appeared that all cases of pure diphtherial angina ought to recover if treated in time. The false membrane ceased to develop twenty-four hours after the first injection, and became detached in all but seven cases before the end of the third day. The temperature fell rapidly in many cases after the first injection, in severe cases only after the second or third injection, and then more slowly.

In cases of diphtherial angina, complicated by the presence of other microbes, the results were equally good, except in those cases in which streptococci were present; the number of these cases was 35, of whom 12 died, a mortality of 34.28 per cent. This must be compared with a mortality of eighty seven per cent. in cases treated by other methods.

With regard to cases in which the larynx was involved, M. Roux distinguished two classes: 1, cases in which tracheotomy was not performed, of which there were 10, with 1 death, a case in which the diphtheria bacillus was associated with streptococci; 2, cases in which tracheotomy was performed, 121, with 56 deaths, a mortality of 46.28 per cent. Among these there were 49 cases of pure diphtheria, with 15 deaths, a mortality of 30.61 per cent.; but four of the patients died less than twenty-four hours after admission, and after deducting these the mortality was 22.44 per cent. Taking all the cases in which tracheotomy was performed, and eliminating 14, which died within twenty-four hours after admission, there remained 107 cases, with 42 deaths, a mortality of 39.25 per cent.

Good as these results were, M. Roux himself thought that they might still further be improved by more perfect isolation of the patients, since many of the deaths after tracheotomy were due to broncho-pneumonia, and it was noticed that a series of such cases might follow the admission of a child suffering from diphtheria of the larynx associated with the presence of streptococci. In favor of this argument of isolation may certainly be urged the larger percentage of recoveries obtained in private practice in this country, although many of the cases have fallen into the hands of practitioners with no previous experience of the serum treatment. It may be also that the source of the antitoxin had a depreciating influence, for nothing is stated beyond that the serum was obtained from the horse. Certain it is that the use of Dr. Aronson's antitoxin in the Berlin hospitals was accompanied by a larger proportion of success.

Dr. Aronson said that in the five months ending with July, he had treated with his serum 192 patients suffering from diphtheria, as ascertained by bacteriological examination. The mortality was fourteen per cent. In 23 cases the children were moribund when admitted; eliminating these, there remained 169 cases, with 19 deaths, a mortality of 11.2 per cent. This contrasted with a mortality in the same hospital varying, in three years before the adoption of the antitoxin treatment, from 32.5 per cent. to 41.7 per cent.

Eighty-two cases had been treated by the serum in other hospitals in Berlin, and the general mortality of the whole series of 274 cases was 15.3 per cent. The antitoxin serum had also been employed with the object of producing immunity in the children belonging to families in which a case of diphtheria had already occurred. Among the 130 children thus inoculated, 2 only contracted diphtheria, and that of very mild type.

Professor Heubner, gives his experience of the use of antitoxin serum in the children's department of the Charité Hospital, in Berlin. He insists upon the importance of early treatment, and pointed out that, as the serum has no toxic effects, it might properly be employed in cases which were only suspected to be diphtheritic. He thought it undesirable to use massage of the part in which the injection was made, as its use was liable to be followed by some pain, and it was quite unnecessary, as the serum was very rapidly absorbed without it. The points to which he considered attention should be

directed in considering the necessity for repeated injections, were the effect upon the false membrane and the swelling of the glands, the behavior of the temperature, the condition of the urine, and the character of the pulse.

Technique of Injection.—Aronson advised me to use the asbestos and linoleum syringe holding 20 c.c. for injecting the serum. This syringe, made in accordance with these requirements, will soon be imported in this country by a leading firm. Our own instrument makers will also manufacture them after the German models so that they will soon be within reach of all. Having properly sterilized the syringe by boiling and using 0.5 per cent. trikresol, I commence by injecting 10 c.c. in mild cases, and 20 c.c. in malignant cases, by pinching a fold of skin in the intra scapular region, and allowing the serum to be slowly injected. I believe it proper, however, to have a syringe of suitable size and inject the required amount, rather than inject several places, which is scientifically incorrect, and besides tends to demoralize the patient by causing pain with each stick of the hypodermic needle. The calibre of the latter must necessarily be quite large, owing to the thickness of the serum, which is at times rather mucilaginous. It is proper to note all differences and effects on the false membrane and the swelling of the glands, the behavior of the temperature, the condition of the urine, the effect on the heart, especially the pulse.

There should be no hesitation in injecting on the second day, and, if absolutely no effect is seen, repeating the injection on the third day, as there is absolutely no risk from the injection. It is a perfectly safe remedy, and shows no immediate reaction. It differs from tuberculin and vaccine in that it causes no reaction. Therefore, a case of antitoxin treatment will show no symptoms directly attributable to the remedy, unless it be in some cases urticaria. The temperature does not fall by crisis, but by lysis, with antitoxin treatment. Massage of the serum after the injection should not be practised, according to Professor Heubner, Aronson, Baginsky, and others.

My opportunities for watching this line of treatment in Berlin last summer, and also my experience with numerous cases in this city in consultation practice, and also more recently a series of cases injected and at the time of writing still under observation, in the Municipal Hospital of Philadelphia,[1] by courtesy of Drs. Welch, Bemis, Davis, Gould, Kyle, and others, makes me emphasize the care of patients and the necessity for permitting absorption to take place without massage.

Practical Points in Treatment.—Let us not lose sight of the fact that in the use of this rather new agent, we are still treating diphtheria, and that all discharges, be they from the nose, throat, or mouth, and possibly fæces and other excrements, should be subjected to a rigid disinfection. This, if possible, before leaving the body. For this purpose local swabbing of all visible membranes with a 1 to 2,000 bichloride of mercury solution, using glass rods with some absorbent cotton—the latter to be burned immediately after swabbing; the glass rod to be put into bichloride solution. We still require most thorough naso pharyngeal antisepsis for this purpose, lukewarm, 105° to 110° F., normal table salt solution, injecting either nostril until the stream flows out of the other side, using considerable force at times. Great attention must be paid to the recumbent posture, which has been so strongly advocated in Berlin, and I was happy to hear from Dr. Campbell White, of this city, in discussing my paper on treatment of diphtheria.[2]

The usual rules of hygienic measures are in all cases more rigidly to be looked after in this serious illness than in any other class of diseases—bathing, temperature of the room, absolute cleanliness, good light (sunlight) to be admitted. The dietetic management to consist of strong supporting treatment—beef tea, broth made of veal, mutton, chicken—should be tried. Milk diet, farinaceous foods, raw scraped steak, fresh eggs, and kumyss or matzoon, sometimes buttermilk. Where we have young children I invariably find them craving for liquids, and here ice-cream is one of my most favorite articles of diet. Naturally, cautiously given.

Stimulation should be cautiously followed out. So, for example, it is wrong to commence stimulating every case from the beginning. It should be used where there is weakness of pulse and where heart's action is slowed, and then, however, if required, it should be freely administered. Good Tokay, and Baginsky advises Greek wines (Mavrodaphne) and other kinds. These latter wines, being sweet, are very greedily taken by children. Neither the ice collar nor any other form of external local application was used, in all my experience abroad or in this country, with the serotherapy.

As all the reports, therefore, from Berlin, Paris, and even America, give good results, it is safe to assume that antitoxin has stood the test of time and is the best remedy therefor used. I do not believe it to be a cure-all, but that, with careful nursing, proper attendance, and early use in the disease, it will do more good than any hitherto known treatment.

The Aronson serum in use in Berlin, London, and also some in New York, has given me better results by far than Behring's serum, although it is now claimed that Behring's serum is as strong as what Aronson recently made. In once case I used 5 c.c. of Aronson serum with the same result as 10 c.c. in another with Behring.

Finally, I desire to state, in answer to very many questions concerning the length of time that serum will keep, that it will keep in a cool place about a few months. A great many unscrupulous people, mostly pharmacists, have already commenced to offer antitoxin, and I would take occasion to warn against using any substance resembling antitoxin.

Although by cabling to Berlin three times I received a small consignment, I am assured that we may receive some in the near future, but that a general supply will be received about spring of next year.

As Paris has already, similar to Berlin, opened a general subscription list for the preparation of antitoxin, would it not be advisable to have someone brought over from Berlin capable of making antitoxin, and thus be assured of the proper technique?

No doubt sterilizing milk benefactors might possibly be induced to aid a project for the cure and extermination of one of the most fatal diseases of to-day.

187 Second Avenue.

[1] A complete report of cases will be published in the American Journal of the Medical Sciences for January, 1895.

[2] See Post-Graduate Journal for October, 1894.

A Long Term of Service.—Sir George M. Humphry, of Cambridge, England, recently handed in his resignation as senior surgeon to Addenbrook's Hospital, a post which he held for fifty two years. He received his appointment very early in his professional career, and it was that chiefly which determined his residence in Cambridge. The governors of the hospital in accepting his resignation adopted the following resolution: "That the governors resolve to place on record their grateful sense of the invaluable services he has during half a century rendered to the institution, both as a place for the relief of the suffering poor, and as an important centre of medical education; that, subject to his acceptance of the office, he be, and hereby is, appointed consulting surgeon to the hospital, and that the chairman be requested to convey this resolution to Sir George Humphry, and to express the hope of the governors that he may long be spared to give them the benefit of his counsel and assistance."

Fabrics and Odors.—Dress materials vary greatly in their capacity for retaining odors; silk allows almost all odors to pass through without leaving any smell behind; linen holds them fast; wool, though it lets many smells pass through, retains the odors of decay, like that of a corpse.

A CASE OF SARCOMA OF THE PALATE SUCCESSFULLY TREATED WITH THE TOXINES OF ERYSIPELAS.[1]

By WALTER B. JOHNSON, M.D.,
PATERSON, N. J.

T. C——, male, aged sixteen, clerk. On October 31, 1893, he was admitted to St. Joseph's Hospital, Paterson, N. J. He was born of Irish and Irish-American parents, and gives no history of any hereditary taint in the family of the father or mother. No malignant disease or syphilis has occurred in any branch of either family. His mother states that when a child she was generally healthy, except the sickness which resulted from the ordinary diseases of childhood; after which she had an affection of the eyes and an abscess of the neck, which was lanced and has left a considerable scar. Since that time she never has been ill except in childbirth; she has borne eight children, four of which died young, of convulsions or of the diseases of children. She never had any still births.

The patient has always been delicate, but has not frequently been confined to the house by illness. He had measles when seven years old, and two years ago had an attack of pleurisy which confined him to his bed for fully two weeks. He has always suffered from catarrhal trouble and hypertrophy of the tonsils, and generally during each winter has had more or less frequent attacks of acute tonsillitis; these attacks were accompanied by fever, and he has never been considered either strong or robust. Six weeks ago he commenced to complain of a soreness of his throat and accompanying difficulty of deglutition, thickness of the voice sounds on phonation, and slight dyspnœa, the respiratory function being performed almost entirely through the mouth. He had suffered so frequently from attacks of inflammatory disease of the throat, and had so strong a prejudice against medical treatment, that he refrained from making complaint and the trouble was somewhat neglected; it progressed and assumed a grave condition before any medical opinion was sought.

On examination, a diseased area was disclosed which extended over the entire soft palate, pillars of the fauces, region of the tonsils, forward over the hard palate to within one-half inch of the incisor teeth, backward and downward, involving a portion of the pharyngeal wall, base of the tongue, affecting the epiglottis, and invading the upper part of the larynx, but not extending to the true vocal cords. The infected parts were thoroughly impregnated with sarcomatous deposit, the soft palate was increased to about three times its normal thickness, the new tissue consisted of cauliflower like granulations varying in size from a rice kernel to a good sized pea; some of the masses which made up the growth were undergoing an apparently superficial ulceration and discharging a purulent secretion; others contained distended and tortuous vessels which gave them the dusky hue frequently observed in sarcomatous diseases; the uvula seemed to have been destroyed. There were several of the cervical glands involved, the largest one, however, was only about the size of a filbert.

The accompanying drawing (Fig. 1) indicates the extent of the growth and appearance about the palate and pillars of the fauces.

The patient did not present a robust appearance, although he seemed to be in fair condition; there was no cachexia. Since the present trouble developed he has been gradually losing flesh, and has become more easily exhausted on efforts at walking or running. His present weight is eighty-six pounds. He has increased difficulty in deglutition, and can only take small quantities of liquid nourishment. He is unable to breathe through his nose in consequence of the great thickening of the soft palate, which compels mouth breathing. A portion of the growth was removed for microscopical examination and submitted to my assistant, Dr. Joseph W. Williams, who subsequently reported the growth to be a spindle-celled sarcoma.

The treatment adopted was the hypodermic injection of the toxic products of erysipelas and the bacillus prodigiosus. The toxines were obtained from filtered cultures of the streptococcus erysipelatosus, and were used in combination with the toxines of the filtered cultures of the bacillus prodigiosus. The toxines were kindly supplied by Dr. William B. Coley, of New York, who also saw the case in consultation in an early stage of the disease. Some of the solutions were prepared by Dr. Alexander Lambert, Fellow in Bacteriology, College of Physicians and Surgeons of New York, and some by Mr. B. H. Buxton, recent Fellow in Bacteriology at the Loomis Laboratory, New York.

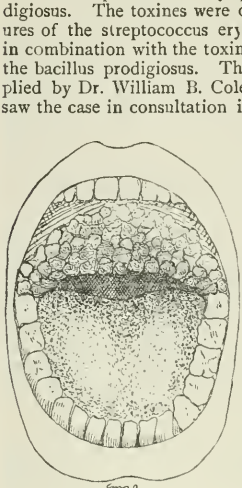

FIG. 1.

October 31st.—The injections of the toxines of erysipelas were commenced daily with fifteen minims. The dose was increased each day until it had reached sixty minims. The bacillus prodigiosus toxines were used in doses of five minims in combination after the dose had reached thirty-five minims. The injections were sometimes given in the arm and sometimes in the leg, and generally caused redness, swelling, and pain almost immediately after they were given; these symptoms were always present and persisted from twelve to thirty six hours. The temperature varied. It was elevated after each injection, to a greater or lesser degree, from 99° to 103° F. The patient always felt cold, and after some of the injections had chills, some of which were much more severe than others, and were accompanied by nausea, vomiting, and pain in the back of the head and neck. When the chills or feeling of coldness had passed away a profuse perspiration would follow, and the condition of the patient would be comemuch more comfortable.

The treatment was continued from October 31, 1893, to June, 1894, during which time it was intermitted on a number of occasions for various reasons. The patient developed, during the entire progress of the treatment, a dozen chills in all; four of them were violent, and after one, which was the most severe, his temperature rose rapidly to 103° F. This chill, which was very violent, was followed by marked cyanosis, pain in the neck and head; his pulse became very rapid and feeble, and his general condition was considered very serious. His nose and lips were subsequently affected by a severe herpetic eruption, and his physical condition was such that he was obliged to remain in bed for two weeks; during this period of time the injections were discontinued. No explanation of the severity of this attack could be given, as the toxic solutions used had been in use in the same doses from the same supply, and the same bottle which was used before, and also after, this attack without any previous or subsequent marked disturbance.

After the patient had been under treatment for five months he developed a peculiar variety of keratitis, which was so severe that the outline of the pupil or coloration of the iris could not be seen through the opacities which, although they were apparently punctate, were so closely coalesced that the entire cornea was opaque; some of the opacities are still present and visible, although their character cannot be defined. The injections were stopped for three weeks, during the most severe period of this attack.

Frequently the patient became so distressed by the sore-

[1] Read at the October meeting, Section Laryngology, New York Academy of Medicine.

ness of his body caused by the repeated injections, that an intermission of two or three days was taken, and the treatment discontinued. Also, on several occasions medication was stopped in consequence of temporary inability to procure the solutions for injection.

The result of the treatment was a constant, steady, but slow, improvement in the condition; two weeks after the injections were first given the soreness had left his throat to such an extent that he was able to swallow not only fluids, without pain, but also considerable quantities of solids. His weight increased to eighty-nine pounds. The granular masses commenced to disappear, this improvement continued, and during the period of treatment the deposit of the sarcomatous material was constantly, but very gradually, disappearing, some of the granulations by necrobosis and some by absorption. During all this time his general condition steadily improved; at the end of the fourth month of treatment his weight had increased to ninety-three pounds. The patient's temperature was generally not materially increased after the injections, except as previously noted. The improvement was slow and the progress of the recovery uneventful, although the constitutional disturbance was marked during the attacks mentioned above. The granular swellings gradually disappeared as the tumor mass decreased in size. The injections were discontinued entirely in June, since which time there has been no return of the disease; the patient is in excellent physical condition, his present weight is one hundred and seven pounds; he states that he never felt so well, and there are no annoying symptoms of any kind present at this time, now about one year since the onset of the disease.

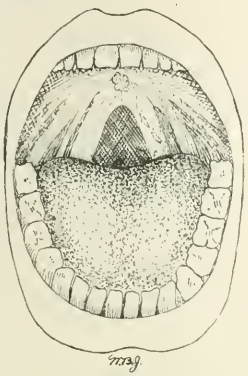

Fig. 2.

October 1, 1894.—On examination a slight central prominence and one or two spots of ulceration is all that remains of the growth; cicatrization and contraction has taken place, and white bands of adhesion extend from the hard palate to all parts of the fauces, as shown in the drawing (Fig. 2). The uvula and a small portion of the epiglottis have been destroyed by ulceration.

Jacksonville Meeting of the Tri State Medical Society.—The third annual meeting of the Tri-State Medical Society of Iowa, Illinois, and Missouri was held at Jacksonville, Ill., October 2d and 3d. The attendance was large and great interest was manifested. Papers were read by Drs. J. H. Etheridge, Bayard Holmes, Boerne Bettman, Robert H. Babcock, F. Henrotin, and W. F. Hubbard, of Chicago; John Punton, of Kansas City; James A. Close and Emory Lanphear, of St. Louis; W. B. LaForce, of Ottumwa, Ia.; E. O. Sisson and F. B. Dorsey, of Keokuk, Ia.; Frank P. Norbury, Anne H. McFarland, Carl E. Black, and L. A. Malone, of Jacksonville, Ill.; Alfred Meyer, of Kankakee, Ill.; W. M. Catto, of Decatur, Ill.; and Charles W. Rook, of Quincy, Ill. The election of officers resulted as follows: *President*, Dr. James Moore Ball, of St. Louis; *Senior Vice-President*, Dr. Bayard Holmes, of Chicago; *Junior Vice President*, Dr. L. A. Malone, of Jacksonville, Ill.; *Treasurer*, Dr. C. S. Chase, of Waterloo, Ia.; *Secretary*, Dr. Frank P. Norbury, of Jacksonville, Ill. St. Louis was selected as the next place of meeting. Time—the first Tuesday, Wednesday, and Thursday of April, 1895.

CONGENITAL ANNULAR STENOSIS OF THE VAGINA—AN IMPROVED METHOD OF OPERATING.

By HIRAM N. VINEBERG, M.D.,

NEW YORK.

INSTRUCTOR IN GYNECOLOGY, NEW YORK POST-GRADUATE SCHOOL OF MEDICINE AND HOSPITAL; ATTENDING GYNECOLOGIST MOUNT SINAI HOSPITAL DISPENSARY, AND MONTEFIORE HOME FOR CHRONIC INVALIDS.

Acquired stenoses and atresias of the vagina are fairly common and have received considerable attention in literature; but not so the congenital stenoses of the vagina. The literature on the subject is very meagre. This, doubtless, is due, in part, to the looseness with which many authors employ the terms "atresia" and "stenosis." For instance, several authors speak of "incomplete atresia"—a solecism which should not occur in scientific medicine. Either an atresia (*ἀτρησία*, from *ἀ*, priv., and *ἀ τρησίς*, a perforation) is complete or it does not exist at all. If there be an opening or a perforation, no matter how small, it is no longer a condition of atresia but of stenosis or stricture.

The meagreness of the literature on the subject of congenital stenosis may be judged from the circumstance that, in 1890, L. Kleinwächter[2] was able to collect only twenty published cases, and in only two of these was the annular stricture situated at the junction of the middle with the upper third of the vagina. In his paper he reports two cases in which the stricture was situated in this portion of the vagina. Ostermann and Odebrecht[3] have each recently reported a similar case. A search through literature since 1890 has failed to find any other cases. These six cases, then, form the total number hitherto published. The two cases that I am about to report will bring the number up to eight. I am loath to believe, however, that the condition is as rare as these figures would indicate. Many cases, no doubt, go unobserved. They are frequently overlooked because they may give rise to no symptoms. When the conditions interfere with marital intercourse, as in one of my cases, the woman may have her attention drawn to it and seek advice. In other instances it is found accidentally, as in my first case, when the physician makes a vaginal examination for some uterine disorder having no reference to the anomaly. In another class of cases the woman may seek advice on account of sterility (Kleinwächter).[4] In a further class of cases the condition is found at labor—Doleris,[5] Murphy,[6] Hemmer,[7] G. Braun,[8] Heyder.[9] But in the latter class of cases I am of the opinion that it is frequently overlooked. For unless the accoucheur made a very careful examination he would be likely to mistake the thick ring for an undilated os. As these rings often yield to the intermittent pressure of the head and the softening processes attending labor, the true condition would not be revealed.

Case I.—A. A——, single, aged seventeen, was seen in consultation with my friend Dr. J. I. Metzger, March 19, 1893. Has had none of the diseases of childhood. At five years she had a vaginal discharge, which seemed so unnatural to her parents that they consulted a doctor about it. He made light of the matter, and it disappeared after a time. In her seventh year she had a similar discharge, and again in her twelfth year. Since then the discharge has continued about the same. In her thirteenth year she had typhoid fever, complicated by pneumonia, but made a good recovery. Apart from this she enjoyed good health until six months ago. Menstruation set in when she was fourteen years of age, and was regular and painless from the outset. For the past six months has been complaining of pain in both groins, backache, and increased vaginal discharge. Exercise,

particularly walking, made the pain in the groin worse. These pains were relieved during menstruation, which continued to be regular. Health otherwise fairly good.

She is a tall, slightly built girl, with small, undeveloped mammæ. The external genitals are normal, though rather undeveloped, the pubes is thinly covered with hair. The hymen is ruptured from previous examination. The examining finger comes into contact with a membranous ring at about the upper two-thirds of the vagina. In the centre of this ring is an opening barely admitting the point of the index-finger. The ring seems to be about one centimetre in thickness, and is smooth

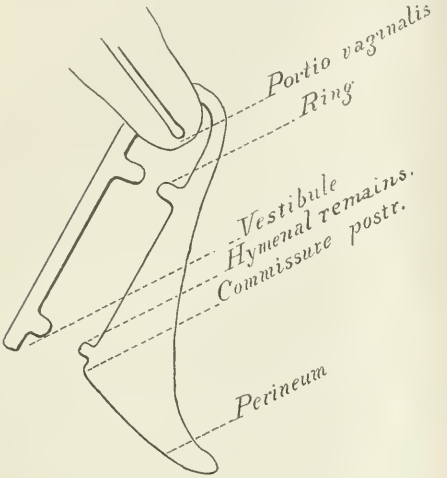

Fig. 1.

and homogeneous in structure (see Fig. 1), revealing no evidences of cicatricial tissue. With the finger in the rectum the cervix of a rather small retro-displaced uterus is felt about one inch above the stenosed part. The left ovary and tube are normal in size. From the right horn of the uterus a moderately thick cord can be felt passing to the right sacro-iliac articulation. The right ovary can be made out of normal size, but the right tube cannot be palpated.

Diagnosis.—Annular stenosis of the vagina, probably of congenital origin, retro-displacement of the uterus.

On June 15, 1893, I assisted Dr. Metzger to do the customary operation of crucial incision and forcible stretching. At the operation it was found that the vagina was quite roomy beyond the stenosis. The wound was packed with iodoform gauze and afterward kept dilated by Sims's glass plug. This part of the treatment was rather unsatisfactory, and the stricture was not very much improved by the operation.

Case II.—B. G——, aged twenty-two, was first seen by me in January, this year, in my service at the Mount Sinai Dispensary. She was married four months, and sought advice because coition was painful to her and unsatisfactory to the husband. He stated that he could enter only for a short distance, and then "something" seemed in the way. Her history was negative. She had always been healthy as a girl, and never had any vaginal discharge. Had none of the diseases of childhood, as well as she could remember. She is a well-built, fully developed woman, mammæ and external genitals normal. At the junction of the middle with the upper third of the vagina a constriction is felt, formed by a membranous ring, in the centre of which is an opening just large enough to admit the point of the index-finger. With the finger in the rectum a normal-sized uterus is felt, in anteversion, lying some distance above the constriction.

On January 22d, assisted by Drs. Rau and Brothers, I excised the ring with scissors, flush with the vagina, for about three-quarters of its circumference, taking care not to injure the rectum. I then stitched the upper and lower edges of the vaginal mucous membrane by a continuous catgut suture. Beyond the first ring the vagina was funnel-shaped, and at about the level of the cervix was a second ring, of larger calibre than the first, admitting the points of two fingers. The portio was very small and short, and the anterior lip seemed to be continuous with the second ring (see Fig. 2). I made one attempt to dilate this ring, but did not persevere in my efforts as there seemed no special indication for its removal. I

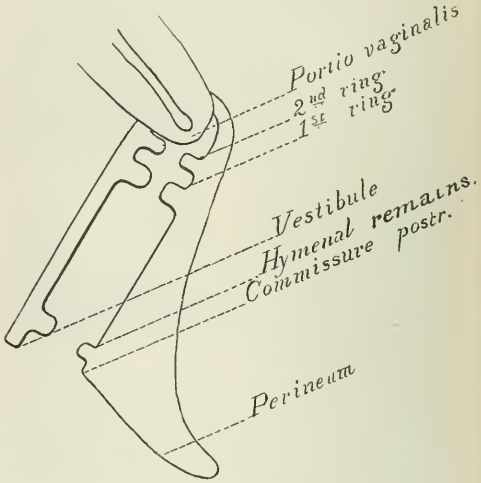

Fig. 2.

was desirous to dilate and curette the cervix, as there was some cervical catarrh, but experienced some difficulty in seizing the small cervix with the volsellum. With the aid and suggestion of Dr Rau the cervix was drawn down by catching hold of the second ring with the volsellum and making traction on it. A dilatation and curettage were then easily done. The vagina was packed lightly with iodoform gauze, which was removed in forty-eight hours. The patient was kept in bed for a week. At the end of that time the vaginal wound had healed by primary union. The vagina was now quite capacious, and the two examining fingers encountered only a small portion of the ring, which had not been excised. This now is fully obliterated. Coition ever since the operation has been satisfactory and unattended with pain to the woman.

The origin of individual cases of malformation of the vagina is always a matter of more or less doubt. It is not always easy to tell whether the pathological condition is congenital or acquired. During severe attacks of scarlatina, measles, and typhoid fever there may be an ulcerative inflammation of the vagina going on without being observed by the attendant physician. The local affection is entirely masked by the more severe and greater disease. As a result of the ulcerative process a ring-like stenosis may form, which may be smooth and homogeneous, having all the characteristics of a congenital formation. It may be well to remember, however, that in children it is usually the vulva and the region external to the introitus that are affected with inflammatory diphtheritis and ulcerative processes.[1] This view of the mode of origin of membranous stenosis of the vagina is based chiefly on what has been found to follow ulcerative processes in the vagina following labor. Some cases in multipara have been reported (Olshausen and Odebrecht[2])

[1] Henoch: Kinderkrankheiten, Auf. IV. Berlin, 1889.
[2] Centralbl. für Gyn., 1894, No. 5.

in which an annular constriction was found in the vagina, apparently showing no traces of cicatrization, and which, were it not for the prior history, might have been looked upon as of congenital origin.

Bearing all this in mind, and recognizing the difficulty in deciding in a given case whether it is congenital or acquired, I think it may be safely assumed that both of the cases reported to-night were congenital. In Case I. some doubt might arise, from the existence of a vaginal discharge at the age of five and seven years respectively. But this discharge was evidently no more severe than is frequently witnessed in young girls, and probably would not have excited the attention of the parents had it not been for its appearance at what appeared to them an unnatural age. A condition severe enough to be attended with an ulcerative process would not have been treated lightly by the doctor that had been consulted. In Case II. there seems to be no room for reasonable doubt. The patient had always been healthy as a girl, had had no severe illness, and had had no vaginal discharge. Still, the existence of a second ring, and a very small, poorly developed cervix would speak in favor of an ulcerative process. But this may have been, and no doubt was, of intra-uterine origin. In fact, Breisky [1] and others maintain that the cause of congenital vaginal stenosis is to be sought in fœtal inflammatory processes, and that they probably most often occur during the later period of intra-uterine development. On the other hand, some other observers, notably Dohrn,[2] hold that they develop in the same way as the hymen. A third theory is that they are due to anomalous development of Müller's ducts. Olshausen [3] claims that it is difficult to explain the origin of vaginal stenosis on the theory of an anomaly of development, and for this reason alone doubts their congenital origin.

The diagnosis offers but very little difficulty. The examining finger comes against a ring-like constriction in the upper part of the vagina, with an opening varying in size from a few millimetres in diameter to that which will admit the point of one or two fingers. An examination per rectum will reveal the cervix lying two or three centimetres above the constriction.

An apparent stenosis is not infrequently observed in pregnant women. It is situated in the upper part of the vagina, not far below the vault, and though the constriction may be considerable, it never offers an obstruction to labor. E. Martin already had called attention to it, and stated it was a constant occurrence in primiparæ at the sixth month of gestation (A. Martin,[4] Olshausen [5]). It is said to be produced by a pressing down of the vaginal vault, forming a duplicature of the vaginal wall.

The treatment usually adopted consists in forcibly rupturing the membranous ring, or making a crucial incision and stitching the torn or incised membrane together in the direction of the long axis of the vagina.[1] The crucial incision was the method followed in the first case, and seemed to me unsatisfactory in that it required considerable after-treatment with vaginal plugs to prevent recontraction and the immediate result was far from gratifying. It occurred to me in the second case that it would be better to excise the ring and stitch the upper and lower edges of the mucous membrane together, which I did. No after-dilatation was necessary, and the result was perfect. Union had taken place by primary intention. There was no constriction to be felt at the old site of the stenosis excepting a small portion of the ring that had been left on the anterior wall. In a similar case I would excise the whole ring, though now in my case scarcely a trace of any constriction can be detected. In fact anyone examining the patient now for the first time would find some difficulty in locating the site of the former stenosis. The late C. C. Lee, in his excellent article on Vaginal Atresias, in the "American System of Gynecology," [1] and, by the way, he also employs the paradoxical term "incomplete atresia," speaks of dissecting out the atresic bands. He followed this method in one case, but left the denuded surface to heal by granulation. "The process was slow, from the necessity of constantly maintaining effective dilatation, but by degrees it resulted in obtaining a perfectly formed vagina." In my search of the literature on the subject I find that Heyder,[2] in 1890, pursued very nearly the same course that I did. He divided the membranous ring into two by a Paquelin cautery, excised each half with the scissors, and brought the mucous membrane together by fine silk. Healing occurred in eight days. There was only a slight constriction to be felt afterward.

In cases where the stenosis is not too long, that is when its thickness is within moderate limits, excision of the constricting ring, with subsequent stitching of the upper and lower edges of the mucous membrane, forms, to my mind, the ideal method. The loss of blood may be reduced to a minimum by beginning with the continuous suture as soon as a small portion of the ring is excised, and following up the cutting with suturing. This plan I pursued in my case, and the hemorrhage was only trifling. By introducing a finger in the rectum and holding the urethra well up with a sound, there should be no danger of wounding either of these structures.

CIRCUMCISION—DANGERS OF UNCLEAN SURGERY.

By HENRY LEVIEN, M.D.,

NEW YORK.

Hebrew male children are generally circumcised on the eighth day of their birth. This operation is postponed only in case of the child's sickness, or when the babe, for some reason, is in such an enfeebled condition that it is feared the operation may prove fatal. Then it is postponed for a week or for a succession of weeks.

Circumcision is practised as a purely religious rite; the origin of its appearance is to be looked for in the sacred literature of the Jews, and as remote as the narrative of Abraham, the Hebrew, who performed the operation upon himself when ninety-nine years old; and since that time his descendants keep it up as a peculiar sacrifice which is acceptable to God. There are some allusions, in the ancient and pre-historic literature, to the effect that this operation has been performed for the sake of cleanliness. Herodotus (ii., 37) ascribes the origin of the custom to the Egyptians. The same cause is given on the authority of Philo the Jew; [3] other causes being avoidance of carbuncle, purity of heart. Sanitary reasons may have been the object in view; but this, as well as the previous considerations, are not very well accepted, for the reason that other nations of that epoch, not less intelligent than the Hebrews, have not accepted it.

Ethnographically considered, circumcision is of a Semitic origin, taken by the Hebrews most probably from the Arabs, though there are certain reasons to presume that the Egyptians were the ones whom the Hebrews imitated in this practice, the only inexplicable feature being, why do Hebrews circumcise on the eighth day, while the Arabs, Egyptians, and those small tribes practising it in the western hemisphere, perform the same on the approach of puberty.

To this short sketch we will add only that this operation was performed in ancient times, as seen in the Bible, with sharp-edged stones, and that a part of the foreskin only was removed.

How is circumcision performed at present, at the house of a Hebrew, under ordinary circumstances?

A look into the operating-room, and a short acquaint-

[1] American System of Gynecology, vol. ii., p. 27. [2] Loc. cit.

[3] Opera, ed. Maugey, ii., 210.

ance with its surroundings, as well as with the ceremony connected with the operation, I believe, will be of interest to those of my colleagues who have never witnessed it, and will probably never have the opportunity to do so. Allow me to preface the description by saying that there is no mystery connected with it, but certain peculiarities of a rather fanatic nature are adhered to, merely because it is a custom kept up for ages. As an illustration, I will mention the custom of hanging up slips of paper, written or printed, containing a psalm and some cabalistic names of some angels, designed to protect child and mother from the grasp of the devil. These slips are to be seen attached to the bed, walls, and doors of the bedroom, and remain there for about twelve weeks, the time limit for the satan to exert his demoralizing influence upon the new-born and his mother.

All religious ceremonies and prayers are best accepted by God when they are performed in the presence of at least ten adults (men, not women). When the eighth day approaches, friends are informed of the coming event, and are invited to be present at the ceremony and at the dinner following it. On this day the father attends church, where a special prayer is given and a hymn sung. In the rural districts the infant would be carried to the synagogue and there operated upon; but this is done mostly by the poor, whose apartments are too small to accommodate fifteen or twenty people. Otherwise, the father, accompanied by all his friends, goes home, where preparations are being made for the operation. The male guests find seats in the front room, which will serve as the operating-room, while the female relatives and friends crowd the bedroom, assisting to dress the baby. By "preparations" is not meant that nurses, or at least one nurse, is in attendance, preparing boiled water, sterilized towels, trays for instruments. Not at all. You see only crowded rooms, where the nearest relatives busy themselves by carrying pillows from bedroom into operating-parlor. One feels there is something remarkable going on, or something remarkable going to take place. To comfort the weary and hungry visitors the father, greatly agitated, goes from one guest to another, telling them that "he" will come soon.

By "him" is meant the chief personality of the day, the surgeon-in-chief, the Mohel. He is a busy man. The Hebrews are a prolific nation, and the surgeon performs often three or four operations in one day. But who is he? Where did he study? Why is he entrusted with the life of a human being? Nobody can tell. All we know is, that he witnessed this operation several times, and announced himself competent enough to perform the same. Generally, but not always, the surgeon is more or less conversant with the teachings of the Talmud, and especially with that part of it which treats of the anatomy of the generative organs. Lister, being born in this century, could not have imparted his ideas to the surgeons of the Talmudical era; consequently the Mohel, who receives his information on this subject from that source only, bravely goes to operate without any knowledge of asepsis and antisepsis. He has come. Fresh murmurs begin to circulate in the rooms; consultations are being held by husband and wife as to upon whom to confer certain honorary rites in handling the infant during operation. At last appointments are made. One man is to serve as the operating table (a highly honored position). This man will be seated on a high chair on pillows, and on his lap the baby will lie during operation. Next a young couple is appointed, generally a maiden and a boy; the first is to take the baby from the mother's hands and transfer it to the young man, who in his turn brings the child into the operating-room, and hands him over to the bystanders. Then the assistant surgeons are appointed. When the father reports to the Mohel that everything is ready, the latter calls the assemblage to order. The man-operating-table takes up his high position, the surgeon his place, the assistants crowding around him.

Now let us have a look into the surgeon's armamentarium. All you find is a wooden case-box, with one double edged knife in it. It is not hard to discover on the knife suspicious spots of dried-up blood, left from some previous operation or operations. I recently called the attention of the Mohel to the condition of his instrument, upon which I discovered a few bloody spots; to satisfy me he tried to rub the blood off with his finger-nails, and believed asepsis was fully attained. I was compelled to interfere and make him do what I considered proper. The operation in its primitive form, as will be seen later, is divided into four parts, each being performed by a separate individual, though improvements and modifications are being instituted.

The signal is given. The baby is on its way from the bedroom, and when it reaches at last the operating-room, the Mohel meets it with a phrase: "Blessed be he who has come!" which is repeated by all present. The baby is kept on a pillow, and in this state it is placed on the lap of the high-positioned man. The operation begins. The surgeon goes to work. There is no washing of hands, no scrubbing of finger-nails.

First part: The surgeon steps bravely forward, adjusts the baby in the right position, and baring the penis, grasps the foreskin with the thumb and forefinger of his left hand, says a prayer, and cuts it off. His work is done. He steps aside to give place to No. 2, who with the pointed nails of his thumbs tears and divides the mucous membrane covering the glans and pushes it backward to the corona. When this is done, forward steps the third party, who takes the bleeding, tender organ into his mouth, which is never cleaned before, and may be full of decayed teeth and purulent gingivitis, and sucks it three, four times, spitting the blood into a specially prepared receptacle with some special (Palestine?) sand in it. Into the same is placed the cut-off foreskin.

Fourth. The surgeon-in chief resumes his duty again, and an attempt is made to dress the wound. It consists in placing a handful of some pulverized decayed wood which is supposed to have astringent power, and covering it with some rags.

To quiet the child during and after the operation, it is customary to put a rag with some predigested food into the infant's mouth, thus preventing him from yelling too much.

Now the child is taken from the operating-table and transferred to some honorary member of the assemblage. A prayer is sung by the Mohel, while keeping a glass of wine in his right hand, and when a certain point in the hymn is reached, he wets the tip of his left-hand little finger in the wine, and saying, "Live with thy blood," he smears the lips of the infant with it. At the same time the name is officially given to the child, he concludes his prayer, drinks the wine, and the ceremony is at an end. The child is now again handed over from one to another, until it reaches the young man, who transfers it to the young lady, the last returning the baby to the anxious mother. Tables are now set in the operating-room, and the feast begins. The dangers of infection the new-born has been exposed to may be seen by the readers themselves.

The improvements in this procedure, as mentioned above, are being instituted in large cities only, where the Mohel comes in closer connection with the physician, and consist in the following modifications: The Mohel does the whole work himself, and instead of sucking with the bare lips, he employs a glass tube through which the suction process is performed. The advanced surgeon uses also a metal plate with a long and narrow hole in it, and uses it as a clamp; he pulls the foreskin through the hole, pushing meanwhile the plate toward the glans, thus protecting the last from direct injury. Again, instead of the traditional powder, plain or even iodoform gauze is used for dressing. But this additional instrument, the plate, serves very often as a new source of infection. I found on this metal piece dried up blood, and had to insist on its disinfection.

I will cite now two cases I recently came across,

which, I believe, will serve, on one hand, as an illustration of the dangers the new-born Hebrew children are exposed to; on the other hand, with the above considerations and the following facts in view, they may be treated as a friendly warning and advice to those of my colleagues who are engaged in obstetrical practice among the Hebrews, to make it their business and a matter of conscience to be present at every operation, and supervise the whole procedure.

CASE I.—I was called to see child R—— on the 30th of March. Infant, aged thirteen days, was circumcised on the 25th; child was not well since operation, but became worse on the 28th. The Mohel was then called in, who ordered an ointment which did not do any good.

Present state: Acute inflammation of the penis, erysipelatous œdema of scrotum and on pubic region. In the cervix, behind the glans, I detected a small ulcer, which was probably the nidus of infection. Temperature, 105° F.; pulse, 160; respiration, 60. Child very restless, crying as if in great pain. Every time the child would pass urine it would scream and have convulsive movements.

March 31st.—The dressing and local applications I ordered seemed to control the pain, but the erysipelatous process was not arrested, and spread farther up, reaching a point midway between the symphysis pubis and umbilicus. Slight diminution in the œdema of scrotum. Temperature and pulse not changed; respiration labored.

April 1st.—Child is reported to have had two distinct convulsions; was very restless. The abdomen very tender on palpation; slight tympanites; redness up to the umbilicus. Baby too weak to nurse; pulse hardly perceptible at the radial artery. There was certainly very little hope to save the child, and I told the parents my opinion.

April 3d.—Have seen the child at 2 P.M. The lower abdomen, penis, scrotum, and upper part of both thighs, cyanotic, just as if gangrene had set in. Child died at 4 P.M.

CASE II.—I was called by a Mohel to see a baby whom he operated upon the same day. The trouble, severe hemorrhage somewhere on the penis, which hemorrhage he could not control by any means known to him. He was very anxious, and justly considered himself responsible. On arrival I learned that the child was bleeding the whole day and had lost about three ounces of blood. It was very hard to locate the bleeding point, as the penis was wrapped up in rags, soaked in a solution of liquor ferri chloridi, and on removing the rags the whole penis appeared dark and swollen. At last I discovered the artery of the corpus cavernosum eroded and laid open at the internal layer of the prepuce. It took considerable time to secure the vessel and compress it, on account of the swelling and tenderness of the parts. Having applied an antiseptic dressing, I left, instructing the mother to call me at once if the hemorrhage recurred. When I called on the next day I found the hemorrhage stopped, the swelling less, but ulcerations of different degrees traversing the mucous layer and the glans. The erosions were caused probably either by the misapplied dressing, or while pushing the mucous membrane toward the cervix. The child recovered.

In view of the above considerations and other facts, the question presents itself: Shall the medical profession and boards of health look upon these mutilations from the hands of ignorant people indifferently, or shall we join with the State of Ohio in introducing a bill prohibiting circumcision entirely?

In attempting to solve the question we should carefully consider the *pros* and *cons* before expressing a positive opinion. I will therefore lay before the medical world some considerations for and against prohibition.

For prohibition speak partly the facts and morals of this paper, *i.e.*, injuries and even death inflicted upon the new-born; secondly, humanitarians find circumcision an act of cruelty and barbarism, especially as practised among the poorer classes of Hebrews.

Thirdly, many consider the whole procedure entirely unnecessary, and in proof of it say that hundreds of millions of people live and prosper, not being circumcised.

Against that bill the following reasonings suggest themselves:

First, circumcision is a religious rite, besides being a custom of a race for about three thousand years, and we believe that no free government has the right to intrude upon anybody's religious convictions.

Secondly, it is a recognized fact that the Jews are less, than uncircumcised nations, prone to venereal ailments, and when so affected are sooner cured than others. Phimosis and paraphimosis, due to venereal infection, is almost unknown among the Jews.

Thirdly, the operation itself, in the hands of skilful and intelligent men, is not a severe one, and children bear it well; and,

Fourth, I would hesitate to stop a process, though a depletory one, in a nation in whom the depletion for hereditary reasons may be a necessity for the well-being of the race, and may prove disastrous if this operation is denied.

There are but few men of the younger generation who have decided to do away with circumcision on their children, and we cannot draw any conclusions yet. I, for my part, would suggest to meet the question in such a way as, on the one hand, not to offend the religious sentiments of a people by passing State laws on their behalf; on the other hand, to protect the innocent young ones from maltreatment.

This could be materialized by introducing a bill prohibiting, not circumcision, but "circumcisers," from performing operations in the way they do now, and passing a law that, at each and every operation, a duly registered and practising physician shall be present, or such physician should be sent from the local board of health. The physician shall superintend the operation, and shall be the responsible party.

Certainly no good can be attained by licensing circumcisers, having them undergo a certain examination, etc. The licensed midwife furnishes us a good example of things half done. Midwives, being allowed to go on in their practice so far, will always take one step further, and a good deal of mischief to the patients under their care is the result. Circumcision is an operation requiring as much care and dexterity on the part of the surgeon as in any other surgical work, and should be performed by a competent surgeon, or at least under his direct supervision.

239 EAST BROADWAY.

The Comma Bacillus and Cholera.—A statement has appeared in more than one of our lay contemporaries of the death from Asiatic cholera of Dr. Oertel (who must not be confounded with the distinguished Munich professor), of the Hygienic Institute at Hamburg, while engaged in bacteriological investigations of specimens of infected water from the Vistula. It is said that he succeeded in making cultures of the cholera bacilli from this water, and in one account it is circumstantially related how he introduced into his mouth a minute portion of the cultures, and, although recognizing the gravity of the accident and resorting to the free use of germicides, he developed symptoms of the disease, which rapidly proved fatal. If substantiated, this sad occurrence not only adds one more to the list of fatalities among experimental investigators, but would form a verification of the value of Koch's discovery; for, although more than one experimenter has ventured to swallow these bacilli with impunity, their negative results cannot weigh against a clearly proved positive one. It is, of course, quite as likely that the disease was contracted in another way, and that the case affords another of the numerous coincidences in which medical history abounds.—*The Lancet.*

A PLEA FOR IMMEDIATE CŒLIOTOMY IN RUPTURED TUBAL PREGNANCY.[1]

By CHARLES E. NAMMACK, M.D.,

NEW YORK.

THE object of this communication is to endeavor to remove the impression existing in the minds of many medical men, that ruptured tubal pregnancy does not require immediate cœliotomy. This impression seems to be founded on the old teaching that when the sac ruptures in the early weeks of pregnancy, the escape of blood may be moderate and run the course of ordinary hæmatocele. Even so recent a book as the "American Text-Book of Surgery" says (p. 972) that when the hemorrhage is into the connective-tissue interspaces of the broad ligaments, the treatment should be purely expectant, but that intra-peritoneal hæmatocele requires abdominal incision, etc. It also gives the differential points between the two varieties of hæmatocele, but the average practitioner who waits until this differential diagnosis shall be demonstrable, will, in the average case, have waited until his patient has lost more blood than she can regain.

However doubtful and problematic the diagnosis of tubal pregnancy in its early stages and prior to rupture may be,[2] there is fortunately a very clear clinical picture presented after rupture has occurred. The marked symptoms are summed up by Joseph Price,[3] and form a group which should be promptly recognized and immediately treated by primary operation in all cases. Price's statistics show ninety-six per cent. of recoveries in personal cases operated on, as against fifty per cent. recoveries in the cases of others when treated expectantly. Duhrssen [4] reports twenty-nine cases of cœliotomy for ruptured tubal pregnancy, with three deaths—almost ninety per cent. recoveries.

It has been the writer's lot to see the consequences of delay in two cases since January, 1893. The first of these he reported in the MEDICAL RECORD of March 18, 1893, p. 348. It was a case in which the surroundings and previous history of intra-pelvic suppuration in the patient were considered by two eminent gynecologists to be sufficient reasons for postponing operation until patient could be moved to a hospital. But the hemorrhage recurred in a very few hours, operation was performed by a third consultant, when all hope had been abandoned by the patient's relatives, and she was literally snatched from the jaws of death. The second case emphasizes so clearly the lesson taught me in that first case that the recital of it may help to firmly fix in the minds of others the conviction that a woman with a ruptured tubal pregnancy should not be left until it is extirpated.

Mrs. Mary L——, thirty-five years of age, consulted me September 8, 1893, and was found to be suffering from tuberculosis of the lungs and larynx. She was treated at intervals until April, 1894, the pulmonary process not advancing beyond the stage of consolidation, and during this time her menstrual periods were regular. Her last child had been born seven years before. She went two weeks over time in April, 1894, but the desired flow finally came in response to hot foot-baths, etc. She then menstruated regularly and normally in May, June, and July, her last flow beginning July 13th. On September 3d she felt a sharp stinging pain in right groin, followed by slight show of blood. The pain yielded to recumbency and the application of a hot-water bag and the patient was up and around next day. On September 16th she lifted a basket of coal from the elevator and immediately the pain recurred, she became nauseated and faint, and had another slight bloody vaginal discharge. The pain after this being persistent, and the weakness and fainting attacks progressive, she sent for me September 21st, and, pending my arrival, called in a neighboring physician, who told her he suspected tubal pregnancy. The evidences of rupture and internal hemorrhage were plain at the time of my visit. Surgical assistance was at once summoned, and upon the arrival of the operating surgeons a consultation was held. My opinion that an immediate operation was demanded was overruled, the other men being unanimous in the belief that the hemorrhage was limited to the layers of the broad ligament, and, therefore, extra-peritoneal, and that nature would be competent to absorb it, or that, at least, expectant treatment was justifiable. The next morning that patient went into collapse from recurrence of the concealed hemorrhage, and there was no longer any difference of opinion as to the proper procedure. Preparations for immediate operation were hastily made, chloroform being chosen as the anæsthetic on account of patient's pulmonary condition, and because vomiting had become a prominent symptom. Abdominal incision revealed a quantity of loose clots and fluid blood, estimated by the operator at three quarts, and a ruptured tubal pregnancy with the fœtus protruding. The ovum was developed so close to the uterus that the extirpation was difficult and tedious, and the patient's pulse stopped when it was finished. She rallied under inhalations of amyl nitrite and the hypodermatic use of strychnia and brandy, with injections of hot salt solution into the cellular tissues and rectum. During these procedures, the operator flushed the abdominal cavity, clamped the cut end of the tube at the uterine junction, and packed with iodoform gauze without waiting to suture the tissues. The patient was then put to bed, collapsed from hemorrhage. Despite all efforts and efficient nursing, she never rallied, and died fifty-two hours after operation. What the result would have been under operation twenty hours earlier cannot be positively stated, but there is no doubt that a recognition of, and prompt operation for, her condition on September 3d, when the first symptom appeared, would have saved her life.

And now a word as to the different indications for treatment, depending on whether the rupture is intra-peritoneal or extra-peritoneal. According to the "American Text-Book of Gynecology," p. 541, "the safest rule is to prepare at once for operation," if intra-peritoneal rupture has occurred, but if the hematoma is extra-peritoneal, "the treatment is usually non-operative," p. 542.

This leaves the patient exposed to the fourfold dangers of 1, recurrent hemorrhage; 2, peritonitis; 3, septicæmia; 4, subsequent trouble in the damaged tube. While not denying the possibility that a pelvic hematoma may remain extra-peritoneal until it is absorbed, the writer considers that the probability of recurrent hemorrhages causing it to burst into the peritoneal cavity is so great as to make primary operation the only safe procedure. On this point Joseph Price [1] speaks with no uncertain sound when he says: "With an experience of eighty-three sections for ectoptic pregnancy, I remain in surgical ignorance of extra-peritoneal hæmatocele, not a single case did I encounter." Mundé's experience with twelve cases of ectopic pregnancy [2] form an interesting study and show the value of prompt operation.

A Census of Medical Men in Alsace-Lorraine shows that there were in those provinces in the first of this year 619 physicians, 10 diplomaed dentists, 123 veterinary physicians, and 230 pharmacists. Of the physicians there were 529 with German, and 90 with French diplomas.

A Cure for Dyspepsia.—A minister in Ohio was deposed some months ago on account of immorality. He admitted the charge of having had irregular relations with some of the women of his flock, but defended himself on the plea that his physician had recommended it as a cure for dyspepsia.

Progress of Medical Science.

Cardiac Syphilis and Angina Pectoris.—At the Berlin Medical Society Dr. A. Fraenkel recently demonstrated a specimen of cardiac syphilis from a woman, thirty-six years of age. When first seen last year, she had aortic regurgitation and suffered from frequent headaches, which were occasionally associated with fainting attacks. The heart disease was supposed to be consequent on acute rheumatism. The husband was syphilitic, and the woman herself had suffered from swellings on the head, which had ulcerated and left scars. She improved at first and left the hospital, but was readmitted this year with severe attacks of angina pectoris, in one of which she died. At the necropsy the left coronary artery was found quite permeable, but the orifice of the right coronary was completely obliterated by a process of arterio sclerosis (much in excess of the patient's years), and its proper position could only be determined by probing backward along the lumen of the artery. There was a gummatous tumor, 4½ ctm. long, in the septum ventriculorum, and Fraenkel thinks this shows that the arterial changes were really of syphilitic nature. The arterio-sclerotic changes in the aorta reached down to the bifurcation. Fraenkel, moreover, remarks on the part played by syphilis in the etiology of aneurisms. Walsh thought that sixty per cent. of true aneurisms were due to syphilis, others think still more. Fraenkel himself, during the last four years, has seen 19 cases of aneurism of the thoracic aorta in which there were necropsies; 3 cases were in women, 16 in men. Of the 19 patients, 9, that is, forty-seven per cent., had had syphilis, and these were all under fifty years of age. The case illustrates the relation of precocious arterio-sclerosis and syphilis.—*Berliner klinische Wochenschrift.*

Pancreatic Colic.—Dr. Minnich has observed a case of this kind in a man sixty-eight years of age. At the age of forty he became troubled with attacks of colic which were attended with jaundice, and continued during a period of three months, but disappeared upon treatment. In the stools were found typical biliary calculi. There then followed a period of freedom from attacks for ten years and a half, when attacks of colic recurred. These again yielded to suitable treatment. Seventeen years later the man was suddenly awakened at night by an attack of colic resembling previous attacks. A second attack took place on the next day, and a third several months later. At this time there appeared a sense of oppression in the epigastrium, together with loss of appetite and distaste for fluids. This condition persisted for about a month, without the occurrence of an actual attack of colic. At the end of this time the man was seized with diarrhœa, lasting for three days, and ending with an attack of colicky pain, referred to the left hypochondrium and to the epigastrium. The patient was well nourished, and presented no œdema. The scleræ were a little yellowish and the skin dry and of normal warmth, but not icteric, although the seat of annoying itching and a chronic desquamative eczema upon the exterior surfaces of the arms. The temporal arteries were slightly tortuous, but there was no other evidence of arterio-sclerosis. There was an absence of abdominal tenderness, so that deep palpation could be practised, but without yielding positive information. The liver was not enlarged, and the gall-bladder could not be appreciated. The spleen was likewise not palpable, and the area of splenic percussion-dulness was not increased. There was no evidence of dilatation of the stomach, and a peritoneal effusion could not be detected. The patient described the paroxysm as beginning with a sense of dull, heavy, constricting pain above the epigastrium and in the left hypochondrium, increasing in intensity and localizing itself deeply in at one point below the left costal margin, just within the mammillary line. At the height of the attack the pain extended from this point circularly to the vertebral column in the course of the costal arch, thence radiating beneath the left scapula. At the termination of the attack pain was still perceptible at the point below the costal margin, in an area about an inch and a half in diameter. Careful exploration of this region failed to disclose any morbid condition, excepting slight tenderness. The attack abruptly came to an end at the expiration of two hours, and was followed by a sense of hunger. The urine passed at this time was free from albumin and sugar, and did not respond to tests for biliary coloring matter. From this time the attacks were repeated almost daily, usually setting in toward the end of the day and lasting from a fraction of an hour to several hours. The condition resisted the ordinary treatment for hepatic colic. An examination of the stools failed to disclose the presence of fat or fatty crystals, or biliary calculi. On several occasions, however, light-gray, round calculi were found, which could be crushed between the fingers, and microscopically proved to be constituted of amorphous matter. They dissolved in chloroform, leaving a turbid solution. They fused in the flame, giving off a dense vapor having an aromatic odor. The residue yielded the reactions of calcium carbonate and calcium phosphate. Subsequent attacks of pain occurred, but no more calculi or other abnormal matter was found in the intestinal evacuations. The condition was regarded as one of calculous formation resulting in obstruction of the excretory ducts of the pancreas, and giving rise to attacks of colic. The subsequent history of the patient is not given, however, and the diagnosis therefore lacks confirmation.—*Berliner klinische Wochenschrift.*

Valerianate of Amyl.—Dr. Blanc describes valerianate of amyl, which is the odoriferous principle of the apple, that is, the essence extracted by distillation together with alcohol. Cider has long been believed by the laity to have some effect on calculous formations, and this seems to be borne out by the fact that valerianate of amyl really has some solvent action on cholesterin. It is a colorless liquid, of pleasant taste when taken in small quantities, and can be prepared in the laboratory by the action of valerianic acid on amyl alcohol; 1 grain of cholesterin is dissolved by 4½ grains of valerianate at 37° C. and by 3 grains at 40° C. (*British Medical Journal*). Physiologically the action resembles that of ether, but the special qualities lie in its being a stimulant and sedative to the liver in cases of hepatic colic. It not only immediately subdues the attack, but it prevents recurrences. If the stomach is irritable, it may be necessary first to employ sulphuric ether, following this with two to three capsules of fifteen centigrammes each, given every half-hour until the crisis is past, and continued at longer intervals during the following days. In nephritic colic the drug acts as an antispasmodic and general stimulant only, but no effect is produced on the renal calculi. Muscular rheumatism is frequently relieved, and much benefit is also derived from its use during menstrual uterine contractions. As a sedative, it is of value in hysterical manifestations. Its toxic properties being very slight, as many as five to six capsules can be taken daily, but it is necessary to guard against gastric disturbance.

Syphilis and Aphasia.—Dr. Jolly reported at the Congress of German Physicians, Vienna, a case of cerebral syphilis in which he was able to demonstrate by autopsy the dependency of word deafness and aphasia on a complete destruction of the entire parietal lobe, the two first temporal lobes, the angular gyrus, præcuneus and cuneus. The patient was unable to read his own name, to write from dictation. The word deafness Jolly considers was due to the lesion in the temporal lobe, and the loss of speech possibly to the entire destruction of the auditory centre and areas.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 17, 1894.

THE CHANNELS OF INFECTION IN TUBERCULOSIS.

THE subject of tuberculosis is to-day the gravest one with which the physician has to deal, and the necessity of lowering its frightful mortality by preventing it, rather than by treatment, was never more keenly appreciated.

Although the general principles of infection have been well worked out, the channels of infection is a subject that pathologists are not entirely agreed upon. Dr. Sims Woodhead has recently made a communication in *The Lancet* which has contributed much to our enlightenment. He concedes that the tuberculous virus may be directly inoculated into the tissues, but this condition is comparatively very rare. Heredity, to which has been attributed such an important rôle in the past, plays an altogether unimportant part in the spread of tuberculosis, ranking only with such factors as insufficient and imperfect food, and defective hygienic conditions.

Tuberculosis attacks the lungs and alimentary canal by preference, because it is here that the bacillus most easily finds the moist mucous membrane with defective epithelial covering for which it has a special predilection. When the tubercle bacillus is carried into the alimentary canal by the saliva, by food-stuffs, etc., it is rendered innocuous in more ways than one; but perhaps the most effectual way is by its being taken into the substance of lymphocytes, which make their way out and in from the lymphoid patches, and which have the power of taking into their substance the tubercle bacilli. These lymphocytes return with their evil burden to the lymph-glands, and the glands assist in the complete destruction of the bacilli. This is the performance that is continually going on, and as the result infection, local and systemic, is prevented. If, however, the lymphoid patches be devoid of epithelium, or if the tissues be so weakened that their power of resistance can be readily overcome by comparatively few micro-organisms, then infection will probably follow. Masses of adenoid tissue, whatever their situation, if the cells are active, are means of protection, in so far as they consist of an enormous number of active cells which are capable of taking up large numbers of micro-organisms.

Masses of adenoid tissue are found at the entrance of the two great avenues through which the tubercle bacillus most commonly seeks entrance to the system, viz., the alimentary and respiratory. In certain animals and in man there is a ring of lymphoid tissue surrounding the entrance to the larynx, and a similar ring surrounding the entrance to the œsophagus. In the pharyngeal tonsil we have simply an enormous local development at the two poles of the latter ring. So long as these tonsils, with their accessory lymphoid tissue forming the protective ring for the pharynx, remain healthy, or so long as they are not attacked by an extraordinary number of micro-organisms, they are capable of resisting attack, and of dealing with micro-organisms even of what would be called a most virulent type.

When the lymphoid tissue is diseased, then it may serve as the locus of infection. The lymphoid cell returning with its burden of a tubercle bacillus, is taken into the tonsil or the adenoid tissue in that vicinity, where, under healthy conditions, it is destroyed or disintegrated. In its depraved state it cannot destroy the bacillus, but, on the contrary, the bacillus liquefies the lymphoid cell, the protoplasm of which then serves as a nutrient medium for the bacilli. This infection does not take place in the tonsil so frequently as in the glands which lie beyond the tonsil, and which the leucocytes include in their itinerary when returning to the circulation.

In cases where there is no distinct lesion in the tonsil itself, it must be held that the leucocytes, although able to take the bacilli into their substance, have not been able to kill them, and then they carry the bacilli to the gland in its immediate neighborhood, where they succumb, and infection takes place at this point. A multiplication and reinforcement of the bacilli by their progeny at this point, will carry the infection farther, with the result that a chain of lymphatics and lymph-glands has ultimately become affected.

In many of these cases the process can be traced from the glands in the tonsil down into the neck, and so on to the thorax, by the mediastinal and post-sternal glands and by the intercostal lymphatics and glands.

What has been stated concerning the lymphoid tissue of the tonsils and surrounding cervical glands, might be repeated almost *verbatim* for the lymphoid patches of the intestine and mesenteric glands.

The very cells, then, which in health have to do with the destruction of bacilli, and with protecting the organism against their invasion, are those which appear to be immediately responsible for the conveyance of tubercle bacilli from the outer surface to the tissues beneath.

The rôle played by the tonsil and the surrounding lymphoid tissue is, therefore, seen to be a very important one in preventing or facilitating infection in tuberculosis. An important lesson to be learned from this is, that tonsil has an important function to perform in the economy, that endeavors directed toward keeping it in a physiological condition, militate against the dangers of tuberculous and other infection, and that its removal other than for disease which might predispose it to infection, is hazardous.

Scarcity of Doctors in the Chinese Army and Navy.—The horrors of war now going on between China and Japan appear to be greatly accentuated by an almost inhuman lack of medical men on the Chinese side. From a letter of Captain M'Giffen, Commander of the Chinese war-ship Chen Yûen, we learn that there are only two Chinese doctors to twenty ships and an army of over 300,000 men.

SMALL-POX FROM CRADLE TO COUNTER.

The fourteen victims of small pox who sailed up the East River on Monday morning last, *en route* for North Brothers Island, furnish a most instructive object-lesson. In the first place, the number was considered unusually large for this city to furnish at one time, indicating that the disease is becoming rare as compared with former periods. Secondly, the subjects all came from a very circumscribed quarter of the city's area; and thirdly, they had all contracted the disease from the same source: a sick baby in the rear of a grocery shop, the mother going from cradle to counter, waiting upon the customer and then upon the child again, until she had sent out the germs to the whole neighborhood along with their purchases of tea and sugar.

A NEW DEPARTURE IN MEDICAL JURISPRUDENCE.

The *American Journal of Insanity* for October publishes three articles by eminent alienists all bearing on the topic which heads this editorial. The departure referred to was connected with the trial of a man named Schneider, a resident of Washington, D. C., who murdered his wife and brother-in-law in January, 1892. He was tried in March of the same year, and condemned to death, no plea of insanity having been put in at the time. The decision was confirmed by a Court of Appeal. In the following fall, a stay of proceedings was granted on the ground of alleged insanity. In January, 1893, the Supreme Court of the District of Columbia, consisting of Chief Justice Bingham and Justices Hagner and Cox, ordered that a commission of experts, consisting of Dr. Allan McLane Hamilton, Dr. John B. Chapin, and Dr. Charles L. Dana, be constituted, with power to examine the prisoner and also employees and officials of the jail in which he was confined. Counsel for the prisoner was also permitted to secure the services of three experts with authority to make special examinations. After the investigation by the experts had been finished the case was tried before the full bench, but without a jury. The prisoner's counsel brought forward his witnesses, including his medical experts. The examination of these latter gentlemen was made for the most part by the experts appointed by the court. The prosecuting attorney then presented his evidence in favor of the prisoner's sanity. The whole proceedings lasted over a week. At the end the Commission appointed by the court made a report in which they unanimously reached the conclusion that the prisoner was not insane. The judges, basing their opinion upon the evidence given at the trial and upon the report made by the Commission, found the prisoner sane and he was executed.

The comments upon this new mode of judicial procedure are made by Dr. John B. Chapin, Superintendent of the Pennsylvania Hospital for the Insane, who was one of the Commission, and by Drs. W. W. Godding and E. N. Brush, who were both experts for the defence. These gentlemen all speak, on the whole, favorably of the method. It is suggested that there was no need in such a procedure for the appointment of experts for the defence, and also that there should be opportunity for the prisoner to appeal from the decision of the Commission if it was unfavorable to him.

Dr. Brush says: "I think I voice the sentiments of all my associates called as experts by the counsel, by the prisoner, that never has it been our experience to have a more fair, considerate, and, touching the case at hand, more intelligent examination than in this case. . . . The examination was undertaken in a dignified manner, and attracted the closest attention of the court. It was undertaken, not with the intention of producing contradictions, or of surprising the witnesses into making faulty or questionable admissions, but to get at the facts of the case and the processes by which the witnesses reached their conclusions. In these respects the inquiry was satisfactory and admirable."

The new departure in medical jurisprudence is one which reflects credit upon the Supreme Court of Washington. While it may need some modifications it is one which deserves the attention of those who desire to see justice secured in difficult medico-legal cases.

READING NOTICES IN MEDICAL JOURNALS.

In these times of intense commercial activity it is not strange that, even the most reputable and high toned chemists and manufacturers of pharmaceutical preparations should seek every legitimate means of commending their products to the medical profession, who are their chief customers. The time has been, and past, when the leading dailies and monthlies of this country did not hesitate to insert in their papers editorial commendations of articles advertised in their columns. It may probably be said with absolute correctness, that none of these at the present time insert anything of this sort without having appended to it in italics the abbreviation "Adv." It seems to us that it is particularly incumbent upon the editor of a medical journal, that he should keep his pages so clear from any suspicion even of anything which would appear to be in the interest of those who advertise in it, that his subscribers may feel the most implicit confidence in his desire to supply them only with that which is distinctly in their interest. It is no doubt a fact that oftentimes preparations advertised by first-class houses are worthy of high commendation, but if once it is found that an advertisement is the means of obtaining directly, or indirectly, editorial notice in any medical journal, the confidence of the patrons of such a journal in its disinterested presentation of scientific facts must surely be more or less weakened. No editor is in a position to speak well of one, and not of another. The only safe course, the only possible course, is to adhere to an inflexible rule, to admit no article and to print no editorial which either favors or condemns the wares of any advertiser. With all the care which is exercised to prevent the insertion of articles which even accidentally commend or condemn, sometimes by inference only, goods advertised in the pages of this journal, articles sometimes creep in which violate this rule, and give not only a great amount of trouble, but have again and again caused the loss of thousands of dollars by the withdrawal of advertisements which were being paid to us by first-class advertisers, responsible houses, worthy the trust and confidence of the profession.

Holding these views as to the proper conduct of a medical journal, we notice with regret that one of our esteemed contemporaries has recently published, not only an article highly commending the product of a house ad-

vertising in their pages—with which house or product we have no controversy whatever—but it has also, most strangely, commented favorably in an editorial upon the same article. We have no doubt that this is eminently satisfactory to the advertisers, but cannot believe that it will increase the respect to which the usual conduct of this journal entitles it.

The true value of any journal to an advertiser is not only the extent of its circulation and the character and standing of its subscribers, but equally, if not more so, the estimation in which a journal is held for absolute impartiality and fairness toward all, and its single eye to the interests of its subscribers.

THE DANGERS OF BUTTER AND BREAD.

A short time ago we called attention to the investigations of certain Swiss and Italian bacteriologists, who showed that the butter of the markets was not sterile, and might contain pathogenic organisms. Now it appears that bread is not sterilized by baking, and takes its place with butter as a possible germ-carrying food. It would be sad indeed to find that the staff of life was really a staff of death, and that the very fundamentals of plain and happy living, bread and butter and kisses, were really things of evil, except under conditions of perfect asepsis.

Drs. F. J. Waldo and David Walsh (*The Lancet*) have made cultivations from sixty-two loaves of bread taken from various bake-houses in London. Someone of thirteen kinds of bacteria were found alive in all these loaves. Here is the appalling list:

Bacteria (or their Spores) found in a Living Condition in Freshly Baked Loaves of Bread: Bacillus subtilis, Variety 1 (hay bacillus); bacillus subtilis, Variety 2 (hay bacillus); bacillus subtilis, Variety 3 (hay bacillus); sarcina (*a*), large; sarcina (*b*), smaller than (*a*); bacillus A (large, thick, rounded ends); bacillus B (large, thick, smaller than A); bacillus C (small, copious spore formation); bacillus D (smaller still, some spore formation); bacillus E (bacillus figurans); micrococcus A (small white colonies); micrococcus B (rosaceus (?), accidental); staphylococcus (very regular, larger than staphylococcus aureus).

From a number of experiments made on loaves baked in a small laboratory oven, it was found that: 1. The average maximum temperature in the middle of an ordinary quartern loaf during baking, varies from 163.4° to 186.8 F., and in small loaves from 186.8° to 203° F. 2. There is a steady increase of temperature in the centre of any loaf during baking; thus, in a quartern loaf during one hour it rises from 25° to 75° C., and in a half-quartern loaf from 25° to 88° C. during the same time. For the first forty minutes the maximum temperature is probably not more than 48° or 50° C. The practical inference is that any organisms that might be present in the centre of a loaf would be exposed for a short time only during baking to a maximum temperature of 73° to 86° C. (163.4° to 186.8° F.) in a quartern, and of 86° to 95° C. (186.8° to 203° F.) in a half-quartern loaf.

It is known that most bacteria are not destroyed by an exposure to the temperatures above mentioned as the average for the centre of a loaf during baking. The death-point of bacteria has been generally expressed by Koch and Wolfhügel in the following passage: 1. Sporeless bacteria are destroyed in one and a half hour by hot air at a temperature slightly exceeding 100° C. (212° F.). 2. Spores of fungi require one and a half hour at 110° to 115° C. (230° to 239° F.). Spores of bacilli require three hours at 140° C. (252° F.). It should be noted that these statements apply to dry heat only. In the middle of the loaf there is presumably moist heat, which is, of course, more destructive to organisms, and on that account we must make a considerable reduction in the figures of Koch when we apply them to fungi and their spores inside a loaf.

The authors draw this significant conclusion:

We see no particular reason why the origin of many mysterious septic invasions of the human body may not eventually be traced to the agency of bread. A generation ago milk was not suspected of being the means of spreading disease, and a similar observation applies to water. At any rate, the subject dealt with in this paper seems to us to be well worthy the attention of all who are interested in the scientific developments of preventive medicine, no less than in the protection of the public that consumes the bread.

No specific remedy is suggested by the writers, except that bake-houses and bakers should be kept clean, and that the whole process of bread-making be placed under sanitary control.

BERI-BERI IN NEW JERSEY.

It is not often we are called upon to announce the presence of beri-beri in or about New York. On several occasions, however, during the past few years, one or more cases have been discovered among the crews of incoming vessels. It is on this account, and especially because of the very fatal nature of the disease, that interest is awakened just now in the ill-favored human cargo of a vessel from Navassa, which has entered port at Perth Amboy. Four had died during the trip, several have since succumbed, and ten or more are ill. There seems to be no doubt that faulty hygiene and lack of suitable food were the factors determining the outbreak. Beans furnished the principal food, it appears, during the two weeks' voyage, and, strange as it may seem, this is just the article of diet which Dr. Simmons recommended in a monograph on the subject in 1880.

One of the chief symptoms is a condition of pronounced feebleness, and it is this which gives the name, made emphatic by repetition. Other symptoms, according to Aitken, are: "Anæmia, culminating in acute œdema, and marked by stiffness of the limbs, numbness, and sometimes paralysis of the lower extremities; oppressed breathing; a swollen and bloated countenance." The urine is secreted in diminished quantities, the œdema is general, and effusion of serum into the serous cavities often occurs. Muscular spasms accompany the acute dropsy. Some of the older authors have supposed the epidemic affection to be confined to Japan, while others have looked upon it as a disease peculiar to Malabar and Ceylon.

Such instances as the present would tend to show that misery and privation go far to determine an outbreak in any quarter, though the chief endemic centres are in China, Japan, and India. In 1886 a vessel arrived in

New York from Hong Kong, with twelve out of the crew of eighteen affected with what was supposed at the time to be beri-beri. Several died, including the captain. The food and water were in this instance found to have been far from wholesome.

Recent studies would indicate that the nature of the disease is a multiple neuritis, and not being contagious, there seems no fear that it will spread beyond the unfortunates who, in returning home from a life of hardship, were subjected to most unfavorable conditions.

THE "INEXCUSABLE ATROCITIES" OF SPORT.

THE President of the Society for the Prevention of Cruelty to Animals says:

"It is an inexcusable atrocity to subject any animal to pain which can be prevented by a conscientious use of anæsthetics."

It might be supposed that the gentleman was attacking hunters and sportsmen generally, who are committing these inexcusable atrocities every day. As a matter of fact the writer, while swallowing the camel of sport is straining at the gnat of vivisection. There are said to be over one hundred thousand men and boys in this country who go out with guns. They mutilate and half-kill birds, they maim the rabbits, deer, and other animals, subjecting them to exquisite pains before they die; they chase deer into the water and murder them in their helplessness, they ride after frightened foxes and drive them to a death of agonizing exhaustion; they hook up fish by the sensitive mucous membrane of the mouth and tear them from their wounds, all for sport.

There are, perhaps, half a dozen places in this country where vivisection is done on anæsthetized guinea-pigs, rabbits, and occasionally dogs.

Why doesn't the sensitive anti-vivisectionist attack the sportsman? Is it because he is afraid, or because he is a sportsman himself?

News of the Week.

Motormen and Conductors.—In St. Louis men seeking employment on the rapid-transit street-cars are obliged to submit to an examination of their eyes by a competent ophthalmologist. This is done by the street railway companies for their own protection, and is a plan that should be pursued by every street railway company.

A Medical College Burned.—On November 3d the Indiana Medical College at Indianapolis was burned to the ground.

The Horace Wells Anniversary Celebration.—The following circular has been issued: Members are doubtless aware of the action of the American Dental Association at its recent meeting, held at Old Point Comfort, Va., with reference to holding a national celebration of the fiftieth anniversary of the discovery of the anæsthetic properties of nitrous oxide by Dr. Horace Wells. The Committee, by vote of the American Dental Association, was instructed to secure two papers to be read at the celebration. One upon the "History of Anæsthesia," by Professor Thomas Fillebrown, of Boston; and one on the "Benefits of Anæsthesia to Mankind," by Professor James E. Garretson, of Philadelphia. The Committee was further instructed to arrange for a banquet to follow the meeting, at which distinguished speakers shall make appropriate addresses; to prepare a full report of the celebration, including the papers and addresses, to be printed and issued as a permanent souvenir of the occasion. Arrangements have been completed to the extent of securing favorable responses from the essayists named, whose papers are now in course of preparation. The banquet arrangements are also largely completed. To cover the expenses attending the celebration, the fee for admission to the banquet has been placed at $6. It is necessary that the Committee shall have ample notice of the number who will be in attendance, in order that places may be provided for all who may desire to attend. Subscriptions will be invited later for the souvenir volume, at a price sufficient to cover the cost of publication. The celebration will be held in Philadelphia, in Association Hall, Fifteenth and Chestnut Streets, on Tuesday, December 11, 1894, at 2 P.M., and the banquet at the Union League, at 6.30, same evening. You are cordially invited to participate in this event, which should enlist the enthusiastic support of every member of our profession. To that end you are requested to send your check and notify the Chairman of the Anæsthesia Committee, at the earliest date possible, in order that an official invitation may be sent to you. It will be proposed at the meeting that subscriptions be invited for a permanent memorial, to take such shape as the meeting shall decide. —J. D. THOMAS, Chairman, 912 Walnut Street, Philadelphia.

Medical Congress of Mexico.—The second biennial Medical Congress of Mexico was held November 5th to 8th, at San Luis Potosi. Dr. Eduardo Liceaga was President; and Dr. Luis Ruiz, Secretary, both of the city of Mexico; Dr. Jesus E. Monjaras was Chairman of the Local Committee of Arrangements, San Luis Potosi, Mexico.

Medical Society of the State of New York.—The following Business Committee has been appointed by the President of the Medical Society of the State of New York: Dr. W. C. Phillips, of New York City; Dr. H. L. Elsner, of Syracuse; Dr. H. DeV. Pratt, of Elmira.

Medical Announcements in the Press.—A New Orleans physician sends the following inquiries to the *Journal of the American Medical Association*: "Please inform me if there is anything in the Code of Ethics to prevent a practitioner: 1, From announcing in the daily newspapers that his practice is limited to the diseases of special organs; 2, ditto in the medical papers; 3, from announcing, in sealed circular letters to the medical profession at large, that his practice, etc.; 4, ditto to laymen at large, etc."

To which the editor replies: "Article I., Section 4: Duties of physicians to each other and to the profession at large: It is derogatory to the dignity of the profession to resort to public advertisements, etc. 2. While in some parts of the country physicians do publish cards in medical papers, it is not regarded as wanting in the true dignity of a physician, but as a question of taste. 3. Certainly, there can be no objection to a sealed circular to the profession, announcing that practice is limited, etc. But we find that when a physician is limiting

work to a specialty, it soon becomes known to the profession of his town, and by his papers on that subject in the medical journals he soon attracts a *clientèle*. 4. A circular to laymen cannot fail to produce in the minds of those who receive it, a doubt as to the ability of the one sending it.

"A large acquaintance with the profession in all parts of the country causes us to believe that the dignified earnest practitioner can acquire a practice without resorting to any of these plans."

And we would add that no physician should do any of these things, except that in smaller towns it seems to be a harmless practice to place a simple card announcement in the local paper.

Alma Mater, A Sonnet by Oliver Wendell Holmes.—The following sonnet, hitherto unpublished, was sent to the *Boston Medical and Surgical Journal* by Dr. H. P. Bowditch, with the statement that the poem was written at the request of Dr. Bowditch, and read by him before the Harvard Club of New York:

"Yes, home is sweet! and yet we needs must sigh,
Restless until our longing souls have found
Some realm beyond the fireside's narrow bound
Where slippered ease and sleepy comfort lie,—
Some fair ideal form that cannot die,
By age dismantled and by change uncrowned,
Else life creeps circling in the self-same round,
And the low ceiling hides the lofty sky.
Ah, then to thee our truant hearts return,
Dear Mother, Alma, Casta,—spotless, kind!
Thy sacred walls a larger home we find,
And still for thee thy wandering children yearn,
While with undying fires thine altars burn
Where all our holiest memories rest enshrined."

Our Medical Students.—England has but 552 medical students; there are 8,000 in the Germany universities, but the United States has 13,000. We could loan England a few thousand and have plenty to spare.

Care of Epileptics and Insane in Minnesota.—The board of physicians appointed by the Governor of Minnesota to investigate the insane hospitals and report on the needs of the insane, have suggested in their report the establishment of an institution for the care of epileptics, and another State insane hospital, the latter to be in the vicinity of St. Paul and Minneapolis.

Association of Southern Hospitals for the Insane.—An association has been formed with the above name, and will hold its first meeting at Birmingham, Ala., on November 20, 1894.

The Temperance Reform League of Massachusetts and the Keeley Cure.—Dr. B. D. Evans, the Medical Director of the New Jersey State Hospital for the Insane, has been admitted to membership in the Temperance Reform League of Massachusetts. This ends a battle between Dr. Evans and the Keeley cure, as far as Massachusetts can decide it, with victory in favor of the former. Dr. Evans, it will be remembered, gathered statistics from insane asylums over the United States and among the one thousand insane patients in the hospital of which he has charge, compiling valuable and detailed "tables of cases of relapse, suicide, mania, and dementia subsequent to the graduation at the Keeley Institute." His article, which was published in the *Medical News*, of May 6, 1893, was reprinted in Boston papers, and his report was laid before the Temperance Reform League. It was bitterly denounced by the "Keeley Cure," which applied to the Temperance Reform League for an examination, for this organization by its charter from the State is a quasi court, whose functions are those of a judge who examines conflicting medical evidence in a suit for malpractice and announces the result. The end of the trial has been reached, and Dr. Evans is honorably welcomed into the society, and thanked for his services in exposing pseudo-reform, while the Keeley offices in Boston have been abandoned.

Randall's Island Hospital, New York.—Dr. Samuel E. Milliken has been appointed surgeon to Randall's Island Hospitals.

No Doctors' Quarrel Over the Czar.—The daily papers have tried very hard to make out a quarrel between the attending physicians of the Czar. As a matter of fact there has been no real evidence that any special differences of opinion existed, and the following cablegram to *The Sun* confirms this view. The correspondent says: "Professor Leyden, since returning to Berlin, has spoken frankly about the case of the dead Emperor. He said that the statements circulating at St. Petersburg about serious differences between himself and Dr. Zakharin were not quite correct. There had been, now and then, diverging opinions, but in consultation the doctors always arrived at an amicable compromise. The statement that a quarrel had taken place about Dr. Zakharin's frankness with the late Czar was a misunderstood report. It was the Czarina, not the Czar, from whom the German professor wished to conceal the truth as long as possible, out of regard for her delicate health and because he believed the full knowledge of the situation could be of no use to her. Professor Zakharin was of a different opinion. It, however, is not probable that a quarrel between the doctors will ensue, as in 1888, after Emperor Frederick's death."

A Co-operative Medical Warehouse.—A considerable number of medical men in Berlin have started a "Warenhaus," or warehouse, for the supply of many other things besides medical stores. It is proper and right for medical men to unite and club together for their own benefit, and indeed it is proper and right for any individuals of any class to act in a similar manner.

Errata.—Dr. H. J. Garrigues writes:—"Will you kindly correct the following misprints in the MEDICAL RECORD of November 10th: Page 578, second column, 29th line from bottom, for 'separated' read 'suppurated.' Page 579, first column, 8th line from top, for 'introduction,' read 'induction.'"

Attempts to Revive the Electrically Executed.—The idea has violently seized some gentlemen that people executed by electricity are not killed by the shock; and the Governor of New York has been petitioned to allow experiments to decide whether those who have been "electrocuted" can be revived.

The Treatment of Diphtheria by Antitoxin.—The first report on the therapeutic value of Behring's antitoxin in the treatment of diphtheria has been communicated to the Budapest Society of Physicians by Professor Johan Bokai, the well-known pediatric physician. He used the serum at the Budapest Stephanie

Hospital for Children from September 21st till October 22d, when the treatment had to be stopped on account of the lack of the serum, which had not been obtainable since then from the German clinical establishment at Hoechst, near Frankfort. During the time stated above 35 cases of diphtheria were treated with the serum. There were 9 cases of pharyngeal diphtheria, 7 cases of pharyngeal diphtheria combined with nasal diphtheria, 4 cases of pharyngeal diphtheria combined with slight laryngeal diphtheria, and 15 severe cases of laryngeal diphtheria. There were, therefore, thirty-seven per cent. of mild and sixty-three per cent. of severe cases. The oldest patient was twelve years of age, and the majority of the cases (20) were below four years of age. Five of the 35 cases died, giving a mortality of 14⅜ per cent. This result seems very satisfactory if compared with the statistics of the previous epidemics. The following table shows the number of children treated from October, 1891, to 1894:

October.	Admitted.	Died.	Recovery.	Percentage of Recoveries.
1891.....	74	72	32	43.2
1892.....	56	24	32	57.1
1893.....	60	37	23	38.3
1894.....	35	5	30	85.6

Regarding the immunizing power of the serum, the results were less favorable, and there were cases which underwent relapse, though injections of the serum had been made. It seems that the serum is excreted within from eight to seventeen days after the injection, and that the organism loses its immunity in the course of this short time.—*The Lancet.*

A Quarrel Over the Diphtheritic Antitoxin.—There is an unpleasantness in Berlin over the diphtheria antitoxin. Professor Behring, who has been made Professor of Hygiene at Halle, recently published an article in a lay journal in which he claimed priority in the matter of the discovery and use of the serum, and accused Professor Virchow of not giving him credit and of recommending the use of Aronsohn's serum. It seems that Aronsohn, as soon as Behring's discovery was made, at once went to work and manufactured a serum by the same methods, but made one that was stronger, and put it promptly on the market. Professor Virchow publicly disclaims any claim for himself or others, however. Evidently there has a good deal of the commercial spirit crept into the manufacture of the antitoxines.

Diphtheria Antitoxin in France.—C. W. Chancellor, United States Consul at Havre, has just made a report to the Secretary of State recommending that the antitoxin should be supplied by every State and Municipal Government in the United States. The difficulties in the way are foreshadowed somewhat by recent experiences in Paris. He says:

So far, Dr. Roux has been unable to meet the demand for the serum, and he has had to confine himself to sending to the provinces only a sufficient quantity for urgent cases; and it is to be feared that this state of things must continue for some time. To provide for the needs of the entire country, the Pasteur Institute would have to possess a permanent establishment of over a hundred and fifty immuned horses, and, in addition to the heavy expense thereby entailed, the present accommodations are insufficient. Already, it has been suggested that auxiliary institutes be established in all the principal towns of France, the expenses to be sustained by the various municipalities. The city of Marseilles has decided to establish an institution, and the municipality of Honfleur, in this consular district, has contributed a liberal sum of money to be applied to the production and distribution of the serum for that particular community. A plan has also taken practical shape at Rouen and Havre to aid in this great humanitarian work. Individual subscriptions have been made to the extent of 40,000 to 50,000 francs ($7,720 to $9,650) in the two cities to supply the necessary means of accomplishing the desired end. At Havre, a healthy young Normandy horse of four years of age, that has never been put to work, has been purchased and is now under observation in the stables of the veterinary department of the Government at this place. In order to take every precaution, and to insure the success of the experiment, this horse has already been inoculated with *maléine*, an agent which, when inoculated on a perfectly healthy animal, produces negative or harmless results. After this, the horse, if perfectly healthy, will be successively and slowly rendered immune by injecting beneath the skin of the neck or shoulder gradually increased doses of the toxine made by cultivating virulent diphtheritic bacilli exposed to the air. Immunity being thus established in the horse, which requires from six to eight weeks, the serum of the blood of the animal when drawn and injected subcutaneously into the human subject will produce the desired preventive and curative action.

Post-Graduate Medical School.—Dr. George T. Elliot has resigned the Professorship of Dermatology at the Post-Graduate Medical School.

Library of the Academy of Medicine.—To meet an apparent demand, it is announced that the library of the New York Academy of Medicine will be open until 10.30 instead of 10 P.M. The new regulation will be made permanent only in the event that the use of the library between the hours named shall be sufficient to justify the increased expense.

Ether as an Intoxicant.—The *Lyon Médical* states that the habit of getting drunk on ether, which originally came from England, has existed in France for the last five or six years. The number of persons addicted to this form of debauchery seems to be growing greater, and cases are not uncommon in which persons drunk with ether are arrested in the streets.

A Biological Laboratory for the Philadelphia Board of Health.—At a recent meeting of the Philadelphia Board of Health the Sanitary Committee presented a report recommending the establishment of a Biological Laboratory and the engagement of a competent bacteriologist and such assistants as may be required for the purpose of conducting investigations of contagious diseases, and facilitating diagnosis, of investigating water supplies and food supplies, and of indicating and, as far as possible, providing the appropriate remedial measures.

The "Laziest" Man has at last met with his just reward. Dr. George Ross reports the death of a man from peritonitis due to rupture of the bowel brought about by

a novel and labor-saving method of taking an injection. This ingenious man simply fastened the rubber hose to the bath-room faucet and turned on the spigot. The last time he gave it one turn too much and hence the result. —*Times and Register*.

Relative Standing of the Graduates of the Various Medical Colleges examined by the State Board of Medical Examiners, representing the Medical Society of the State of Pennsylvania, June 11–14, 1894.

Medical College from which applicants graduated.	No. examined.	No. failed.	Per ct. of failures.	Aver. grade.
University of Pennsylvania	76	1	1.32	87.76
Woman's Medical College	18	2	11.11	83.44
Jefferson Medical College	67	5	7.46	83.29
Medico-Chirurgical College	26	3	11.54	82.48
Western Pennsylvania College	44	3	6.82	81.13
College of Phys. and Surgs. (Balt.)	3	1	33.33	80.68

Total	268	29	10.82	82.18

—*Medical News*.

The Craig Colony for Epileptics.—The managers of the Craig Colony for Epileptics met in Albany, N. Y., November 14th, and consisted of Dr. Frederick Peterson, of New York; Mrs. J. B. Wadsworth, of Geneseo; George M. Shull, of Mount Morris; Mr. Cudderback, of Buffalo; and Dr. C. E. Jones, of Albany. A report was adopted which will be presented to the Legislature recommending an appropriation of 300,000 dollars for the permanent establishment of the colony and the construction of the necessary buildings. The colony, which is situated in Livingston County, a few miles from Mount Morris, where 1,800 acres have been purchased by the State, is to be modelled after the German Epileptic Colony on the cottage plan. The managers are of the opinion that the colony can be made self-supporting with the introduction of appropriate industries for the patients. There are 12,000 epileptics in the State, 1,200 of whom are now cared for in the State hospitals.

Dr. William P. Spratling, of New York City, was elected Superintendent of the colony.

Twelve Hundred Physicians have already registered as medical practitioners in Massachusetts.

Tulane University.—Dr. Tiffany, of Baltimore, succeeds Dr. Miles in the chair of surgery.

Typhoid Fever at Wesleyan University.—An epidemic of typhoid fever has broken out among the students of Wesleyan University, and ten cases were reported on November 3d and 4th. One death has already occurred (a Freshman), and one of the faculty is dangerously ill. The origin is thought to be the water from an old well which has been found to be contaminated.

For the Religious Care of Medical Students.—A religious guild, called the Guild of St. Barnabas, has been started in London for the benefit of medical students. In making the announcement *The Guardian* remarks that probably the class most overlooked by the Church, amid all her various forms of work, is the class of educated young men generally. The urgency of the case, so the writer thinks, becomes even more obvious when the intellectual temptations of the necessary studies of medical men are considered.

Johns Hopkins Medical School.—The second year of the Undergraduate Department in medicine opened on October 1st. There were 31 entries, making in the two years 50 students in all. Of these, 13 are graduates of Johns Hopkins University, 8 of Yale, 5 of Harvard, and the others of the smaller colleges.

Obituary.

AMANDA SANFORD HICKEY, M.D.,

AUBURN, N. Y.

Amanda Sanford was born in Rhode Island in 1838. When seven years of age she came with her widowed mother to Scipioville, in Cayuga County, N. Y. In later years, when speaking of this time, she said: "I am glad I was poor." Her education was obtained at the Friends' Academy in Union Springs. After graduation, in order to recover her health, which had suffered from school work, and to earn money for the furtherance of her plan to study medicine, she started a vegetable garden, the while applying herself to Greek as a diversion. At the end of a year, one hundred dollars in pocket and restored in strength, she began teaching at the Hawland School, in Union Springs, and reading medicine by herself. In two or three years she was able to enter the Woman's Medical College in Philadelphia. After graduating there, she spent eighteen months in the New England Hospital in Boston, and in the autumn of 1871 went to Ann Arbor, Mich., graduating there the following spring with the first honors, the only woman in a class of ninety. In 1872 she settled in Auburn, and was rapidly successful in practice. The year 1879 was spent in study in Paris and London. She was a member of the original staff of the Auburn City Hospital, and continued an active member till her death. She married Mr. Hickey, of Auburn, in 1884.

These are the outlines of a career, unusual in the impression left upon the hearts and minds of associates and friends. She was a woman of dignified and stately presence, which, united with natural reserve, would have made her appear cold, had it not been for her finely modulated, sympathetic voice, and the gracious serenity of her smile. She possessed in a rare degree the gifts of silence, deliberation, and perseverance. But though self-reliant and self-contained, as all strong natures are, she won the affection as well as the esteem of those with whom she came in contact. The gratitude of patients, poor as well as rich, and the warm attachment of persons of varied temperaments, attest the charm and unselfish devotion as well as the power of her personality; while the thorough-going confidence and respect of her colleagues rewarded the honor and magnanimity of her professional relations. In her calling she possessed courage and skill, operating with success in cases of varied intra-abdominal disease. It was, however, as the trusted family physician, friend, and counsellor, that her gifts and character best expressed themselves. Many mourn for her as for an ideal and an inspiration lost.

Dr. Hickey died October 17, 1894, of pneumonia, contracted, it is supposed, by chill after assisting at a tedious abdominal operation in an over-heated room. Death did not take her unawares. Her intuition was, even in her own case, not at fault, for she foresaw the danger while yet distant, and with characteristic calm made dispositions for the future. In accordance with her wish, her body was committed back to earth in the village cemetery at Scipioville, where her life of study and labor and high usefulness in this vicinity had its beginning.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, November 8, 1894.

JOSEPH E. WINTERS, M.D., CHAIRMAN.

Ductus Omphalo-entericus Persistens.—DR. SARA WELT presented for the second time the child which had had a tumor first observed soon after birth at the site of the umbilicus, and which was proved by recent removal to be formed on the ductus omphalo-entericus persistens. There was but little hemorrhage, and it was checked by cautery.

Antitoxin Treatment of Diphtheria, Based upon a Series of Cases Treated at Willard Parker Hospital.—DR. A. CAMPBELL WHITE read the paper. (See p. 609.)

Observations in Berlin.—DR. HERMAN M. BIGGS opened the discussion, and spoke essentially as follows: Perhaps it may be of more interest to you if I simply give an account of my own observation of work done in the antitoxin treatment of diphtheria in Berlin the past summer. The institute for infectious diseases in Berlin was founded by the German Government under special act, and is devoted solely to experimental, original investigation. It has a corps of men connected with it, the very best men in German scientific medicine, such as Koch, who is director, Ehrlich, Behring, etc.; men who have been known for a long period for their observations in bacteriology. Attached to the institute is a hospital for infectious diseases. A large part of the work on the antitoxin treatment of diphtheria has been done in the institute, or in connection with it. We must remember, in judging of its value, that it is not, as with most other discoveries, or alleged discoveries, in bacterial therapy, simply a discovery. It is an original development, the result of a long series of scientific observations which have been going on for years.

In going over the work in Berlin I was very much impressed by the fact that, among these men who had been working up the subject for two or three years, or longer, and who had treated a large number of cases of diphtheria, the first series of five hundred having just then been completed, there was not the faintest shadow of a doubt as to the value of the antitoxin treatment. They seemed to feel absolutely convinced that the experimental stage had been passed, and that the value of antitoxin as a specific in the treatment of diphtheria was a thoroughly established fact. That seemed to me a most surprising and a most encouraging feature of the question at that time. And when one turns to the other side and considers for himself the evidence to justify belief in the treatment, it seems to me he has even a stronger basis for confidence than the positive testimony of others.

Observations in bacteriology have shown conclusively that, so far as infectious diseases are concerned, the constitutional manifestations are not due immediately to the micro-organisms, but rather to the products of their life-processes, and that death, whenever it occurs, is almost invariably the result of chemical poisoning, the absorption of these bacterial products. That these toxins, or tox-albumins, or ptomaïnes, whatever they may be, depend on the micro-organisms and are their main offensive weapons, and that without them the micro-organisms become almost harmless, and are unable to compete with the tissue-cells in their struggle for life. We know further that in all the infectious diseases, one attack gives more or less complete and more or less permanent immunity against future attacks. It has been shown further, experimentally, that this immunity can be induced artificially, not only by the inoculation of animals with the micro-organisms themselves, but also by inoculation with the chemical products obtained through cultures of such micro-organisms. Further observations along this line have shown that this immunity is due to the development of something in the circulation. This something gives immunity by neutralizing the products of the infectious organisms.

Now, it has been possible to separate these chemical substances in some of the infectious diseases; they are the most powerful and virulent poisons we know of. In diphtheria it has not yet been possible to separate the toxin, but we can measure its strength biologically by its influence on susceptible animals, and a standard has been fixed for determining the strength of the toxin.

A normal toxin solution is one of which one-tenth of a cubic centimetre will destroy a guinea pig in a definite time, about forty-eight hours. This forms the standard by which the dosage is determined, as already stated; we do not know what the antitoxin is which is developed in the circulation as the result of inoculation with the chemical products of micro-organisms, but we suppose that it is an albumin; it is certainly allied to albumin. But we do know that it has the power to neutralize the poison of the micro-organisms which produce a specific toxin. We know that the amount of antitoxin in an animal can be enormously increased by repeated inoculation with the toxin. At first small doses are employed and gradually increased. Tolerance is thus rapidly increased. This increased tolerance is due to increased antitoxin in the circulation of the animal which is being immunized, until finally the amount of the neutralizing principle is relatively enormous.

The amount of antitoxin action can be measured by the amount of the normal toxin solution that it will neutralize. The blood-serum which has been taken from the immunized animal is mixed outside the body with the toxin solution, and by the amount of toxin solution which it neutralizes is its strength and curative value determined.

There is no reason why this antitoxin should not have the same power inside the human body that it has outside. We know that the toxins cause the poisoning in diphtheria, producing constitutional manifestations and death. We know that the antitoxin serum derived from animals which have been immunized, will destroy this toxin outside the body, so that it becomes absolutely harmless. We know further that the value of the antitoxin serum in the treatment depends upon its dosage and its strength; that the dose must be graded not only to the strength of the serum, but also to the age and body-weight of the individual. This is further confirmation that it does not act in a biological way, but chemically. It acts by neutralizing directly, and its action is proportioned to its strength and its amount.

It seems to me that it is the history of the development of the antitoxin treatment of diphtheria which gives it peculiar significance, and gives the greatest encouragement for belief in its efficacy. It is not a discovery, an empirical observation, but it is a logical development from a long series of careful and thoroughly confirmed scientific observations.

DR. W. H. PARK said: I shall try, in discussing the antitoxin treatment, to avoid, as far as possible, repeating what has already been said, and will speak a little more in detail of animal inoculations, as showing what we may expect in the treatment of disease in man. All know how difficult it is to tell in human beings just what the therapeutic effects of drugs are, and perhaps in no disease is this more true than in diphtheria. Some of you may have read Professor Loeffler's recent article, in which he described a new method of local treatment of diphtheria, stating that in about seventy nine cases he has not had a single death, and he apparently believes that in this local treatment he has almost a sure cure for diphtheria, leaving out, of course, laryngeal cases. Now and then we read of some person having treated a number of cases with bichloride of mercury without the loss of a patient. Yet we know that in neither bichloride nor in a mixture of alcohol and other substances which Professor Loeffler uses, can we hope to have a much better percentage of recoveries in all cases of diphtheria than we have had ordinarily, for it is in little children

that the laryngeal and the fatal cases occur mostly, and in them such local treatment cannot be carried out. So I think it is well to look a little more at the experimental evidence regarding the antitoxin method, in order to judge of its value in the treatment of diphtheria in human beings.

When bacteria are grown in broth or other culture mediums, they at the same time develop the toxins which produce lesions, and you have been told that when these toxins of bacilli are injected in animals, large or small, in less than fatal doses, the animals gradually get tolerance; so that in three or four months you can give them what ordinarily would be fatal doses, and produce no symptoms. Doses which would kill a thousand guinea-pigs will cease to have any effect upon a single guinea pig which has been thus immunized, so that something marvellous has occurred and has produced antitoxin in the blood. As you have already heard, we do not know what this antitoxin is chemically, but we know it is there, since we can measure it by its results. It neutralizes the toxins. But how? Different observers have different ideas on this question. It certainly does not destroy them. The antitoxins have been injected into animals and into human beings, and the toxins have thereupon ceased to produce their harmful effects, yet they are still there—both antitoxins and toxins. That is proven in a number of ways, and it is only necessary to mention the fact here. In diphtheria they are so much alike that you cannot separate the toxins and the antitoxins when mixed. But it has been found that if you put a certain amount of antitoxin in with a certain amount of toxin, there will be no effect from the injected fluid, while the toxin taken separately would kill speedily. Now, it has been found that if you inoculate an animal with toxin and immediately afterward inject antitoxin, a very small amount of the latter will suffice to prevent the development of diphtheria. If three or four hours elapse, it will take a larger dose of the antitoxin; after twelve or twenty-four hours the dose will have to be very greatly increased, and if the animal is already dying, no amount of antitoxin will save it. So in diphtheria treated by antitoxin in the hospitals, it has been found that where the injections have been begun on the first or second day, they have done very well and have required only one or two doses; while in cases treated not before the third or fourth day, it has required repeated large doses, and even then one may not succeed in curing the patient.

Differs from Tuberculin.—Now, some of us may have a misty idea that this antitoxin treatment is like that by tuberculin, and is liable like it to inspire too great hope to withstand the test of time. But the two are quite different processes. With tuberculin we inject a toxin to develop antitoxin in the body, while in diphtheria we first produce antitoxin in the bodies of animals, and only inject the antitoxin, which is absolutely harmless, into the patient afflicted with diphtheria.

You know that when serum from certain animals is injected into man it may create some disturbance, and this will account for the rash which has been produced in some instances of the antitoxin treatment of diphtheria. It was not due to the antitoxin. The serum from the horse scarcely ever produces any symptoms.

We have, then, in this treatment of diphtheria, a method which need not interfere with any other being carried out at the same time, and one which will do no harm to the patient.

My own experience with the antitoxin treatment has been chiefly in watching the cases, through the kindness of Dr. White, at the Willard Parker Hospital. Outside I have had only two cases, and these I believe would have recovered any way, but they probably recovered more quickly under the antitoxin treatment. The physicians in attendance were struck by the almost immediate improvement in the patients following the injections.

Effect on the Membrane.—Now, it may strike some that if the antitoxin has no effect upon the duration of the membrane and on the duration of the bacilli, it shows it has not much influence on the disease. It must be remembered, however, that the antitoxin is not to any marked extent a general antiseptic. It is not what we may have been seeking, something to kill bacilli without killing the patient. It is quite different. It simply neutralizes the poisons which the germs develop, but does not directly influence the growth of the bacilli, nor directly affect the membrane, except in so far as it may neutralize the effect of the poisons in producing membrane upon the throat. In animals, however, in which large doses have been employed the membrane has always separated much more quickly than it usually does.

In looking over the cases treated by this method I found about 1,180, the mortality of which, instead of being forty-four per cent. as it ordinarily is under exactly the same conditions, fell to twenty per cent. Although we cannot judge in local epidemics by figures, I think that in general hospitals, where all the other conditions remain about the same, we may be pretty sure any marked reduction in the mortality is due to the special treatment employed. I certainly feel that we have in this antitoxin treatment a great outlook, and I hope we shall soon have the remedy accessible for use in every case here as well as elsewhere.

Dr. George F. Shrady supposed that he had been invited to make some remarks on the subject on account of his connection with the Willard Parker Hospital, and because of the opportunities which were thus afforded him for verifying the reports and endorsing the statements of Dr. White in his very interesting and instructive paper. He could therefore give his impressions of the results of the antitoxin treatment only from a clinical aspect, and as one who had survived very many epidemics of specific remedies for diphtheria. So far as present results showed in Berlin, Paris, and New York, antitoxin appeared to give better statistics than any other form of treatment. Then it was so simple in its administration that anyone could use it. He was much struck with the remarkable change for the better which occurred in some of the cases related by Dr. White, seeming to prove that some profound and radical curative processes had manifested themselves in the general system. The remedy appeared to reinforce the natural vital resistance to systemic poisoning. The rationale of treatment was founded on a sound bacteriological basis, and commended itself accordingly to progressive clinicians. Indeed, the principle of immunization would doubtless prove as important to therapeutics as had been asepsis to operative surgery. It seemed to him that we were, as far as the fundamental principle was concerned, on the eve of brilliant discoveries along that line.

The present difficulty in testing the remedy was its great scarcity, and the difficulty of obtaining supplies in the near future. A month ago he had cabled to Berlin for antitoxin, and had received a limited supply, but not enough for extended experimentation. Aside from the opportunities of witnessing Dr. White's cases, Dr. Shrady's personal experience had been limited to one case, which was sent to him by Dr. Fischer from the Messiah Home for Children. The antitoxin (Behring's) was injected into the intra-scapular region, with the result of relieving the grave systemic symptoms, and eventually curing the child. Thus far he believed that the remedy deserved a more extended trial, and he hoped that soon the supply of the antitoxin would be equal to the demand.

Dr. W. P. Northrup thought the paper of Dr. White hopeful. Like the opening chapter in a novel, it promised well, and one felt like turning over to the back pages to see how it would come out. There were several things which had to be proved at so hopeful a period of any remedy. In the first place, the cases treated may have occurred at a time when everybody suffering from diphtheria got well. As far as he had been able to learn, the percentage of recoveries in institutions at this particular time was especially good. He wished to join in the general hopefulness of this occasion. But he

would not forget that we had had in the past many disappointments in remedies.

Dr. Northrup had observed, with others of his colleagues, that in some of the European hospitals they claimed to get results by certain methods of treatment, say by intubation, which were much more favorable than had been obtained here. He mentioned the fact as one to be borne in mind when judging of the value of any method of treatment based on experience over there. He had had some of the antitoxin sent him for use in diphtheria, but had not been able to find a case in which to employ it, at the Foundling Asylum or elsewhere. This showed very well the sporadic nature of the disease at this time. A special test of the new treatment would be found in rather rare cases of rapid toxæmia from the commencement, in which death sometimes took place within twelve hours from the first symptoms of diphtheria. In such cases nothing else than possibly the antitoxin could have any effect. It seemed that the influence of the antitoxin on the pulse was the most hopeful indication.

Dr. Louis Fischer spoke of his observations in Berlin of two methods of treatment, one by Aronson, the other by Beginsky. The latter informed him that the mortality in diphtheria had fallen from thirty-seven per cent. to thirteen per cent. under antitoxin treatment. The course pursued was to inject at once every case brought to the hospital with a pseudo-membrane. Next day, the bacteriological examination having been made, the cases of pseudo diphtheria were separated from those of true diphtheria, and in the latter the antitoxin treatment was continued. Dr. Fischer had had some personal experience with the treatment very recently, in a hospital in Philadelphia, and it would appear to have had more influence on the membrane in the throat than had been described by others. Although he had been favorably impressed by the antitoxin results, he did not think it safe to become too enthusiastic.

Sceptical.—Dr. Henry Berg said the difficulty in judging of the value of any method of treating diphtheria related to prognosis, or our ability to judge of the severity of the cases. Frequently the very ones which we expected to terminate favorably died, while those which we expected to die took on a marked change for the better in a few hours, and went on to recovery. He had seen nearly all the cases treated by antitoxin by Dr. White at Willard Parker Hospital, and while he could not say that all of them were not severe cases, yet he could not say that they were. Some of them seemed to him to be only ordinary cases of diphtheria, while some seemed to be very severe ones, although he was not positive that he would have made a fatal prognosis. These facts simply showed that if we were going to draw deductions with regard to the efficacy of any given treatment in diphtheria from figures, the number must be very large, and the only way to test the new method was to place the antitoxin in the hands of all the physicians of the city. Dr. Berg thought statistics here and those abroad would point to the fact that our treatment of diphtheria was either better, or that epidemics here were less severe.

New Syringe for Cleansing the Nostrils.—Dr. Sommerset presented a syringe for cleansing the nasal cavities in diphtheria, and said that with it one could give more force to the stream than with the Davidson syringe, which was necessary in rare cases where the occluding membrane held tenaciously and had to be removed to prevent sepsis.

The chairman, Dr. Winters, testified to the value of this syringe. Regarding statistics of mortality-rate as basis for judging of the efficacy of the antitoxin treatment, he thought they were apt to be misleading. Ordinarily the entire number of deaths was meant, but in some of these special statistics certain cases of death had been excluded, which, of course, would make a better showing for the antitoxin. It seemed that abroad the mortality rate without this treatment had been placed enormously high. In this city the Board of Health record gave a death-rate of only twenty five to thirty-three per cent. This must necessarily be too high, if it was remembered that all fatal cases were reported, while many non-fatal cases were not reported at all. He thought it certainly did not exceed twenty-five per cent. Again, he doubted whether there was any serious infectious disease so badly treated as diphtheria. Faulty methods being omitted under the antitoxin treatment, would in itself cause a better mortality-rate. Further, mortality statistics were usually made up from cases to which a reputable physician was not called until the disease had well advanced, say after three or four days. These facts had to be taken into consideration in judging of the value of the new antitoxin treatment. It would be necessary to wait until long use by many physicians had tested the method.

Dr. Andrew H. Smith said a very good nasal syringe could be made out of any ordinary one, by attaching to it a rubber nipple the opening in which was smaller than that in the end of the syringe, so that the nipple would be made to dilate by the stream and fit closely to the nostril. Regarding antitoxin, he thought it would prove of inestimable value if it had no other effect than to stop the pernicious practice of applying frequently local remedies against the struggles of the little patients.

Dr. White closed the discussion.

SECTION ON LARYNGOLOGY AND RHINOLOGY.

Stated Meeting, October 24, 1894.

Dr. D. Bryson Delavan, Chairman.

A Case of Sarcoma of the Palate Successfully Treated by the Toxins of Erysipelas, was the title of a paper read by Dr. W. B. Johnson, of Paterson, N. J. (See page 616.)

Dr. W. B. Coley said: I saw this case before treatment was begun. The case was grave, and I had no hope of treatment doing more than giving temporary relief. The result of my experience with toxins up to last May I reported at Washington, before the Section on Surgery, Congress of American Physicians and Surgeons. The cases reported were 25 of sarcoma, 9 of carcinoma, and 2 or 3 where examination was not made. Of these cases, I reported in detail 5 which I hoped to cure. None of them have shown any signs of recurrence of the trouble. Since that time 3 cases have gone over a period of three years; 2 over two years, and others over one year. Since the publication of the paper, I have treated 10 cases of sarcoma, 3 having been extraordinarily successful. One was an enormous sarcoma of the ilium, filling the right side of the abdomen. I began toxin treatment, then the tumor began to break down and slough out, and after five weeks of sloughing the injections were stopped. The result of treatment and consequent breaking down of the tumor was depressing to the patient, but by stimulation and careful nourishment he began to recover, and I showed him a week ago without any tumor left. On August 15th he weighed 115 pounds; now he weighs 140 pounds.

I have a case of a girl, aged sixteen, with a sarcoma of four months in left scapular region, extending to the median line in front, attached to chest-wall. In three weeks she was able to raise her arm. Injections were given in scapular region only. Improvement immediately was marked, and she is now cured. I had and have other cases, the results of which are similar. The preparation which Dr. Johnson used was erysipelatous and prodigiosus toxin, used in separate bottles, given in small doses in combination. The two cultures are now grown together and subjected to heat; 58° C. is sufficient to kill the germs without destroying the chemical toxin, and no loss occurs as in filtration; after subjecting to heat add sufficient thymol to make a saturated so-

lution. The value of the toxin lies in the virulence of the culture.

The Chairman, Dr. D. Bryson Delavan, said no efforts that we can make will be too great to further the success of these experiments, which have gone so far as to prove that they amount to something more than mere experiments. They have cured one case of malignant disease of the palate, at least.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, October 5, 1894.

Henry F. Walker, M.D., President, in the Chair.

Angio-neurotic Œdema.—Dr. Charles L. Dana presented a man with this affection. He was twenty-seven years of age, a bar-keeper, had used alcohol moderately since early youth, and had used tobacco excessively since the age of twelve, smoking, since his twentieth year, as many as thirty to fifty cigars a day. He had never had any venereal disease, malarial affection, rheumatism, or digestive disorder. He had been rather nervous, but that was all.

One morning last February, he awoke to find the right foot swollen. The swelling went down, but next day the left foot was affected in the same way, then the face; and since then all parts of the body had been affected by such œdematous swellings, mostly, however, the face, hands, feet, and scrotum. The swellings would increase until the skin became very tense and hard, resisting pitting, and would disappear in from two hours to twenty-four, none having lasted longer than a day and night. Some would make their appearance while others were fading away. They were whitish in color, with a little rose tinge, but never resembling wheals. Sometimes one side of the face would be swollen to the point of closing the eye, and present a white appearance; sometimes the hand would be of enormous size. The patient stated that he could sometimes bring the swellings out on the face by scratching, and quinine, which some physicians had prescribed for him, had been quickly followed by their appearance. There was no organic trouble with the kidneys, lungs, or heart. The pulse had been rather fast, about ninety, and of very low tension, but not intermittent. He complained a good deal of palpitation. There was no scotoma, no evidence of alcoholic injury of the optic nerve.

Dr. Dana said that in his experience these cases were rare, and their cause and progress was involved in considerable obscurity. Some of the causes which had been mentioned were malarial affections, fright, trauma, exhausting influences of various kinds. This man's case seemed directly due to tobacco, and that which seemed to promptly relieve him was to stop the use of this article. He had had scarcely any trouble since he had given up smoking. In addition, Dr. Dana had prescribed a tonic of mineral acid and strychnia.

The speaker had observed that the excessive use of tobacco, beginning early in life, sometimes produced curious vasomotor disturbances. The tobacco seemed to have a special effect in some cases on the vasomotor nervous system. Writers on angio neurotic œdema classed it as having some relationship to urticaria, giant wheal, and like conditions, but in this case there was no dietetic influence nor resemblance of the swellings to the wheals of urticaria. Until lately, the patient had not been free from the swellings since February, except two weeks in June.

Dr. Francis Delafield had hoped to hear of some particular treatment of the disease. He recalled two comparatively recent cases in women who gave no neurotic history, had no bad habits, were in comfortable circumstances; the swellings continued to develop without apparent cause for several months, and then ceased. He did not know why they had the affection, nor why they stopped having it. It seemed to be not very uncommon, and an efficient plan of treatment would be a great convenience.

Dr. Dana remarked that the cases were probably seen oftener by the general practitioner and dermatologist than by the neurologist. He had seen but three, and had not been able to keep track of them, but knew that two got along fairly well.

The president, Dr. Walker, had seen a man in a few of the several attacks which he had been having for two or three years, consisting in great swelling of the tongue, causing it to protrude from the mouth, and less swelling of the lips, the condition gradually disappearing after some hours. At first there was fear the glottis or larynx might become affected and cause strangulation, but this fear had passed off. The man was a smoker, a moderate drinker, had a rather gross appetite, slight rheumatic trouble, no constitutional disease.

Dr. G. L. Peabody had also had a case in which the attacks of swelling were confined chiefly to the lips and tongue, in a man of thirty-five, without bad habits, not a smoker, but of gouty heredity. Dr. Peabody prescribed colchicum, and since then the patient had taken this drug when there was a recurrence, but had now been free a long time. He was unable to say whether the colchicum had given the relief.

Extirpation of Tongue for Cancer; Taste and Speech soon Regained.—Dr. Robert Abbe presented a man, fifty-three years of age, whom he had first seen about five months before, when he presented a cancer on the back portion of the tongue, beginning on the left side and extending to the right. There was a little glandular involvement under the left jaw. The patient was dribbling saliva, was unable to masticate, was markedly cachetic, and in deplorable general condition. Dr. Abbe performed Kocher's operation for removal of the whole tongue, and showed the patient because of the remarkable power of speech which he had regained since the operation, four months ago. He had no difficulty in making himself understood in a large room, and was able to utter all the sounds of the alphabet except k, which he pronounced p, saying, for instance, pip for kick. The general health had again become perfect. There was a slight recurrence on one tonsil, which it would be necessary to remove.

Dr. Dana elicited from the patient the fact that he had power of taste, recognizing sweet, bitter, salt, acid, etc. Dr. Dana confessed his inability to explain the existence of this power where the tongue, with the nerves of taste and taste buds had been almost entirely extirpated. It was supposed that normally there was slight sense of taste in the soft palate, but he had himself never been able to recognize taste in that locality.

Dr. Sexton brought out the fact that the patient had a slight burning sensation at one part of the stump, and stated that he had frequently found division of the chorda tympani followed by a feeling as if the tongue were scalded.

Remarks on the Education of the Stomach.—Dr. Samuel Sexton read the paper of the evening, bearing this title. In having chosen as the subject for his paper one which most of those present were better able to discuss than he, he wished to elicit a discussion which might add to the comfort and more perfect manhood of the coming generation. He was of the opinion that most people greatly abused their stomachs by taking too much food, and food of improper or injurious kind. It was especially the excessive quantity and variety consumed at a single meal which had most forcibly attracted his attention at the hotels and in private families. He cited several notable examples of gluttony on the part of children at the expensive hotels here and in Paris, where they did not fail to partake of all the numerous courses printed on the ménu. The parents, so far from reprimanding them for their greediness, took pains to have the little heroes or martyrs fill their pockets with such dainties as might prove tasteful between meals. The author thought it was necessary, for a healthy development, to accustom the stomach to plain, simple, but nutritious food, in rea-

sonable quantity, with periods of intermission sufficient for complete digestion and rest. The agonies which children suffered from colic and frightful dreams constituted a part of the punishment inflicted upon them through the ignorance or thoughtlessness of parents who permitted and even tempted them to make their stomachs a dumping ground for all possible foods and drinks, and many things which were neither food nor drink.

During the discussion Dr. Beverley Robinson said he supposed all would agree that most people ate too much, but he thought there was a tendency among intelligent people to educate the stomach and limit the food of their children. Sweets were ruled out, and the food was given in moderate quantity and at stated intervals.

Gluttony not an American Characteristic.—Dr. Dana could not agree with Dr. Sexton if he meant to imply that over-eating and gluttony were at all characteristic of the American of to day—that was to say, the educated American, the type we were developing in this country. It seemed to him the tendency of the times and of the race was to eat rather less, and he believed it would become still more so. A neurotic people, he thought, would have to live simply and on a small amount in order to retain their health, and the Americans appeared to be learning that fact. His observation had been that it was rather hard to get children of nervous temperament to eat enough. They often left the breakfast table after having eaten very little, and they ate a light dinner. He did not mean to say they carried this to an unhealthy extent, but he certainly had not seen gormandizers among children of a fairly healthy neurotic type. When one did see gormandizing in a child it was almost always a sign of a degenerative taint in that particular person. It was a perfectly well-known characteristic of the epileptic and imbecile or partially developed children, and he supposed, as Dr. Sexton had suggested, that gormandizing was some evidence of atavism. He also thought the paper was quite correct in teaching that we, as a neurotic race, who lived on the nerves and drew largely on the brain, must eat plainly and simply. The only point where Dr. Dana differed from the author was, that he thought Americans had found this out largely, and did live in that way. He had always thought that the American's stomach was a great safeguard to him; it was delicate, and he soon found out that he could not eat excessively, drink excessively, nor smoke excessively. He could not do as the Germans and English.

Dr. Peabody remarked that the Germans had no term expressing dyspepsia, and agreed with Dr. Robinson that they probably had better beer if not better food.

Dr. Dana said he had not stated that the Germans had dyspepsia, but he thought that if the same classes here, as lawyers and teachers, should eat and drink as they did in Germany, they would get sick.

Becoming a Larger and Fuller Developed Race.—The President thought he had observed that the children and youth in New York to-day were larger and better formed than those of eighteen or more years ago, and that it was due to their better feeding and manner of bringing up. In other words, the tendency seemed to be toward a larger and fuller developed race.

Dr. Peabody queried whether that was not due to athletics, and Dr. Walker agreed that athletics had something to do with it as a part of the better training.

Brewers Drink a Keg of Beer a Day.—Dr. Sexton said he once had occasion to examine men who worked in a large brewery, and learned that it was the custom of those who had free access to the beer to drink a keg apiece each day. It was not uncommon for Germans in this country to drink twenty-five glasses or more a day. Children in this city, he thought, had too little exercise and were over-fed, and were not properly educated with regard to diet. One way of entertaining a child was to feed it. Possibly he was wrong, but he believed a very large amount of nervous energy was consumed in digestion, and that over-feeding deprived the heart of a good deal of nervous power which it should receive. The condition of many patients was markedly improved simply by diminishing their food supply.

Surgical Suggestions.

Stone.—Litholapaxy is the operation when the patient is an adult with a capacious and tolerant urethra, with a bladder free from severe chronic inflammation, and with a small or medium-sized stone, or, if large, of soft consistence. The suprapubic is the best operation for large and hard calculi. The medio-bilateral operation should be chosen in all other conditions, because it is the easiest, safest, and best.—Briggs.

Carbolic Acid applied in officinal strength in surgery.

1. No systemic absorption attends its use, and hence no danger, no shock.

2. It is a local anæsthetic. Hence there is not as much pain after the operation.

3. It is in a measure a hæmostatic, acting especially upon the capillary vessels.—Gardner.

Ingrowing Toe-nail.—Remove all of the redundant, hypertrophied, or granular tissues of the skin, and leave the nail alone.—Nuding.

Lung Surgery.—In tuberculous cavity the advantages do not seem to be of sufficient magnitude to warrant an operation, except in a very few instances. Removal from the lung of pieces affected with tuberculous infiltration is obviously in the realm of pure experiment. —Chaplin.

Repeated small rectal injections, it is said, will relieve the intense thirst following abdominal operations.

Local Anæsthesia.—A mixture of ten parts of chloroform, fifteen of ether, and one of menthol, used as a spray, is recommended as an excellent and prompt means of obtaining local anæsthesia lasting for about five minutes.

Cracked Ice, Sawdust, and Salt thoroughly mixed and applied over abscess, felon, tumor, or bubo, will deaden the skin sufficiently to allow of painless incision.

Alcohol will be used less and less in surgery, because scientific investigation has shown the causes of many of the evils it was imagined to counteract, and because, thanks to Sir Joseph Lister, these causes have been got rid of.—Horsley.

Hydroceles of the Neck, after tapping and iodine injection, either quickly refill, or such extensive inflammation is set up as to endanger life.—Stokes.

Granular Lids.—Curetting and brushing with corrosive sublimate is successful in mild, but not suited to bad cases.—Trousseau.

Palpation of the Vermiform Appendix.—Pressure deep enough to recognize distinctly the posterior abdominal wall, the pelvic brim, and the structures between them and the examining finger, forms the whole secret of success in the practice of palpation of the vermiform appendix.—Edebohls.

Rectal Tube.—As a means of diagnosis, or in treating stricture beyond the reach of the finger, tubes of any kind are absolutely useless.—Cripps.

Acetanilide is curative in wounds, lacerations, and internal hæmorrhoids. It is cleanly, odorless, antiseptic. —Woods.

Castration for Hypertrophy of Prostate.—Existing evidence would certainly seem to establish the claim of the operation to further and much more extended trial; and it shows, I think, that even on a basis of experiment and theory alone, I was justified in suggesting it to the profession.—White.

Peat Fibre, as now prepared for surgical purposes, is a fine, brown, glossy wool, with a faint aromatic smell. It feels a little rougher than fine absorbent wool, but makes a more comfortable dressing, as it is much more elastic. Its chief advantage seems to be that it is a deodorant.—BURGESS.

Spinal Cord.—In compound fractures, in fractures of the spinous processes and laminæ, with injury to the cord, in simple fractures and dislocations of the bodies of the vertebræ, if there is a reasonable probability that the injury is due to hemorrhage, operation is advisable; but in all other cases, laminectomy is not an eminently valuable surgical procedure.—THORBURN.

Internal Hæmorrhoids.—The ligature is the safest method of operating for internal hæmorrhoids, as there is less likelihood of its use being followed by hemorrhage, stricture, or ulcer.—DUNDORE.

Sterilize Catgut by means of the vapor of alcohol heated to 120° C., verifying the sterilization by placing bouillon in the same tubes with the gut; if the bouillon becomes turbid the ligatures should be rejected, as the tubes are infected.—RÉPIN.

Management of the Intestines after Abdominal Section.—When the general condition of the patient is fairly good and the abdomen is not distending, and when there is not much colic, let things take their natural course. This advice holds for the great majority of cases.

When the physician is summoned to a case of intestinal obstruction, he should at once point out to the patient the possible necessity of an operation. The neglect to do this has cost many lives, for a considerable time usually elapses before a seriously ill person consents to a dangerous operation.—GERSUNG.

Hypnotic Insensibility to pain can be applied to such operations as extirpation of the breast without the patient manifesting the slightest sign of pain.—SCHMELTZ.

Stricture.—External urethrotomy with Syme's staff and Teale's probe gorget, is preferable for all strictures of the deep urethra where gradual dilatation is impossible.—ROSENSTEIN.

Catgut Drains. — By interlacing in a gabion-like manner the separate filaments of catgut, a tube of any desired size and length can be made. It has the advantage of being capable of perfect sterilization, does not present the inconveniences of decalcified bone, is not rigid, has all the advantages of rubber, resorption can be accurately calculated, and by reason of the openings along its whole extent realizes an ideal drainage.—DESGUIN.

Intubation.—The comparison of the results from tracheotomy and intubation gives, in the first two years of life, better results from intubation than from tracheotomy. —VON RANKL.

Hysterectomy.—The operation should always be begun with the intention of performing the intra-peritoneal method, and removing the whole organ if possible, but the operator must be prepared to adopt any method, should it seem best to do so when the exact conditions are found out during the progress of the operation.—KEITH.

In Cancer of the œsophagus a gastric fistula should be established as soon as the scales show a steady decrease of the patient's weight.—MEYER.

Depressions of the skull in the new-born should be treated by immediate resort to operation, if there are symptoms calling for its performance.—JENNINGS.

Uterine Fibroid.—In all cases of simple myoma or of diffuse progressive hyperplasia (the "soft fibroid" of many authors), complete removal should be practised as soon as the diagnosis is established.—REED.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

OPENING MEETINGS OF THE ROYAL MEDICO-CHIRURGICAL AND PATHOLOGICAL SOCIETIES — SURGERY IN SEPTIC PERITONITIS — LAPAROTOMY IN PERFORATING ULCER— MEDICAL SOCIETY OF LONDON—TREATMENT OF CANCER BY CINNAMON—PAY-PATIENTS IN HOSPITALS.

LONDON, October 27, 1894.

THE Royal Medico Chirurgical Society held its first ordinary meeting on Tuesday evening, when Mr. Lockwood read an important paper on the Surgical Treatment of Diffuse Septic Peritonitis. In the cases he referred to the inflammation had no defined limits, the membrane was smeared with lymph, and the cavity contained thin purulent fluid, often with a fecal odor, or it might be full of gas. The intestines were paralyzed and distended. In these very rapidly fatal cases Mr. Lockwood had operated for fear of overlooking a mechanical obstruction rather than with a view of curing the peritonitis; but he had had success when there was not mechanical obstruction and now detailed the proceedings he adopted. To meet the exhaustion, collapse, and distention he used strychnine and brandy, before operation— and warmth both at the time and afterward, also nutrient enemata, stimulants, and warmth as required. Rapid but methodical operation was important. He punctured the several coils of intestine to withdraw the gas and then let out the fæces through an incision, which he afterward closed. Then of course he irrigated and drained. Two successful cases were described. The object of the paper was not to bring forward novelties, but to insist on the methodical use of known proceedings, and the general feeling seemed to be that the cases related were encouraging. In the discussion some interesting points were raised. Thus Mr. Hulke regarded the paper as valuable, but mentioned that he had sometimes found the intestines so soft that the puncture continued to leak and the attempt to close it by ligature only increased its size. He thought no surgeon would hesitate to enlarge by incision a perforation he found to exist. Mr. Knowsley Thornton regarded the combination of puncture with incision and the protection of the patient from shock as the essential features of the treatment advised and regretted that he had not been more careful in the past to guard against chill, shock, and prolonged exposure. He had long recognized the danger of distention as well as of the septic material spread over the surface for which thorough irrigation was necessary. Mr. Harrison Cripps congratulated the author on showing how to deal with cases which were the bane of abdominal surgery. In cases after childbirth or erysipelas or operations, he thought the poison had passed into the system and was beyond the reach of surgery. Mr. Alban Doran thought so too and doubted if it would be justifiable to operate in truly pyæmic cases, as the viscera were in them almost always affected with secondary deposits. Dr. Norman Moore said some of the collapse might be due to the size of the opening, and mentioned a case he had seen within two hours of rupture of a gastric ulcer. Death occurred in seven hours and very few signs of peritonitis were found at the autopsy. Mr. Marmaduke Shield had often punctured through the abdominal wall for chronic obstruction, but the punctures were apt to leak and set up peritonitis. The trocar should be as fine as a sewing-needle and passed obliquely through the muscular coat, so as to make the opening somewhat valvular. Mr. Bowlby said two incisions, one above and one below the umbilicus, were necessary to ensure complete flushing when the peritonitis was due to gastric or duodenal rupture.

Laparotomy for perforations was also discussed this week at the Medical Society of London, where Mr. Marmaduke Shield read a paper on Ulcerations of the Duo-

denum, with special reference to the latent perforating ulcer of that part, and related two cases in which he had operated. In both the fluid found in the cavity was sweet, and he thought if laparotomy was performed early in such cases the fluid would be found very different from that met with when the perforation was in the cæcum or lower. The importance of thorough flushing, a second incision for this purpose, and other points were insisted on by the author and the speakers who followed.

The Pathological Society opened its session with a good show. Mr. Stephen Paget showed a specimen of ventral hernia from a woman of fifty years of age. Laparotomy had been performed, but she did not rally. He also showed another specimen—tuberculous recto-vesical fistula from a man of about fifty years of age. At the autopsy both lungs were tuberculous, the right testis a caseous mass, and the cord thickened; the wall of the bladder had miliary deposits; a mass of old tuberculous glands and scar-tissue lay between the bladder and rectum, and two fistulous tracks were traced in this, one of which led from the bladder to the rectum, the other from the rectum to the mass, and back again to a lower rectal opening. Mr. H. Fenwick thought the fistula originated in a tuberculous deposit of the vesiculæ seminales which had broken into both bladder and rectum. Mr. Bowlby was also of this opinion, and Mr. Paget said he would make a careful examination of the vesiculæ, and report the result.

Dr. Rolleston showed a tumor growing from the upper end of the left supra-renal capsule. It was as large as a chestnut; on section firm, brown, with hemorrhagic spots.

Mr. Targett showed a polypoid tumor of the œsophagus, which appeared like a fibrous growth which had been invaded by epithelioma. There was an ulcerating carcinomatous growth four inches below, and as catheterism had been sometimes ineffectually attempted, Mr. Shattock suggested it had so become inoculated. Had the positions between reversed it would have been possible for auto-inoculation to have occurred—not so as it was. It was stated that the cervical glands were full of epitheliomatous growth, but no secondary nodules were found in mucous membrane.

Mr. Jackson Clarke gave some account of his investigations into variola and vaccinia. He said his recent work confirmed his conclusions regarding carcinoma and sarcoma. Drs. S. M. Copeman, Ruffer, and D'Arcy Power controverted the views of Mr. Clarke, who replied to their criticisms. We shall probably hear more about protozoa during the session.

Cancer is always a topic of sad interest. Yet, notwithstanding many disappointments, how naturally one listens to any reasonable suggestion as to its treatment! Chian turpentine has had its day. Now, another medicine is proposed. Neither more nor less than cinnamon in the form of decoction administered freely. Dr. Carne Ross, of Manchester, is responsible for reviving this remedy. I say reviving, as I believe is has been previously employed and fallen into desuetude. I should state that Dr. Ross distinctly disavows all pretence that cinnamon is a specific, but he has found it useful in mitigating pain, so much as to be a substitute for morphia. Moreover, in some of the cases related the progress of the disease seems to have been delayed or arrested. Still we know that this sometimes occurs under other treatment or none, and further trials are needed before subscribing to the expectation of being as fortunate as Dr. Ross seems to have been in his run of cases. I have no doubt that cinnamon will be largely prescribed for a time and so we shall be able to judge whether it is of use, and if so, to what extent.

Great indignation is felt and has been expressed at the determination to admit pay patients into the Great Northern Central Hospital. These patients are to have the attendance of the Honorary Staff. A petition against this proceeding, signed by upwards of two hundred medical men in the northern suburb, has been presented by an influential deputation, but has not turned the committee from their purpose. It is certainly open to question whether the committee are within legal rights to use a building provided for charity, to let as lodgings for invalids who are able to pay. The injustice of thus robbing local doctors of their patients is obvious; but we have made our services so free that the public sets little value on them, and the reasonable protest of the practitioners affected will be called selfish jealousy and trade-unionism. So let it be, the general practitioners have their positions to maintain, and if the consulting staff will not listen to reason, should adopt the trade-union plan which will be attributed to them, and boycott the staff. Mr. Spencer Watson has resigned his surgency rather than be a party to the contemplated injustice. He has thus set an example which his colleagues should not have left him to do single-handed, and which they would be well advised to follow at once and in a body.

GOAT SERUM IN TUBERCULOSIS.

To the Editor of the Medical Record.

Sir: Referring to the present treatment of tuberculous disease by "immunized serum," it appears from Viquerat's investigations that he found the ass and mule to be the only non-tuberculous domestic animals—though he admits that the immunity enjoyed by these is not absolute.

There are, however, two other domestic animals which enjoy a far greater resistance to tubercle than the ass or mule, viz., the common goat and the ewe. The immunity of the goat is particularly noticeable in Ireland, where consumptives abound, and where the goat—an omnivorous feeder—has been known to eat paper and other articles covered or contaminated with the expectoration of consumptives, without injury or any loss of health. Warm goat's milk has been highly regarded as a remedy in consumption or "decline," since the days of Galen (who, by the way, was the first to treat tuberculosis by strychnine—or rather "Ignatius Bean"), and ewe's milk boiled with mutton suet was at one time a famous remedy in all chest diseases.

Perhaps it may be worth while to test the natural and artificial immune serum of the goat in future experiments.

C.

IS SALMON POISONOUS TO DOGS?

To the Editor of the Medical Record.

Sir: There is a widely spread belief among people in Oregon and Washington, that salmon is very dangerous, and in many cases fatal, to dogs, when eaten. It is claimed that the flesh, and blood more particularly, contain something that is poisonous to the canines. Now, I am very sceptical in regard to this salmon theory, and find that many intelligent persons disbelieve it, and point to the fact that dogs in Alaska are fed on salmon almost exclusively, and no harm results.

There is no doubt but that more dogs die here than in the East, but they all have the same symptoms, which are there known by the general term of distemper, which is in reality a catarrhal fever with dysentery. A young dog will be taken sick and mope around the house, refusing to eat. The nose becomes hot and dry. The ears, feet, and lips feel cold, and the mouth has a bluish tint, eyes are suffused. Constipation is present at first, but is soon followed by the most offensive dysenteric discharges, until finally the poor dog succumbs from exhaustion. This is a type of the so called salmon poisoning. I have never seen, in any work on diseases of dogs, mention made of "salmoning," as it is commonly called, and doubt the existence of any such thing as dogs dying with the above-described symptoms miles from any streams of water. Myths die hard, and superstition is as widely diffused as it ever was, only it continually changes its form. I should like the opinion of the readers of the

MEDICAL RECORD, either through its columns or by letter, on this subject, as it is one of much interest to dog owners in this part of the world. Yours,

F. W. VAN DYKE.

GRANT'S PASS, ORE.

THE RESORCIN TEST FOR FREE HYDROCHLORIC ACID.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with interest Dr. Julius Friedenwald's article on the use of the resorcin test of Boas for hydrochloric acid. For the last eighteen months I have used this test to the exclusion of the phloroglucin vanillin test and have found it sensitive and convenient. Although I have occasionally verified my tests with known dilutions of hydrochloric acid, I have made no such exhaustive study as that of Dr. Friedenwald. Still, as practical experience is always good evidence, I am moved to add my mite and to thank the doctor for his careful research.

A. L. BENEDICT, M.D.

BUFFALO, N. Y., October 13, 1894.

CAR SANITATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The letter in the MEDICAL RECORD of November 3d, by W. Washburn, M.D., on the subject of "Car Sanitation," is of great interest, and I beg to point out an additional source of danger and cause for complaint.

To those of us who are obliged to ride on the elevated trains in the late afternoon, it will be remembered that there is a peculiar disagreeable odor, quite distinct from that due to the presence of a large number of people. Indeed, it is more often observed when entering trains at either terminus of the road, when the cars are empty. This odor is due to the imperfect combustion of the oil-lamps, which produces carbon monoxide (CO), instead of, as is the case when combustion is perfect, carbon dioxide (CO_2). This carbon monoxide, as is well known, is a very poisonous gas, and the milder symptoms of headache and malaise resulting from it I have frequently observed, after riding in these cars for twenty minutes. The reason of the existence of this condition is a total disregard on the part of the railroad authorities for the welfare of its patrons. The blame cannot be thrown by them upon the passengers, as perhaps might be done in the case of collection of filth from expectorated matter. It is all owing to their desire for economy. The lamps are lighted in the early afternoon, before they are needed, and then the wicks are turned down as low as possible. Complaint to the guards is of no avail, they have their orders from those in authority, and cannot be blamed for the existing condition.

Perhaps this has been pointed out before. If so, my excuse for writing now is the fact that the condition still exists, and only by continual agitation of these questions of vicious abuse of power on the part of certain corporations, can we hope to have them removed.

FRANK A. BOTTOME, M.D.

NEW YORK.

The Song of the Girdner Telephone Bullet Probe —

After the "shootin's" over,
After the scrap is done,
After the "Dago's" punctured,
After the cowboy's fun (?)
Many's the gun "not loaded,"
I can attend to all;
Merrily I will meander
After the Ball.

S MORRIS CONANT.

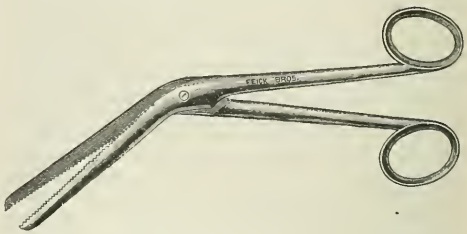
New Instruments.

A NEW SERRATED NASAL SCISSORS FOR THE REMOVAL OF HYPERTROPHIES AND TURBINATED TISSUES.

BY D. N. RANKIN, M.D.,

ALLEGHENY, PA.

THE Serrated Nasal Scissors devised by me has proven a very valuable instrument for the removal of hypertrophied turbinated tissues, warty growths of the nares, and exostoses of the septum. In many instances it has taken the place of the nasal saw, from the fact that it requires



less time, pain greatly diminished, and less hemorrhage in removing the growth. The accompanying cut will show its appearance, and is one-half the actual size of the scissors. This instrument was made for me in a most excellent manner by Feick Bros., 49 Sixth Street, Pittsburg, Pa.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 10, 1894.

	Cases.	Deaths.
Tuberculosis	117	77
Typhoid fever	16	3
Scarlet fever	53	4
Cerebro-spinal meningitis	2	3
Measles	25	2
Diphtheria	137	37
Small-pox	19	0

The Chinese Imperial Medical College of Tien Tsin.—The honor of establishing the first medical school, where the healing art will be taught after western models, belongs to Surgeon-Captain F. S. Heuston, of the British Army. The president of the new Medical College is His Excellency the Viceroy Li Hung Chang. The vice-presidents are Sheng Taotai, Lu Taotai, Lohfeng Luh Taotai, and Mr. A. Irwin, F.R.C.S.I. The two last and Dr. Lin Leien Fai are the directors. Mr. F. S. Heuston is the professor, and he is assisted by the following instructors: Dr. Kin, Dr. Chow, and Mr. Li. The dean is Dr. Lin, and the proctor Dr. Kin. The rules, subjects of study, and examinations are comprehensive. Candidates for the degrees in medicine and surgery of the College, before they are allowed to present themselves for the first professional examination, must produce evidence that they have passed a preliminary examination in general education and have been registered as medical students. Before receiving his diplomas to practise medicine and surgery the student must be over twenty-one years of age, and must have successfully passed each of the four professional examinations of the College. There are two sessions: spring (from after Chinese New Year to 1st of July) and autumn (from September 1st to Chinese New Year); and the examina-

tions are held at the close of the latter session. There are four professional examinations, held at the end of each year of study, and directed by a specially appointed Board of Examiners. At least two thirds of the lectures must be attended. Before admission to the second professional examination, evidence must be produced of having attended a medico chirurgical hospital for a period of six months after the first professional examination, and of having taken notes of surgical and medical cases to the satisfaction of the medical officers of the hospital. Attendance at a hospital for six months is also required for the third examination. At the same time the candidate must take personal notes on six medical and surgical cases, which are to be produced for inspection, if required by the professor. A two months' course in the compounding department of a hospital, under a qualified person, is also necessary. The fourth, or degree examination, requires a further six months' attendance at a medico-chirurgical hospital, attendance at the out-door dispensary, and notes, taken daily, on at least five cases of fever (typhus, typhoid or enteric, scarlatina, small-pox, or measles). The candidate must also produce evidence of having attended surgical operations at the hospital, and of having received practical instruction on the treatment of ophthalmic and [illegible] in which The [illegible] survived the dangerous catastrophe of primary tubal rupture, and continues to develop to maturity. The question of the proper treatment of those cases of advanced ectopic pregnancy in which the fœtus is living and viable is still in a somewhat unsettled state, and the cases encountered so rare that the history of every such case forms an interesting contribution to the study of this uncommon condition; and also, especially if successful, assists in the development of a proper technique in its operative treatment. For this reason I will ask your kind attention to the report of the following case. On January 23d I made the following entry in my case-book:

Mrs. F. McC——, referred to me by Dr. Wallace, of East Brady, Pa., aged thirty-five, had one child, nine years old, since which time she remained sterile. Her puerperium was complicated by a slight febrile attack lasting a few days only, after which her convalescence was normal. Health fairly good until three years ago, when

The Collection and Preservation of Anatomical Material.—At the last meeting of the Association of American Anatomists, a committee was appointed to consider the question of the collection and preservation of anatomical material, and to report, at the next meeting, what, in their opinion, are the best means of accomplishing these objects. In order to make the work of the committee as comprehensive as possible, and to obtain information which will be of service in arriving at definite conclusions as to the best methods of accomplishing the purposes indicated in the resolution, it has been deemed desirable to send to the teachers of anatomy, in this country and abroad, a circular letter, with the following questions appended:

1. Is anatomical material obtained in accordance with a legal enactment, wholly or in part? 2. If there is an anatomical law in your country or State, please send a copy of it to the chairman of this committee, Dr. J. Ewing Mears, 1429 Walnut Street, Philadelphia, Pa. Please state whether the law is satisfactory, whether it is readily obeyed by those upon whom duties are imposed by it, and mention any improvements you would suggest as to its requirements? 3. Is the material received in good condition? 4. What disposal is ultimately made of the remains? 5. Please state what means are employed to preserve anatomical material for the purposes of dissection or operative surgery. If injections of preservative fluids are used, state their composition and the methods of use, at what point injections are made, whether at the heart or in the large arteries, and their effect in accomplishing the preservation, with any changes in the color or character of the tissues. What length of time can material be used in dissection by the methods employed by you? If preservation by means of "cold storage" is employed, please state the cost of the machinery which it was necessary to construct for this purpose, and what means are taken to prevent decomposition after the subject is placed upon the table for dissection. 6. Please state the cost, by the method employed by you, for each subject, (*a*) for receiving it, (*b*) for injecting and preserving it. 7. Do you obtain an adequate supply of material for the purposes of anatomical instruction? How many students are assigned to each subject, and what is the method of allotment? 8. Please give any information which you may deem of importance. As the report will be general in character, the name of the informant or institution will not be mentioned by the committee unless requested.

Education and Crime.—Sir John Lubbock recently addressed the Sociological Congress in Paris upon the effect in England of education upon crime. Since 1870 the number of children in English schools has increased from 1,500,000 to 5,000,000, and the number of persons in prison has fallen from 12,000 to 5,000. The yearly average of persons sentenced to penal servitude for the worst crimes has declined from 3,000 to 800, while juvenile offenders have fallen from 14,000 to 5,000. Sir John Lubbock sees in these figures a confirmation of Victor Hugo's saying, that "He who opens a school closes a prison." In France, according to the Paris *Temps*, criminal statistics and the statements of magistrates show that as schools have been opened prisons have filled, and that the diffusion of education has been accompanied, apparently, with increase of crime, and especially of juvenile crime. In attempting to acccount for this phenomenon the *Temps* points out that in France, under the republic, education is simply intellectual instruction. In England there is not only instruction, but training. Moral and religious influences are brought to bear upon the children.

Bacteriology of Hospital Bed-Cards.—Dr. Trousholiavski, in an inaugural dissertation recently presented to the University of St. Petersburg, gives the results of some curious researches made by him on the bacteriology of hospital case-books and papers. Before use these are almost free from microbes. Old case-books which have been used at the bedside, and have afterward been shut up in drawers from eighteen months to two years, also contain very few microbes. On the other hand, papers which have been close to, or in contact with, patients, yield a large number of micro organisms. In forty-six bed-cards and admission-cards examined for the purpose, the average number of micro-organisms found was 43 per square centimetre of paper. By the side of indifferent micro-organisms, pathogenic microbes such as B. pyocyaneus, the bacillus of tubercle, and streptococci were found. Virulent micro-organisms placed on dry sterilized paper preserved their virulence for a considerable time; the comma bacillus from five to fourteen days, the typhoid bacillus for sixty-three days, the diphtheria bacillus for thirty-eight days, the streptococcus for ninety-eight days.—*British Medical Journal.*

Chicago is Almost the Healthiest City in the World, if its own statisticians and health officers are to be believed. According to a report of the Health Commissioner there is but one city, Berlin, that had a lower death-rate for the year 1893, that being 16.3, while Chicago's rate was 16.9. The population is estimated at over 600,000 above the United States census of 1890, and the area of the city includes a large tract of territory that is practically open prairie, where the death-rate is naturally much below that of cities.

Frost Burns.—In the accidents which have attended the manipulation of liquid air and other substances in his laboratory, M. Raoul Pictet has distinguished two degrees of burns from the intense cold. In the first the skin is reddened, turning blue the next day. The spot doubles in area on the following days; there is intense itching, and five or six weeks are usually required for

healing. In the more severe burns, those of the second degree, the skin is rapidly detached. A long and stubborn suppuration sets in, and healing is very slow, and altogether different from that of burns from fire. On one occasion, M. Pictet, while suffering from a burn due to a drop of liquid air, seriously scorched the same hand. The scorched portion was healed in ten or twelve days, whereas the cold burn was still open six months afterward.—*British Medical Journal.*

Acromegaly and Gigantism.—Dr. Sternberg concluded, at the Congress of German Physicians, that the study of the skeleton of the giant showed that there exists a physiological and a pathological gigantism, and that the latter are cases due almost entirely to acromegaly. He thinks that gigantic growth and acromegaly can exist in the same individual. Twenty per cent. of the patients with acromegaly show evidences of gigantism, and forty per cent. of giants have acromegaly. Gigantic development predisposes to vegetative disturbances, and especially to acromegaly. Enlargement of the thymus he thinks is a part of the natural history of acromegaly. Thyroid feeding was productive of slight amelioration of the symptoms of the disease in one case in which it had been employed.

The Use of Quinine in Influenza.—Dr. Mossé (Academy of Medicine of Paris) concluded from his researches that quinine, when given in moderately large doses, tends to exert a preventive action on the manifestations of influenza infection. In three cases of severe pneumonia complicating the grippe, recovery, which the writer attributed to the use of quinine, resulted.

The Decline of the Pessary.—"No one invents a pessary nowadays, in strange contrast to the time when scarcely a man prominent in the practice of diseases of women did not invent one." One may conclude from this that either all available pessary devices have been invented, or that the use of the pessary is to be discouraged. It is the latter view that Dr. J. G. Blake holds in a communication to the Obstetrical Society of Boston, April, 1894; his alternative for the pessary, is, of course, surgical procedure. His complaint is more of the abuse than the use of the pessary, although he quotes Fritsch, a German writer, who declared that he had spent ten years in learning the treatment by pessaries, and considered it the most difficult in the whole range of gynecology, and that it is easier to perform a laparotomy than to apply an accurately fitting pessary. The same author criticises their use, declaring that the pessary heals palliatively, but injures definitively; for it distends the fornix vagina so enormously, that even after it has been worn for years, a cure is not to be hoped for. On the contrary, retroflexion of the uterus returns after the removal of the pessary. The longer the uterus has been displaced, the longer the time necessary to enable the reflexed ligaments to return to a normal condition; and a few days have been sufficient, after its withdrawal, to have the uterus fall back into its old position. Among the means for attaining permanent cures, Blake mentions narrowing the vagina; pregnancy followed by prolonged rest in bed; dilating and curetting; and shortening the round ligaments. The first, he says, is only called for in complete prolapse, where no instrument, without external support, will keep the uterus within the vagina, but where it can be accomplished by narrowing the canal and outlet: these cases are comparatively rare. The operation of dilating, curetting, and packing is particularly adapted to the cure of anteflexions, and to the removal of enlargements which attend all forms of backward displacement. The combined dilating, curetting, and Alexander, is to his mind the true solution up to date of the vexed problem of backward displacements. Ventral fixation, by opening the abdomen, and by various other methods (the vaginal, for instance) of fastening the uterus, has been advocated by many writers. He sees no advantage in them over the simple, harmless, and in most cases effective, operation in proper cases, and of dispensing with pessaries. He thinks no one has yet devised a simpler, less dangerous, or more effective measure for the emancipation of women from the wearing of pessaries, than the two operations of dilating and curetting, and Alexander.—*Omaha Clinic.*

The Treatment of Basedow's Disease by Thyroid Feeding.—Dr. P. Brund reported at the recent meeting of the Congress of German Physicians (Vienna), that favorable results had followed the feeding of sheep and calves' thyroids in several cases of exophthalmic goitre in which he had followed this plan of treatment. Of 12 cases so treated, 9 showed marked improvement, reaching to cure in some, while 3 cases were not affected. In all cases, with one exception, the treatment was well borne; in this case the sinister symptoms produced were headache, nausea, anorexia, tachycardia, and loss of flesh. The symptoms disappeared when the thyroid feeding was stopped.

CŒLIOTOMY IN ECTOPIC GESTATION WHERE THE FŒTUS IS LIVING AND VIABLE, WITH THE REPORT OF A SUCCESSFUL CASE.

By X. O. WERDER, M.D.,

PITTSBURGH, PA.

FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS; GYNECOLOGIST TO MERCY HOSPITAL.

Ectopic gestation is still a fruitful and interesting topic for discussion, particularly that rare form in which the fœtus has survived the dangerous catastrophe of primary tubal rupture, and continues to develop to maturity. The question of the proper treatment of those cases of advanced ectopic pregnancy in which the fœtus is living and viable is still in a somewhat unsettled state, and the cases encountered so rare that the history of every such case forms an interesting contribution to the study of this uncommon condition; and also, especially if successful, assists in the development of a proper technique in its operative treatment. For this reason I will ask your kind attention to the report of the following case. On January 23d I made the following entry in my case-book:

Mrs. F. McC——, referred to me by Dr. Wallace, of East Brady, Pa., aged thirty-five, had one child, nine years old, since which time she remained sterile. Her puerperium was complicated by a slight febrile attack lasting a few days only, after which her convalescence was normal. Health fairly good until three years ago, when she was under treatment for some uterine affection, of which she was relieved until August of last year. Menses regular, duration one week, moderate in quantity, accompanied by some pain, especially in her back; rarely cramps. Last regular menstrual period began July 16, 1893. In August they were delayed one week, and when they returned they lasted fully six weeks, but never profuse. During the first three or four weeks she was able to be on her feet, though she complained of some occasional pains, was sick at the stomach, and felt weak. In the latter part of September she was suddenly seized with very severe cramps and a feeling of faintness, which returned in paroxysms for several weeks, confining her to bed for at least six weeks. In the early part of November she was able to leave her bed for short periods, but was unable to be about until Christmas. She is still very weak, anæmic, and emaciated, and has pains in her abdomen, especially in her left side and in her back. Her menses have never reappeared since October; no leucorrhœa; bowels obstinately constipated. Micturition frequent, sometimes accompanied with bearing down pains. Appetite poor. Since Christmas she has noticed an enlargement of her abdomen, especially on her left side.

The lower part of her abdomen is enlarged by a tumor of the size of a five or six months' pregnancy, two-thirds of which occupies the left side and extends to a line midway between symphysis pubis and umbilicus, which is tender on palpation. Distinct fœtal movements can be felt, but the heart-sounds are inaudible. The breasts have become enlarged lately and present the characteristic appearances of pregnancy. The external genitalia show the peculiar discoloration of pregnancy to a slight degree. The cervix presents a bilateral laceration to the vaginal fornix; it is soft and patulous. To the left of the cervix, pushing the uterus over against the right iliac bone, is the tumor, reaching low down into the pelvis and filling out Douglas's space. The uterus in its lower two-thirds can be felt distinct from the tumor and is enlarged, and when under the influence of an anæsthetic, the following day, the upper third or fundus could be palpated; but the internal or left cornu and the border of the body seemed to merge into the tumor to such an extent that they were unrecognizable to the palpating finger. The examination without anæsthesia was very painful, and she seemed unusually sensitive about her pelvis.

The diagnosis made was ectopic gestation at six months with a living fœtus, which was subsequently confirmed by my friends Drs. F. Blume, J. J. Buchanan, and John M. Duff. The patient was advised to remain at the hospital, where she could be under constant surveillance and receive prompt attention should occasion demand it. In spite of our earnest solicitations she went home, a distance of seventy-five miles, but was prevailed upon by Dr. Wallace to return a month later. An examination corroborated our former diagnosis, and also noted a perceptible increase in the size of her abdomen. She had suffered less during the last month than previously, and her general health had improved. She remained now at Mercy Hospital for six weeks, going about her room and through the building, and enjoying fairly good health, though she complained of a more or less constant soreness in her abdomen. It was decided to defer operation to about two weeks previous to the end of her term, unless some change in her condition should demand earlier interference.

After the usual preparations the operation was performed April 4th of this year, at Mercy Hospital, in the presence of over twenty physicians. Having placed her on the operating-table another vaginal examination was made, when a finger could be introduced into the uterus up to the fundus without any difficulty, proving conclusively that the uterus was empty. The incision was made in the median line and a yellowish-white cystic tumor was exposed. As the placenta at previous examinations had been located a little to the right of the median line, the sac, the walls of which were very thin, was opened cautiously by a small incision a little to the left of its centre, through which at once the child's scrotum prolapsed. The opening was rapidly enlarged with the fingers, the feet seized, and the child extracted. The head was in the left iliac fossa, with the occiput and back pointing to the spinal column. Only a few drops of amniotic fluid escaped from the sac; the child had no other fœtal covering except the cyst-wall. The anterior surface of the cyst was perfectly free from adhesions, but above and on the left side of the sac numerous loops of intestines were found adherent; on the right it terminated between the folds of the broad ligaments at the uterus, which was enlarged to the size of a two months' pregnancy. It was decided to extirpate the sac if at all possible, and separation of the intestinal adhesions was therefore begun, when all at once a terrific hemorrhage from the bottom of the sac, evidently the placenta, put a sudden stop to our efforts. While my assistant used sponge pressure, I rapidly clamped the ovarian artery in the infundibulopelvic ligament very close to the ileum, and with another forceps compressed the branches of the uterine artery along the left border of the uterus, which at once controlled the bleeding. The placenta, which was spread out over the spinal column and the right posterior wall of the pelvis, and adherent to intestines only by a small portion of its upper margin, could now be separated with comparatively

little loss of blood. It was of rather larger size than an ordinary placenta, and devoid of any fœtal membranes. Another effort was now made to peel off the very thin cyst-walls from the intestines, but the adhesions were firmer than the membranous sac-wall, which tore at every such attempt, and was therefore abandoned. The free portion of the cyst was now excised, the ovarian and uterine arteries compressed by clamp forceps, tied with strong silk ligatures, the forceps removed, and the remainder of the sac gathered and drawn together by silk sutures attached to the parietal peritoneum, the cavity packed with a Mikulicz dressing of iodoform gauze, and the abdominal incision closed, as far as the gauze dressing permitted.

The child, which at first was considerably asphyxiated, soon responded to the efforts of resuscitation made by Dr. J. M. Duff, and seemed hearty, strong, and well developed, though sadly deformed. There was marked asymmetry of the head and face; it had club feet, and on the left side of the thorax there was an ulcerated surface about an inch square, probably produced by the pressure of the left elbow against that side of the body. The first two days it seemed to be thriving; it took its nourishment—sterilized milk—readily, but on the third day it became very restless, its breathing was rapid, and the temperature 104° F., in which condition it continued until it died, four days after birth. The cause of death was supposed to be pneumonia, but no autopsy was held.

The patient rallied well from the operation, and the convalescence progressed very favorably and smoothly, and she never gave rise to the slightest anxiety. She was discharged from the hospital perfectly well, excepting a small fistulous opening in her abdominal wound, and has remained in excellent health ever since, as a letter received from her a few weeks ago indicates, though she has never menstruated since last October.

Anatomically, the case was undoubtedly one of tubal pregnancy primarily, with rupture between the folds of the broad ligaments; but that it was not a purely intraligamentous pregnancy was shown by the fact that a part of the sac seemed to be formed of amnion only. There must, therefore, have been a secondary rupture during the course of pregnancy, at which the largest portion of the ovum became extruded into the abdominal cavity, while a part still continued to develop within the broad ligaments. When this secondary rupture occurred is not clear from the history of the case, but I am inclined to the belief that it happened early during her gestation, as there were no symptoms pointing to any such accident after the sixth month.

In looking over the literature of this subject I have been able to find sixteen successful cases of cœliotomy for ectopic gestation with living fœtus at or near term, not counting my own, the operators being Jessup, A. Martin, John Williams, J. Lazarewitch, August Breisky, Hector Treub (two cases), Joseph Eastman, R. Olshausen (two cases), Carl Braun von Fernwald, G. Rein, John W. Taylor, Professor Schauta, Mordecai Price, and William T. Lusk. In Schauta's and Lusk's cases the operation was performed before viability of the child, namely, at the end of the sixth month, but as the technique is the same as at the end of term, I have included them in my list. In eleven, or with my own, in twelve cases, the placenta was removed at the time of operation with complete or partial enucleation of the sac, namely, by Martin, Lazarewitch, Breisky, Treub's two cases, Eastman, Olshausen (one case), Carl Braun, G. Rein, Schauta, and Lusk; in the others the sac and placenta were left and drained. The latter class of cases had, without exception, an unusually stormy and protracted convalescence, complicated by sepsis, venous thrombosis, etc., so that Lusk very properly remarks that the "fortunate results belong to the domain of miracle and do not invite to imitation," while the cases with removal of placenta, particularly those in which the whole sac could be enucleated, made uneventful and speedy recoveries.

The gravest element of danger in removing a living placenta is, as is well known, uncontrollable hemorrhage, which has induced many of the older operators to postpone operation until after the death of the fœtus, because after the placental circulation has ceased the risk from hemorrhage is comparatively slight. Though this method finds a few advocates even at the present time, the fear of sepsis in the ovisac, which so frequently follows the death of the fœtus, aided by a commendable desire to save the child's life, has undoubtedly been working a rapid change in favor of operative interference during fœtal life, especially as this has been justified by the more favorable results obtained in this operation during late years by an improved technique.

The blood supplying the placental circulation must, undoubtedly, be derived mainly from the ovarian artery and its anastomosing branches of the uterine artery. That these are the principal feeders was well shown in my case, in which compression of these arteries checked an alarming hemorrhage at once. Just as conclusive an example of the correctness of this anatomical fact we have in a case reported by Sippel,[1] in which he enucleated an ectopic sac at seven months, with a living child, with comparative ease, until it tore at the placental insertion, followed by a very profuse hemorrhage which compression of the placenta did not affect, but which promptly ceased after ligation of the ovarian artery—unfortunately too late for the patient, who succumbed to the acute anæmia one hour after operation. He strongly emphasizes the importance of securing the ovarian artery previous to the removal of the placenta. Olshausen and Breisky also call particular attention to this point in the technique of this operation, which has been followed by Lusk and Schauta. On account of the very extensive anastomosis of the internal ovarian with the uterine artery it seems safer to me to ligate both vessels, as done in my case. If further experience bears out the correctness of this view in regard to the relation of these blood-vessels to the placental circulation, an important advance will have been made in the technique of this operation, and the cases in which, at least, the placenta cannot be removed will be very exceptional, and limited to that class in which it has formed extensive intestinal adhesions. Considering the great danger of packing and draining, usually practised in such cases, it would seem preferable to me to leave the placenta without drainage, sealing up the abdominal wound hermetically. That the placenta can become absorbed, if undisturbed, is demonstrated in those cases in which the fœtus has died, and in which everything has disappeared excepting the fœtal bones. Braithwaite[2] reports a case in which the placenta was left and nothing escaped from the abdomen subsequently except a very small piece. Dr. Austin Lawrence reports two cases before the British Medical Association, held at Bristol, 1894,[3] in which he left the placenta; in one case it was absorbed, in the other the patient died from septicæmia on the twenty fourth day. He advises leaving the placenta, but reopening the abdomen if symptoms appear. Cullingsworth, at the same meeting, narrated a similar case, with living child, in which the opening in the membranes was sutured and the cord cut short. There was satisfactory progress for three weeks; on the twenty fourth day, however, a rigor occurred, and on the twenty-sixth he reopened the abdomen and found purulent fluid in the remains of the amniotic sac, which he washed out, but the patient died the same day. At the autopsy he discovered that there was no suppuration in the substance of the placenta, but the sepsis arose from the remains of the amniotic sac, which being of non-vascular tissue, was more likely to decompose. He advises, therefore, to leave the placenta, allowing it to bleed from the divided end of the cord, so as to lessen its size; to cut the cord quite close to the placenta, and to remove all the amnion possible, stripping it off from the placental surface, and to reopen the abdomen at once

	Date of Operation.	Name of Operator.	Age.	Number of Pregnancies Preceding.	Period of Gestation.	Result to Child.	Details of Operation.	References.
1	Aug. 14, 1875.	Mr. T. R. Jessup, Leeds, England.	26	1	33d to 34th week.	Living, but died at eleven months from croup.	Placenta not removed; no sac, fœtus free in abdominal cavity among intestines.	Tait on Diseases of Women and Abdominal Surgery, vol. i, p. 495.
2	July 9, 1881.	Dr. A. Martin, Berlin.	39	2	7 months.	Alive, cord pulsating, but did not breathe; had a large encephalocele.	Placenta removed after ligation at three points.	Berlin. klin. Wochenschrift, December 26, 1881. R. P. Harris, Extra-uterine Pregnancy, Am. Jour. of the Med. Sciences, September, 1888.
3	June 6, 1885.	John Williams, London.	30	1	35th week.	Died in a few minutes.	Placenta not removed, sac drained.	Brit. Med. Jour., December 5, 1887. R. P. Harris, ibid.
4	Nov. 4, 1885.	J. Lazarewitch, Kharkof, Russia.	27	1	9 months.	Lived 26 days.	Placenta and cyst drawn out, pressed up in the abdominal wound; ligated and large portion removed.	Vrach, St. Petersburg, 1886. R. P. Harris, ibid.
5	May 29, 1887.	Hector Treub. Leyden.	34	1	2 to 3 weeks before end of term.	Living, weight over 4 pounds. A year later a strong, healthy boy.	After incision of the sac, which bled freely, placenta was perforated with hand, and after extracting child bleeding was controlled by compressing each half of placenta by the hand of operator and assistant until removed; portion of sac extirpated, the rest intimately adherent to intestines, sewed to abdominal wound and packed with Mikulicz dressing. Supposed to have been an ovarian pregnancy or a pregnancy in tubo-ovarian cyst.	Zeitschrift für Geburtsch und Gynäk., Band xv., p. 384, 1888.
6	Oct. 29, 1887.	Aug. Breisky, Vienna.	39	..	End of 8th month.	Alive and well, weight 5 pounds, but died 3 weeks later from phlebitis of umbilical vein.	Tubal intra-ligamentous pregnancy. After removing child from the sac, the latter was drawn out, ligated at its juncture with the uterus and removed, containing placenta and membranes, and cavity drained. Mother recovered perfectly in three weeks.	Wiener med. Wochenschrift, 1887, Nos. 48, 49, and 56; and J. Eastman in Am. Jour. of Obstet., vol. xxi., 1888.
7	July 10, 1888.	Joseph Eastman, Indianapolis.	39	1	7 months.	Living, weight 4 pounds. Died at 8½ months from pneumonia.	Intra-ligamentous tubal pregnancy. Clamped uterine end of tube and broad ligament, and enucleated fœtal sac containing placenta intact, and quilted the pedicle with cobbler's stitch, using iron-dyed silk.	Am. Jour. of Obstet., 1888, p. 929.
8	Nov. 1, 1888.	R. Olshausen, Berlin.	30	1	9 months.	Living, weight 5 pounds. When a year old weighed 14 pounds.	Fœtus free in abdominal cavity, also largest part of placenta, between loops of intestines; the latter adherent to right broad ligament with only about one third of its periphery. This last portion was easily surrounded and proved so thin that two mass ligatures of silk were sufficient to securely tie off the placenta with attached portion of broad ligament. Only shreds of fœtal membranes were attached to placenta.	Deutsche med. Wochenschrift, 1890, p. 171.
9	Feb. 11, 1889.	Carl Braun von Fernwald, Vienna.	..	2	End of term.	Living, weight over 6 pounds. Died 72 hours after birth from lobular pneumonia due to inspiration of amniotic fluid.	Child free in abdominal cavity, placenta adherent to posterior surface of uterus and right broad ligament, extends deep into Douglas's cul-de-sac, and firmly attached to descending colon. After ligating right broad ligament in number of places, placenta can be detached in a number of places without much hemorrhage. But removal of sac necessitated elastic ligature around uterus to check bleeding and supra-vaginal hysterectomy.	Archiv für Gynäk., Heft ii., 1890.
10	Feb. 27, 1889.	R. Olshausen, Berlin.	32	4	9 months.	Alive, but very much deformed. Died ½ hour after birth.	Sac and placenta left undisturbed and drained with iodoform gauze packing. Spontaneous expulsion of placenta on thirty-fourth day. Interesting is the daily copious discharge of fluid per vagina during the eighth month, which was undoubtedly amniotic fluid draining away through tube. No amniotic fluid present during operation.	Deutsche med. Wochenschrift, 1890, p. 171.
11	Feb. 4, 1890.	G. Rein, Kiew, Russia.	35	..	37th week.	Living, weight 6 pounds; slight asymmetry of head. Two years after operation was hearty and well.	Intra-ligamentous tubal pregnancy. Sac, placenta, and fœtal membranes removed entire by enucleation from the peritoneum, in the same manner as practised in removal of intra-ligamentous ovarian cyst.	Centralblatt für Gynäkol., No. 50, 1892.
12	1891.	John W. Taylor, Birmingham, Eng.	..	..	9 months.	Living.	Fœtus free in abdominal cavity, placenta left behind and drainage-tube introduced, and umbilical cord drawn out of the lower angle of the wound. Patient recovered after very protracted convalescence complicated by sepsis, thrombosis of left iliac, the inferior cava, the right iliac and right renal veins.	Obstet. Trans. of London for 1891, p. 1151, and Wm. T. Lusk in New York Jour. of Gynecol. and Obstet., July, 1893.
13	Jan. 10, 1891.	Prof. Schauta, Vienna.	..	..	7 months.	Living.	After tying ovarian artery at the peritoneal fold, which constituted the residue of the ligamentum infundibulo-pelosium, he incised the peritoneal covering in a circular line corresponding nearly to the largest circumference of the sac. The enucleation of the latter was readily accomplished without rupture of sac-walls. Considerable hemorrhage resulted from detachment of the ovum from the uterus, which was temporarily controlled by pressure and later by sutures. The peritoneal borders of the cavity were then sutured to the parietal peritoneum, and the cavity itself was drained by a Mikulicz tampon.	Beiträge für Casuistik Prognose und Therapie der Extra-Uterine Schwangerschaft, Prag, 1891; and Wm. T. Lusk in New York Jour. of Gynecol. and Obstet., July, 1893.
14	Oct. 23, 1892.	Dr. Mordecai Price, Philadelphia.	..	..	.....	Living.	Placenta attached to uterine attachment of left tube and the entire pelvic viscera of the left side from the spine at the back, and extending up to the kidney and covered the descending colon. It was slightly wounded in the abdominal incision and the cause of considerable hemorrhage; this was controlled by clamping forceps, which were allowed to remain until first dressing. The child was enveloped only by amniotic sac, to which were attached the transverse colon and also small intestines to a slight extent. Placenta left and sac packed with iodoform gauze. Last portion of placenta removed on thirty-fifth day.	Transactions of the State Medical Society of Pennsylvania, 1893, p. 152.
15	Aug. 19, 1893.	Wm. T. Lusk, New York.	33	1	6 months.	Lived 24 hours.	Pregnancy started in right tube and subsequently developed to a great extent between the folds of broad ligaments. Tied ovarian and uterine arteries of right side, and then enucleated entire sac with placenta.	Wm. T. Lusk, Technique of Primary Cœliotomy in Advanced Ectopic Gestation, in N.Y. Jour. of Gynecol. and Obstet., July, 1893.
16	1894.	Hector Treub, Leyden.	..	..	3 weeks before term.	Lived several weeks.	Fœtus free in abdominal cavity. Supra-vaginal amputation of uterus; removal of placenta and sac. (Private communication from R. P. Harris.)	Bulletin Mem. Soc. Obstet. et Gynecol. de Paris, 1894.
17	April 4, 1894.	X. O. Werder, Pittsburgh.	..	1	2 weeks before term.	Lived 4 days.	Child enveloped in amniotic sac and also partly by folds of broad ligaments. Placenta removed after clamping and subsequently tying ovarian and uterine arteries of left side. Part of sac incised, but portion had to be left on account of firm intestinal adhesions. Edges of sac and stump of left broad ligament drawn together by sutures and attached to parietal peritoneum, and drained by Mikulicz gauze packing.	

should septic symptoms appear.[1] In addition to lessening the size of the placenta by allowing it to bleed from the severed cord, I would suggest to tie the ovarian artery on that side, and by so doing its blood-supply would be greatly diminished, though sufficient circulation would remain from the adhesions to keep it alive. Considerable shrinkage of the placental tissues would, no doubt, follow this interference with its normal circulation, and absorption could take place more readily. The method of leaving the placenta and sac and draining it, causing them to slough out, is certainly such an unsatisfactory procedure, fraught with the greatest risk to the patient, that it has little to recommend itself, and I feel confident will have no place in the future treatment of these cases.

The time of operation in advanced cases of ectopic gestation with a living child, is still a matter of discussion. In my case I followed the advice of Tait,[2] who advises the careful guarding and watching of the mother, though I did not go as far as he, to wait until false labor sets in before operating. Werth and Olshausen,[3] on the contrary, advocate operation regardless of the child's life, from the fact that such children only very rarely live long after birth; the latter says, "on the mother's account it is wise to operate as soon as possible, because every delay is apt to become dangerous, and in intraligamentous pregnancies the technical difficulties will only increase." While no doubt the welfare of the mother is first in importance, we owe some consideration to the life of the child, and I think we are justified in postponing operation in the interest of the child, providing we do not jeopardize the chances of the mother thereby. We should, therefore, be largely guided by the condition of the mother; she should be carefully watched and prepared for emergencies, but as long as no untoward symptoms require prompt interference, the period of viability should be waited for. In a similar case, however, I would not postpone operation much beyond viability, but would perform cœliotomy between the seventh and eighth months, in order to save the mother a long, anxious suspense, and because the child would be smaller, and therefore, especially in the absence of amniotic fluid, less subject to compression and consequent deformity.

It is a matter of considerable interest to ascertain the fate of the ectopic children which were delivered alive. I have been able to obtain the record of 40 such children. Eighteen of these died within a week after birth; 5 within a month; 1 died at six months, of bronchopneumonia; 1 at seven months, of diarrhœa; 2 at eleven months, 1 from croup, in the other, cause not given; 1 at eighteen months, from cholera infantum—making a total of 26 deaths, and leaving 14 children to be accounted for. Of these, 5 were reported as living and well after operation, with no subsequent report; 1 was strong and healthy after three weeks, but no report since; 1 was well at six months, then lost sight of; 1 well at last report; 2 live and are well at one year; 2 living and well at two years; 1 (Beisone's case) well at seven years; and 1 (Tait's case) well at fourteen and a half years. In regard to the latter, Dr. R. P. Harris has kindly furnished me the following interesting information: The child is Marian Sylvester, who is in good health and has grown to be quite a comely girl, living near the Woman's Hospital in Birmingham. Her mother, Mary Ann Sylvester, was thirty-three years of age at the time of operation; pregnancy in right broad ligament; she died on February 4, 1880. Operation, January 31 (Tait), or Sunday, February 1, 1880 (Savage).[4]

The greatest mortality of ectopic children occurs, therefore, during the first few days after delivery, almost fifty per cent.; of 22 surviving that period, 8 are known to have died within the first year and a half; 5 cases were said to be strong and healthy at birth, but no subsequent report. Five lived from six to eleven months; 5 from one to two years; two, seven and fourteen and a half years, respectively.

While this table does not present a very hopeful prospect for the saving of ectopic children at a viable period, the fact that some of them have survived the most dangerous periods of childhood, more than justifies us, in my opinion, to postpone operation until the viability of the child has been reached in all those cases where we can do so without danger to the mother.

The list appended contains all the successful cases of cœliotomy for advanced ectopic gestation with living children which I was able to find in literature up to the present time, with such important data as may prove of interest in connection with the report of this case.

[3] Deutsche med. Wochenschrift, 1890, p. 195.
[4] Tait operated on but one ectopic case in which the child lived. The boy seen in Tait's house, and generally regarded as an ectopic child, is Hemlingford Powell, son of Elizabeth Powell, delivered by Cæsarean section on October 11, 1881—a private case, delivered near Tait's house. Woman died; boy, believed to be now living, was seen last at Tait's, in December, 1892. The confounding of these two cases lies at Tait's own door. This boy became ectopic, and the girl was not mentioned.—R. P. Harris in private communication.

A CONTRIBUTION TO THE STUDY OF THE ETIOLOGY OF TUBERCULOSIS.[1]

By HERBERT M. KING, M.D.,
GRAND RAPIDS, MICH.

In the light of the masterly discussion upon the etiology of tuberculosis by Professors Gibbs, Vaughan, *et al.*, at the recent meeting of the Michigan State Society, to which many of us had the pleasure of listening and which it will soon be our privilege to peruse at leisure, in the volume of the Transactions of the Michigan State Medical Society, 1894, the remarks and suggestions which I offer for your consideration this evening will possibly seem very like a repetition, in which much of the more delicate definition and technique is lost, and only the grosser and possibly more superficial elements are preserved.

The case which I shall report, however, has in some of its features such a direct bearing upon this subject of etiology that I am induced to submit it for your discussion, together with my interpretation of the evidences deduced, from the clinical as well as the pathological aspects of the case, which, I am convinced, are in support of the theory of the bacteriological origin of the disease in question. A theory to which the great majority of modern pathologists incline, and one which would have little or no opposition were it not for such indefatigable observers as Professor Gibbs and Dr. Shurley, who, when least expected, and when scepticism has been lulled by the constantly accumulating proofs on the part of the German school, published reports, the results of their observations and experiments, well calculated to stagger confidence in preconceived ideas and shake the faith of any save the most persistent germ theorist.

At best, it seems to me, we are still groping in the dark for the missing links, which shall, when found, connect the bacillus tuberculosis in an intelligible manner with the morbid processes of phthisis and make complete the fabric of our etiological scheme. I believe that these "links" exist, and will sooner or later be discovered and understood. But whether as a result of the efforts of the microscopist or of those of the physiological chemist, it remains to be seen.

That the bacillus itself is not the absolute and direct cause of those earlier changes in the parenchyma of the lung, which if unchecked, lead on to cavity, I think all must concede, in view of recent investigation, which has established by repeated experiment two facts which seem to me to be insurmountable objections to the theory of the direct relationship existing between the bacillus and the destruction of tissue, even to the most sanguine champion of the renowned Koch.

1. In the earliest stages of tuberculosis, the hyperplastic interstitial tissue, while clearly showing the presence of

[1] Read before the Grand Rapids Academy of Medicine, May 28, 1894.

an inflammatory condition characteristic of tubercle, and while still having present all of the other elements found in any stage of the series of changes which follow, except, perhaps, pus, does not invariably contain the bacillus until the degeneration of the infiltrated tissue supervenes. Since, therefore, the bacillus is not necessarily present, it cannot be the direct and only cause of the localized hyperplasia which constitutes the tubercle.

2. Tubercle bacilli can be produced by repeated cultures which, apparently possessing all of the characteristics of the specific micro-organism in question, are inert to cause the disease, even when inoculated into the most susceptible animals.

This is not quite so convincing an argument when taken alone, for it can easily be imagined that in the process of artificial cultivation the bacillus may lose its virulency; but taken together the two facts mentioned offer an argument which cannot well be met on the theory of the bacillus itself being the direct cause of the first morbid changes.

On the other hand, I am thoroughly convinced that the bacillus is the ultimate and essential factor in the production of tuberculosis; that without its agency, no matter how predisposed by heredity, cachexia, or diathesis one may be, one can never develop tuberculosis. The exact nature of that agency, however, and the rationale of its action are still subjects for speculation.

In considering the few points which I wish to discuss here, it will be necessary to call attention to one or two etiological factors, which, I think, are pretty generally established.

1. Phthisis involves, necessarily, a predisposition to the disease, either by an inherited tendency or an acquired cachexia, constituting what may be termed a pre-tuberculous state.

2. The disease itself arises from causes which invariably originate outside the body, and

3. Tuberculosis in its incipiency is never a local manifestation of a general disturbance, but is, in the first place, a purely local lesion.

This theory is fully as tenable as that of the local origin of cancer. The encroachment of the disease from its local origin, however, is so very insidious and the symptoms arising from the local disturbance so masked by those arising from the early absorption of the specific poison generated, and which are the expression of its effect upon the vasomotor system, that it is not strange the theory is slow to gain credence. That such a theory, however, if generally adopted, would have a material bearing upon our treatment of the disease, must unquestionably be conceded.

The communicability of phthisis from the sick to the well is no longer a question, and I am lately advised that in many parts of the country health boards and railroad managements require the same precautions to be taken, with respect to the shipment of bodies of persons dying of phthisis, as with those in which death has resulted from any other of the infectious diseases. How far this course is justifiable I am not prepared to say; but in my opinion, if some like precaution could be taken in the transportation of the many thousands of tuberculous patients who migrate semi-annually throughout the country, it would be serving a far more reasonable purpose; and while we might not, for many years to come, be able to estimate with any degree of certainty the value of such a precaution, the end, I am sure, would justify the means.

Arguing, then, upon the premise that tuberculosis is communicable, we have arising at the start, three questions: 1. What is the direct agent of communication? 2. What is the vehicle or medium of that agent; and 3. How does that agent reach the point at which the first serious pathological changes take place, viz., the interstitial tissue of the lung.

This last consideration, I am aware, has really more to do with the subject of the pathology than that of the etiology, but may with propriety, perhaps, be touched upon in this article.

In answer to the first question, it may be said that while at present we have no positive proof that the bacillus may not, in some instances, itself be the immediate irritating presence which causes the infiltrated deposit of tubercle, we do know pretty conclusively that certain matter which contains absolutely no bacilli, is capable, when inoculated into the bodies of susceptible animals, of producing morbid changes identical with tubercle, and furthermore, that the pathological product thus generated, does not, at first, at least, contain bacilli, but simultaneously with the breaking down of this new tissue, appear the bacilli. Thus some of our most conservative observers still incline to the belief that the bacillus is the effect and not the cause of the disease.

Without entering into an exhaustive discussion upon this question, I may say that I am induced to take the following view of the subject; *i.e.*, the mature bacillus itself is not the immediate irritating presence; neither is any ptomaïne to which its existence and presence give rise, the direct cause for which we are searching; but, those forces upon which are dependent the growth and development of the spores of the micro-organism in question, require and necessitate that hyperplasia, degeneration, and ulceration which constitute the tuberculous process, and that each step of this process, as it were, marks a certain stage of embryonic development on the part of the bacillus. Furthermore, if this process of infiltration of hyperplastic tissue be positively arrested for a sufficiently long time, the spores become devitalized and the bacillus never develops. Thus it is seen often in sections made in hyperplastic lung tissue in close proximity to a softened tuberculous mass, swarming with colonies of bacilli, absolutely no bacilli are to be found, and yet the appearance in every other respect is pathognomonic of the specific disease. With this in view, it is still an open question whether certain agents, not necessarily germicides, but exercising a specific action upon the interstitial tissue by preventing or aborting the hyperplasia, would render impossible the conditions upon which depend the development of the bacillus. I very much doubt if the mature bacillus itself ever gains access from without, through any natural channel, to those points where tuberculous disease apparently originates. It seems to me far more reasonable to suppose that the spores deposited in the epithelial layer of the lining membrane of the bronchioles and terminal vesicles are absorbed by the lymphatics and conveyed to the contiguous connective tissue and undergo development, either along the course of such absorption or in tissue immediately adjacent.

In short, that if bacilli exist in the infectious matter received, that particular generation of bacilli never reaches a point further than the epithelial lining, and only the infinitely minute spores which are beyond the possibility of demonstration, by the microscope, at least, reach the point at which subsequently the tubercle appears.

In answer to the second question, it is only necessary for us to consider what is generally conceded to be the common source of infection; viz., the sputum from persons or animals suffering from tuberculous disease of the lung, and to this may be added the various excreta from those in whom the disease is located at points more or less remote from the lungs. Thus the urine, the seminal fluid, the fæces, and in some instances even the perspiration, might be, under favoring conditions, the vehicle of infection; and here again, it is worthy of consideration that it is by no means necessary that the material of infection contain one single bacillus sufficiently developed to be recognizable as such. Of course the sputum from tuberculous patients in the vast majority of instances contains colonies of bacilli, easy enough of demonstration, and naturally such a product is much more infectious than that which contains only the elementary molecules, simply, however, because in it there is correspondingly a greater quantity of infection.

The manner in which the infectious material is most

commonly conveyed to the vulnerable parts of the susceptible individual in the case of pulmonary tuberculosis, is generally thought to be by means of dust, which has either been in contact with, or is made up in part of, the expectorated matter from the unfortunate sufferer.

We have no proof, however, that the vapor in the expired air may not contain infectious molecules, and although the probabilities are against it, I think we are justified in exercising precautions with respect to its possible conveyance in that way. It is an interesting question, and one which has a very practical bearing, just how long matter which in the first place is highly infectious, can retain its virulency. Experiments with a view to determine this question have recently been made, and I have been surprised to be unable to find an instance where such experiments have proved that tubercle bacilli, in a non-parasitic state, have retained their virulency for a period of six months. In a series of experiments conducted by Dr. G. A. Heron and Dr. T. H A. Chaplin (London *Lancet*, January 6, 1894), both of the City of London Hospital for Diseases of the Chest, a number of guinea pigs (the number is not given) were inoculated with tuberculous sputum three months old. Most of the animals died from septicæmia within a week after the operation. The few that survived were in due time killed by chloroform, and of these not one showed any signs of having developed tuberculosis. The authors in this instance regret that the number was too small to be a very valuable addition to statistics, but thought it remarkable that two months after inoculation with stale sputum three months old, in which colonies of bacilli swarmed, five guinea pigs were free from tuberculous disease.

My third question is answered in part with the first. The spores having found their way into the epithelial lining of the mucous membrane, are with more or less avidity, according to the subject, taken up by the lymphatics and carried to and deposited in those parts for which they appear to have a peculiar predilection, naturally locating in that particular part best suited for the conditions which their development necessitates and always as near as possible to the seat of absorption. Thus in the bronchial glands the interstitial tissue of the lung, the mesenteric glands, the lymphatic glands, points in and about certain of the bony articulations, the testicles, etc.

The case which I cite illustrates to a certain extent, I think, some of those features in the early history of the development of phthisis which have been and are still obscured in the uncertain light of speculative theory.

It is one of acute tuberculosis, and the short time which elapsed from the development of the earliest symptoms to its termination, the rapidity with which the several stages supervened upon each other, and my constant association with the case, all conduced to make my opportunities for close observation rather unusual in the experiences of private practice.

The patient, a young man, aged twenty one, medium height, of better than the average physical development, owing perhaps to a military training, which he had recently enjoyed, consulted me first, on December 5, 1893, having been placed in my care by his family physician. He was unmarried and his occupation was that of a clerk in a dry-goods establishment. A Canadian by birth, of Irish extraction.

Family history: Father and mother, paternal grandmother, five sisters and one brother living, all in apparently good health. The others of his grandparents died at old age, and none from any lung disease, as far as could be learned. One younger brother died about a year previous from phthisis; the last few months of whose illness were passed in the same house and in ordinarily close intimacy with the patient. The habits and hygienic surroundings, which form no inconsiderable factor in the etiology of phthisis, were in this case as follows: The patient, occupying alone a small but comfortable room at home, was surrounded with all the necessities of life and those of the luxuries which over-fond parents and a very moderate purse could bestow upon a favorite child. The house, isolated from its neighbors and situated upon a hill, had all the advantages of light and pure air; but, on the other hand, ranged against these, as it were, the patient himself had lived a life of dissipation in late and irregular hours, sexual excesses, and indiscretions in the matter of food and drink for a number of years prior to the inception of the disease; and thus a constitution, which might otherwise, perhaps, have withstood the encroachments of the disease, or at least have so mitigated its course as to have prolonged life, by making the conditions essential to the acute form impossible (when, to theorize, the case might have been one of the ordinary form or, what is possible, that variety known as fibroid phthisis), was undermined and the powers of resistance were greatly enfeebled. The history given was in brief as follows:

The general health had always been good, save for a tendency to contract influenza upon the slightest exposure, which had been noticeable for several years. In the summer of 1892 the patient had malarial fever. For about a month, however, he had noticed a more or less persistent cough, especially annoying in the morning, unproductive of expectoration; but four days prior to my examination an acute exacerbation of the cough, together with severe laryngeal symptoms, had supervened and now appeared a very slight expectoration of tenacious mucus, which, on one occasion after smoking, had been streaked with blood.

Physical examination revealed the following signs: Temperature, 98.6° F.; pulse, 80; respiration, 24.

The pharynx and larynx showed evidence of intense congestion. The membrane was hyperæmic and the vocal bands could not be distinguished by difference of color from the adjacent walls. Speech, above a whisper, was impossible. Inspection and palpation of the chest gave negative results, while percussion elicited a barely perceptible dulness over the left apex, by no means sufficient of itself to go far toward establishing a diagnosis. Auscultation revealed a somewhat prolonged expiratory sound, a slight increase in vocal resonance, and just a perceptible lessening of the normal vesicular murmur. On the 5th, 8th, and 13th of the month the expectoration was saved from six o'clock at night to eight o'clock on the following morning and carefully examined with the microscope. As many as ten mounts were made from each of the first two specimens and in none were any pathological elements to be found. Meanwhile, the inflammatory condition in the pharynx and larynx subsided without ulceration. From the sputum of the 13th several mounts were made, and owing to a mere chance of staining, I believe, the specimen was obtained which was the only one of the whole number of mounts which showed the existing condition, and I therefore attribute my success in this instance to some fortunate accident in the process of staining. There was no pus present, and no free bacilli. Throughout the whole specimen the same condition existed, and so far no yellow elastic fibres were to be found. In some of the other mounts epithelium cells were present. Indeed in very few were they absent; but in none could the presence of bacilli, either free or, as in this particular mount, involved and seemingly embryonic in the protoplasm of the cells, be demonstrated. The cells, in a number of instances, were found to be apparently swollen, and to contain between the periphery and the nucleus a cloudy or granular mass, on the outer edge of which, but still within the protoplasm, were found the minute particles which gradually approach the appearance of bacilli as they near the periphery, until at the outer edge, and in some even breaking through the cell wall, they appeared as fully developed bacilli. In most of these cells the nuclei appear granular and in all, even those in which the cloudy swelling is not discernible, an unusual appearance is manifest.

Up to this time and for two days subsequent there had at no time in any of the thirty odd mounts, ap-

peared the least evidence of breaking down of tissue, no pus, and no yellow elastic fibres. Wherever bacilli appear about to emerge from the cell, it is noticeable that they are more fully developed and that they take the stain in a more characteristic manner. (I might say here that the staining process employed was a modification of that recommended by Ehrlich, requiring an immersion of about twenty-four hours. I do not think that any of the more rapid methods would have demonstrated this condition.)

On December 15th, began a series of severe and exhaustive attacks of hæmoptysis, recurring at intervals of from two to twelve hours, up to the 24th. These hemorrhages originated from the bronchial walls, in close proximity with that portion of the upper left lobe which had previously given the slight evidences of partial consolidation.

On January 1, 1894, the blood having pretty thoroughly cleared from the expectoration, another microscopical examination of the sputum was made. Bacilli were scattered here and there throughout the specimen, not in large colonies, but taking the stain in the usual manner, and perfectly pathognomonic. Some pus was also found. The evidences of breaking down of lung tissue were also distinguishable by the elastic fibres which now made their appearance in the matter expectorated.

On February 14th, less than a month before death, another examination of the sputum was made, in which were seen evidences of the rapid destruction of tissue and the vicious ravages of the tuberculous process. Pus appeared in large quantities, while bacilli were seen in thickly crowded colonies. Yellow elastic fibres were found in increasing amounts, and particles of sloughed tissue, even perceptible to the naked eye, could be distinguished, while physical examination revealed a rapidly growing cavity. Death occurred on March 10th, from asthenia. No autopsy was held.

Now, in conclusion, the point which I wish to make is this: It is not the presence of the fully developed bacillus to which is due the destructive process of tuberculosis.

I believe, not that the bacillus originates, *de novo*, in the tubercle, but that its development from the spore is the result of the disease process, to which the necessary requirements of the life and growth of that spore give rise; that furthermore, when the bacillus is mature and has deposited its elementary spores in the body, it has fulfilled its mission, is no longer an element of disease and is cast from the body as an effete product. How visionary may be my deductions I leave to your discussion to determine.

86 Jefferson Avenue.

The Etiology of Cancer.—The French Surgical Association recently held its eighth annual congress. The etiology of cancer was the most important question discussed. According to M. Bard, who opened the debate, the differentiation of malignant tumors in a pathogenic sense is an error, whatever may be their origin or their structure. All the tissues of the human organism may engender cancer, and there is no reason for applying this term to epithelial tumors. Each tissue may be the seat of a specific cancer, and this cancer owes its origin to a young cell endowed with an exaggerated power of reproduction. It is superabundant vitality which differentiates the cancer cell from the normal cell. M. Bard rejects the microbic theory as to cancer. Considerable diversity of opinion on this point was expressed by other speakers. It is decided that in future the French Surgical Congress will always meet at Paris in October, at the same time as the General Assembly. Many of the *congressistes* who visited the Lyons Hôtel-Dieu were disappointed to find the old white bed curtains (which have been discarded elsewhere), the old hospital smell of bygone days, and the food being prepared in the wards. M. Poncet's wards are being remodelled.

THE RECENT TYPHOID EPIDEMIC AT WINDSOR, VT.

By J. D. BREWSTER, M.D.,

windsor, vt.

In compliance with the request of our secretary and others, I will endeavor to give a brief account of the epidemic of typhoid fever which prevailed in Windsor, beginning in March, 1894. The first case reported was on March 15th. This case was in a family residing at the extreme southern limit of the village, and at the time no apparent cause could be found. No other case developed until March 24th and 25th, at which time a large number of people were attacked, almost simultaneously, with a febrile condition which soon showed itself to be unmistakably typhoid fever. These cases were among all classes of people, rich and poor alike, but all within the village limit.

Observation soon showed the disease was confined entirely to families using the village water supply, those having wells being entirely exempt, except in cases of children who drank the village water at school. This fact led immediately to the examination of the water system. Windsor was supplied by a series of springs situated about two miles or more from the centre of the town; these springs formed a small brook, which ran along a valley for about a mile, passing six farms and dwelling-houses, and then emptying into a reservoir, whence iron pipes conveyed the water into the houses of Windsor.

Now, about forty rods above the source of this brook a farm-house is situated, where it was ascertained a person had, the previous January, suffered from a feverish condition about four weeks. It was supposed to be a non-infectious form of fever, and was not reported to the local board of health, and consequently no care was taken of the discharges of the patient, and they were thrown into the vault; and to make matters worse, the sink drain was frozen at the time, so all wash-water was thrown out upon the snow. During the very warm weather which we had the first week in March, the snow melted, and all this accumulation easily found its way into the brook, and thence into the reservoir and our homes.

This explanation was unanimously indorsed by the State Board, who made an official visit to the place soon after the outbreak. The local Board at once issued orders to have all water used for cooking and drinking purposes, boiled. At the same time the town provided a water-cart to deliver water from an adjoining spring.

From March 24th to 30th, about eighty cases were reported; from this date to April 27th, the cases became less frequent, this time being probably the limit of the primary cases; the later ones were secondary, and mostly occurred in families already suffering from the disease. Up to July 28th there were 130 cases, these occurring in sixty eight families. The largest number afflicted in one family being 5, the majority only 1. The ages ranged from ten months to ninety-two years, but the majority were under twenty years of age, and a large per cent. were children; the latter withstood the disease to a remarkable degree, even with a protracted evening temperature of 104° F. The population of Windsor is 1,300, so about ten per cent. of the inhabitants were affected by the disease. We were fortunate in having only seventeen deaths, or thirteen per cent. Six of the fatal cases had intestinal hemorrhage.

S. H ——, aged forty four, died from complication of erysipelas. One died from perforation. Mr. V. —— had temperature of 106° F., at death, and there was a rise of a degree a short time after.

M. K——, a girl fourteen years of age, was afflicted with infantile paralysis. She died in the tenth week, and at death had seven bed sores, those on each hip leaving bone exposed, which was also carious. Three

died before the end of the second week, the average fatality was at about the end of the third or beginning of the fifth week.

I will now give a brief history of a few of the cases which have recovered. Perhaps the most remarkable one was Mrs. C——, about thirty years of age. She showed all the symptoms of typhoid—coated tongue, enlarged spleen, rose spots on abdomen, etc.; but developed no fever until the fifty-first day, when the evening temperature was 99° F. It ranged from this to 99$\frac{5}{10}$° F., until the sixty-third day. Convalescence being very protracted after the thirteenth week.

A. A——, aged seventy, had typhoid symptoms, with evening temperature of 103° to 105° F., with croupous pneumonia, rusty sputa, which continued to the twelfth day; from the 14th to the 21st, no fever. From twenty-second to thirty-second day average temperature, 102° F.; symptoms wholly abdominal; rose spots present. Temperature normal to the fortieth day, from the fortieth to fifty fourth there was fever, the highest point reaching 101° F. Symptoms: Catarrhal pneumonia. Convalescence protracted.

C. A—— had relapse on the twenty-first day with remarkable eruptions, some thirty or forty large papules which soon became vesicula and many of them pustular, while one was a true adenitis which went on to suppuration, the abscess containing one-half drachm of pus. This certainly was due to sepsis. This same case at the beginning of convalescence had suppurative otitis media and inflammation of the mastoid, with one recurrence.

G. B—— had evening temperature of 105° F. first week, delirium beginning on the fourth day. On the twenty-first day had subsultus and picking of clothing, and insomnia, continuing for a week. Temperature ranging from 103° to 104° F. at night. Convalescence set in after the seventh week, but delirium continued two weeks longer.

Two cases had phlebitis of the leg. Ten cases had intestinal hemorrhage.

Mrs. B—— was confined on the fourth day. Temperature, 104° F. The fever ran the usual course, and recovery took place after the fifth week.

Arthur K——, aged thirteen, after a mild form of the fever, appeared convalescent, when malaria made its appearance. Temperature, 105° F. After the second day the same symptoms recurred with the usual course of malaria. A large dose of quinine prevented a return. His history showed he had had malaria eight years before.

The most prolonged case was that of Henry S——, who had a temperature for one hundred and two days. This case had severe hemorrhages on the forty-ninth day. He was not moved from his bed for one hundred and sixteen days. After convalescence he gained twenty-three pounds in twelve days.

I could give many more interesting cases, if time would allow.

From July 28th to August 30th only two cases were reported, but during the month of September there have been twenty cases, thus making a hundred and fifty cases in all since the beginning of the epidemic. All of these later cases, with two or three exceptions, have been among the poorer classes, living in tenement-houses. Two of these died of perforation; in both cases the patients having been in a state of collapse for forty eight hours before death. Temperature, 93° to 97° F., and pulse, 125; abdomen extremely distended. The accidents in each case being sudden, when everything seemed progressing to a speedy convalescence.

One fact is worthy of mention: in several cases there seemed to be secondary infection coming from four to six days after apparent convalescence, when there had been no change in diet or management of the patients; they usually had fever for seven days, when true convalescence occurred.

Throughout the whole time the sickness prevailed, all possible precaution was taken to disinfect discharges and the clothing of persons afflicted. The discharges were buried after disinfection with either corrosive sublimate or copper, and the clothing was put in boiling water. We all know how difficult it is to impress the importance of this upon everyone, and doubtless, among some of the more ignorant classes the instructions given were disregarded, thus causing the later outbreak of the disease among that class.

Windsor has for twelve years been remarkably free from the disease, not averaging more than five to seven cases a year. I will here state, that the prison was entirely exempt from the disease, the water-supply being from a different source.

The village voted to discontinue the old supply, except for motor purposes, and now have their water from springs which flow from the hillside directly into a covered reservoir, from which the water is pumped into a stand pipe, also covered. The springs are far distant from any dwellings, and furnish no possible opportunity for pollution. No water supply that is exposed to drainage from dwelling-houses can be safe, for only the most untiring vigilance can prevent some accidents which will involve its consumers in as sad an experience as Windsor, after using the water system for over fifty years.

I cannot close this paper without paying some tribute to the noble way in which our citizens responded to the needs arising from such a calamity; a mass meeting was held in one of the churches, and a committee appointed to solicit money and clothing, such as was needed for the sick, and to provide food for the needy ones. Many volunteered as watchers, and every day the village was canvassed to ascertain the needs of all; the sum of $700 was raised to provide nurses for those who could not provide themselves. Twenty-eight nurses were employed, coming from Burlington, New York, Hartford, Ct., Worcester and Boston, Mass., thus aiding the physicians in no small degree. No disease needs more careful watching than typhoid fever, and many owe their lives to the never-tiring care of the faithful nurse. Windsor may well be proud of the generosity of her people, as this test has proved them. May the time be far distant when any other town shall be called upon to prove herself her equal.

Removal of the Restiform Body.—Dr. Biedl showed (Royal Medical Society, Vienna) a cat in which the restiform body had been completely removed a fortnight previously. The first symptoms after the excision were rotation in the opposite direction, rotation of the eyeballs, and forced decubitus. After a few days, when the cat essayed to walk, it found great difficulty in doing so, not, however, on account of paralysis, but because of loss of cognizance of place and surroundings. The head was held toward the left and near the ground, and the itinerary was toward the left in a circle. Disturbance in coordination of the muscles of the right side of the neck and throat caused it to eat on the right side. The experimenter thought the conditions presented by the animal could be explained on the supposition of functional suppression of a track along which nerve-stimulation proceeds from the cerebellum.

Von Bülow's Brain.—Hans von Bülow, the eminent pianist and conductor, who died at Cairo, in February last, had for years been a martyr to maddening headaches. In accordance with his often-expressed wish, after his death Professor Kaufmann, of Cairo, who performed the post-mortem examination, extracted the brain, and sent it to a German physician for examination. It now appears that the surface origin of two nerves leading to the scalp was imbedded in a scar, left by an attack of meningitis in early youth. Whether this scar can be held responsible for the great artist's many eccentricities must remain an open question.

A PLAN OF INFANTILE MEASUREMENTS.[1]

By HENRY DWIGHT CHAPIN, M.D.,

PROFESSOR OF DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE extremely rapid growth of the infant after birth makes a careful observation of all the phenomena connected therewith not only interesting but important to the physiologist and practical physician. As a partial index of this growth an accurate system of measurements is desirable, not only as noting a proper rate of evolution, but also for comparative purposes, after a sufficiently large number shall be made. In proposing a plan of measurements two extremes are to be avoided; first, in having too few for valuable data, and, second, in advancing a system too cumbersome or complicated for general adoption. It is with an effort to avoid these evils that the present plan is submitted. All that is required is a tape measure, a strip of sheet-lead, a pencil, a pair of calipers, and a table.

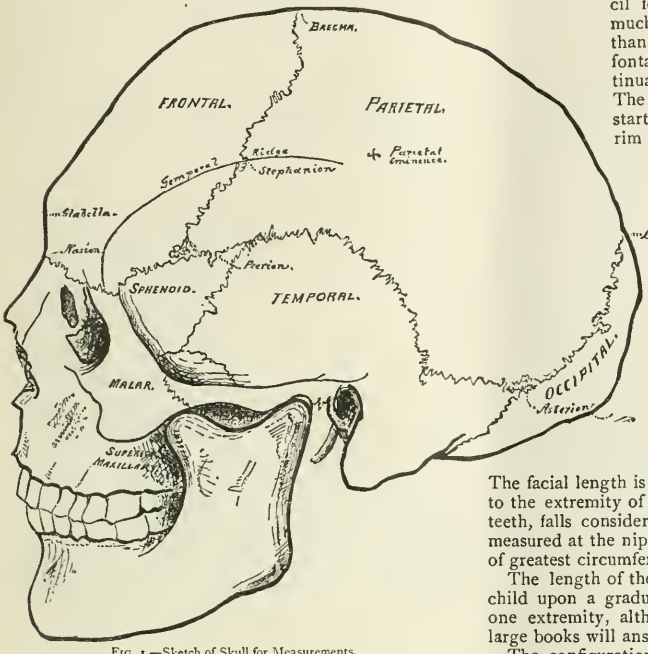

FIG. 1.—Sketch of Skull for Measurements.

Diet.			
Notes.			

The rapid evolution of the brain during infancy, and the fact that the future efficiency and well-being of the individual depend so largely upon its normal and healthy growth, renders a study of the head of great interest, and accordingly ten of the measurements are made upon the skull. As the skull is fairly representative of the brain during the years of its development, the measurements taken during infancy are more instructive as to brain size and development than those taken in later years. The skull changes considerably in its proportions during the first three years of life, and then more slowly up to the end of the seventh year when it has very nearly attained its full size.

The circumference is taken by passing the tape horizontally around the head, passing over the glabella and a point just above the external occipital protuberance. When this is procured, the following data will give a very rough approximation of the volume—x: circumference:: 1350: 50. Thus, if the circumference is 42 ctm., the approximate volume will be 1.134 cu. ctm. The naso-occipital arc is measured from the glabella to the external occipital protuberance. Before removing the tape, the three arcs composing the naso-occipital can be read off, namely, the naso-bregmatic, the bregmato-lambdoid, and the lambdo-occipital arcs. In order to do this accurately, the bregma and lambda should be previously marked, and I have employed an aniline pencil for this purpose. These points are much more easily indicated in an infant than in the adult. Where the anterior fontanelle is widely open, a line in continuation of the frontal sutures is marked. The binauricular arcs are measured by starting, in both cases, from the anterior rim of the meatus, and passing the tape respectively over the bregma and the lambda. When the anterior fontanelle is open, the antero-posterior and lateral diameters are taken. The cephalic, or length-breadth index, is measured by calipers, which are applied at the greatest biparietal and antero posterior diameters. The formula for obtaining this index is as follows—Length: Breadth:: 100: x. All cephalic indices falling below 78 are classed as dolicocephalic; from 78 to 80, mesocephalic; and above 80, brachycephalic. The facial length is measured from the root of the nose to the extremity of the chin, and, in the absence of the teeth, falls considerably below the adult. The chest is measured at the nipple line, and the abdomen at its point of greatest circumference.

The length of the body is measured by extending the child upon a graduated board with a movable slide at one extremity, although a flat table with a couple of large books will answer.

The configuration of the skull is taken by carefully applying a strip of sheet-lead horizontally around it, just above the ear, the free ends always being on the right side, for the purpose of uniformity.

The tracing is put upon the chart by running the point of a sharp pencil just inside the lead. It is well to mark the centre of the lead in front, so as to be able approximately to draw a median line through the configuration and thus detect asymmetry. It is not contended that this is an absolutely accurate method of obtaining a configuration of the skull, as the metal is so yielding that there is a possibility of its springing somewhat in transferring it from the skull to the chart.

With care, however, it is fairly accurate, and will exhibit any form of asymmetry that is at all marked. I have tried harder substances, such as block tin, but found it more difficult and somewhat painful to apply, without being appreciably more accurate.

A lateral configuration is taken by applying the lead over the parietal region, from one meatus to the other.

Ninety-eight cases, from birth up to two years, have

[1] Read by invitation before the Section on Diseases of Children of the British Medical Association, at Bristol, August 2, 1894.

been carefully measured and are incorporated in the accompanying table.

	Under 1 week. From birth. 9 cases, all on breast.	From 1 week to 1 mo. 20 cases, 18 on breast.	From 1 to 3 mos. 18 cases, 7 on breast.	3 and 4 mos. 9 cases, 3 on breast.	5 and 6 mos. 4 cases, 1 on breast.	7 and 8 mos. 5 cases, 1 on breast.	9 and 10 mos. 8 cases, 2 on breast.	11 and 12 mos. 6 cases.	From 12 to 18 months (inclusive). 8 cases, 2 on breast.	From 18 mos. to 2 years. 6 cases.

While broad and positive generalizations cannot be made from so few cases, a study of the table is not without some interesting suggestions. It must be remembered that they were all hospital cases, taken either from the Infant Asylum or the babies' wards, and many were thus much below par. This will explain the low average weight, being actually less in the cases from one week to one month old, than in those under one week. Infants collected together in numbers, especially in a hospital, nearly always lose weight, if kept very long. This tendency to scant weight does not seem to have had much influence upon bony diameters, in comparing the skull measurements of the table with adult measurements already published. The shrinkage falls principally upon the adipose tissue. While the degrees of health, and the irregular number of cases give some varying results in the ten classes into which the cases are divided, yet it is believed, on the whole, they represent a certain type of infant development. With increase in the age of the infants there is noted a gradual and steady enlargement of the great circumference of the skull, and, from this, of its estimated volume. The naso-occipital arc likewise increases at about the same general rate as the great circumference. In comparing the naso-occipital arc with the great circumference, there is an increasing difference as the children grew older. Thus, the difference under one week is 12.39 ctm., while at two years it is 14.58 ctm. The naso-bregmatic and bregmato lambdoid arcs are very similar in the series, but after seven months the former arc becomes slightly larger from the development of the frontal part of the brain. Although no intellectual growth can be said to take place under two years, there is an active evolution of the front of the brain, with increase of the perceptions. The binauricular arcs through the bregma and lambda are quite similar, the average of the eight cases between nine and ten months being identical. The size of the anterior fontanelle, as shown by the antero-posterior and lateral diameters, varies according to the development of the infant. Where the fontanelle remains widely open with the increased age of the infant, there will always be marked symptoms of rickets elsewhere. Thus, in Case 49, a boy, aged ten months, with both diameters 5 ctm., the configuration shows a markedly rickety head, and the notes give other symptoms of the disease. By eighteen months the fontanelles were all closed.

The cephalic indices showed the cases to be divided as follows: Under one week, mesocephalic; from one week to one month, dolicocephalic; from one to three months, mesocephalic; at three and four months, dolicocephalic; five and six months, dolicocephalic; seven and eight months, brachycephalic; nine and ten months, dolicocephalic; eleven and twelve months, brachycephalic; from twelve to eighteen months, dolicocephalic; and from eighteen months to two years, dolicocephalic. None of the averages being below 70 or above 90 could be considered abnormal. In a few individual cases, however, the head was abnormal. Thus, a Polish infant of eight months gave a cephalic index of $\frac{12}{13} = 92.30$. The facial length increased slowly, as would be expected from the absence of teeth, except in the older infants.

A study of the configuration shows slight asymmetry in all the cases, but only in a few instances is it well marked. It is interesting to note that the posterior transverse diameters of the configurations are nearly always greater than the anterior diameters. This would be expected, as the sensori-motor parts of the brain are more developed in infancy than the other areas. I regret that horizontal configurations were not taken higher up, through the parietal bosses, as I believe the contrast would have been greater. Through the courtesy of Dr. Peterson I have made configurations upon two fetal skulls in his possession, one between three and four months, and the other at seven months. The first shows an oval, undeveloped brain, and the second exhibits the forcing out of the parietal bosses by the rapid evolution of the sensori-motor area of the brain, while the front of the skull appears stationary, from the size of the configuration.

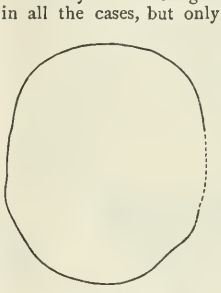

FIG. 2.—Fetal Skull, between Three and Four Months.

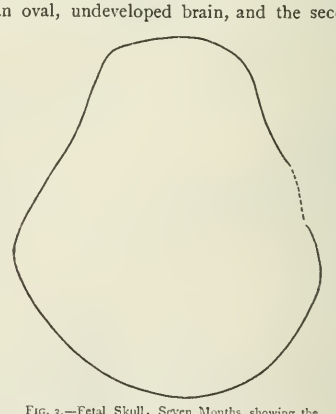

FIG. 3.—Fetal Skull, Seven Months, showing the forcing out of the Parietal Bosses by the Development of the Sensori-motor Area of Brain.

The circumference of the chest is several centimetres larger, on an average, than that of the abdomen. There would probably be a greater difference were it not that so many of the cases presented evidences of rickets. Indeed, I have come to look upon a disproportion of the measurements of the chest and abdomen as a handy way of recognizing rickets. In some cases the circumference of the abdomen was greater than that of the chest, and then the other evidences of rickets were equally well-marked. Thus, in one case, the chest was 23 ctm. and abdomen 29 ctm.; in another, chest 38 ctm. and abdomen 38.5 ctm., with bony changes severe. An acute digestive fermentation will not produce the enlargement of the abdomen that is seen in the chronic flatulent distention of rickets. Hence the ratio between the circumference of the abdomen and chest is not only a sign, but, to a certain extent, a measure of the degree of rickets. The length of the body increased steadily in all the cases measured. The breast-fed babies invariably presented larger measurements than those artificially fed.

The sketch of the skull seen upon the chart was designed by Dr. C. L. Dana, and I am indebted to him for its use.

AN ACCOUNT OF THE LATE EPIDEMIC OF TYPHOID FEVER IN MONTCLAIR, N. J.

By THOMAS HORTON, Sanitary Engineer,

MONTCLAIR, N. J.

During August of this year there appeared in Montclair a small epidemic of typhoid fever numbering in all nineteen cases, resulting in one death. Its close succession to the more severe epidemic in the early spring caused a natural anxiety in the town, and placed the Board of Health in a responsible position. As agent and inspector of such board much of the work was left to me, and an outline of the epidemic and the efforts of the Board of Health in dealing with it is briefly as follows:

About July 20th there appeared simultaneously in the town two cases of typhoid fever, one in a hotel and the other in a French bakery and ice-cream saloon situated about half a mile from the hotel. Little attention was given these cases beyond the ordinary precautions of the attending physician until about August 1st, when the appearance of two new cases, one in each of the above buildings, caused a slight suspicion of an outbreak. All the cases were removed to the hospital, and on the development of five more cases by August 4th, a systematic investigation was begun to discover the course of the epidemic.

I visited the house of every case, made an inspection of the premises, left instructions to be observed in the care of the patients, and filled out a blank form to aid in discovering any common source of infection which might exist. In each instance the water, milk, and ice-cream supply was investigated, and the date of sickness and the occupation and place of business of the patient obtained. Of the nine cases thus far developed, nothing was found in common but the public water-supply and the use of a few of the old wells which are so numerous in the town, and which, in many instances, I knew to be badly polluted. At this time I hardly suspected the wells because three or four would have been involved, and I thought it very improbable for so many wells to be infected at once, and, besides, two patients claimed not to have used well-water at all. We made, however, an investigation of the public water supply, which is a mixture derived from driven wells and the Newark aqueduct. There was practically no typhoid in Newark and other places supplied by the aqueduct, at the time, so that only the well water was examined. Samples taken from the driven wells and suspicious, large crevices in the pump-wells, showed the water to be of high organic purity and that the typhoid had presumedly no connection with it.

Being confident of the purity of the milk and public water-supplies, I again turned my attention to the wells and the possibility of secondary infection. On closer investigation I discovered that, in the case of the hotel, the first patient was a transient guest who had arrived only two weeks before developing the disease. Two weeks is barely within the "incubation period" for typhoid fever, and the assumption is more strongly in favor of this being an imported case than that infection took place almost immediately on arriving in Montclair. Continuing on this assumption, I discovered further that great carelessness had been practised, in the care of the patients before the attending physician had been called, and that the four cases which developed later in the hotel were either in the direct family of the first patient, or among those who had acted at times as nurses. This information, added to the fact that the cases developed in successive intervals during three weeks, seemed to justify my opinion that these cases spread through secondary infection, being transferred from one to the other through some of the many conceivable ways where careless habits and ignorance prevail. In fact these cases may be considered a small epidemic in itself, being situated away from, and having no connection with, the other typhoid cases in the town.

The other portion of the epidemic, numbering fourteen cases, was confined almost wholly to the locality of the bakery, and I am inclined to believe originated in much the same manner, being infected in some way from an old case in the building a month previous. On inspection the bakery was found to be a filthy place, kept by filthy people. The cellar, from leakage and want of proper drainage, was little more than a mire, and was dark and mouldy. Old cloth sacks, bottles, and ice-cream cans were piled promiscuously on the floor, and the ice was delivered through small windows on to a wooden grating, or into the mud, as chance happened. On learning that the ice cream was made in this cellar, and further, that those who made the ice cream and worked in the bakery had helped in the care of the first patient, I saw the dangers which might possibly follow. Moreover, by this time another case had already developed in the house, and if, as it appeared, the case was secondarily infected from the one a week previous, there was a great possibility that the ice-cream might be infected also and the disease spread very rapidly.

I had the bakery immediately closed, and to leave no stone unturned I began an analysis of the suspicious wells in this vicinity. The worst two wells I had closed —one of which was used by the bakery, and, as was soon seen, by most of those who developed typhoid later. That this well was infected at the time of the outbreak I very much doubt, or else the remaining cases would have developed earlier. That it could have been infected by the people in the bakery is very possible, for the germs may have been washed from infected hands or utensils on to the floor of the well, or into a wooden catch-basin connecting with the pump, and from thence sipe through into the well.

At all events ten cases developed within the two weeks following the closing of this well and the bakery, and, of these, eight had used the ice-cream and milk from the bakery, and seven had used this one well. Whether both these influences acted together, or whether the use of the well was merely incidental from its public location, can hardly be settled. But since all these cases developed within the following two weeks and a half, or within the "incubation period," there seems the strongest evidence that they originated from one or both of the above sources, and that by cutting off these sources of infection we prevented a further spread of the epidemic.

After this epidemic no case of typhoid fever appeared in Montclair for over two months and a half.

Cremation in England makes slow progress. A crematory recently erected in Liverpool is only the third in the country, the other two being at Woking and Manchester.

BERIBERI ON THE BARK ROBERT S. PATTERSON AT PERTH AMBOY, N. J.

By ALBERT S. ASHMEAD, M.D.,

NEW YORK.

THE bark Robert S. Patterson, of a gross tonnage of seven hundred and fifty-eight tons, Captain Henry L. Burton, thirteen days from Navassa, West Indies, arrived at Perth Amboy on November 10th, with a European crew, all in good health, and seventy surviving negro passengers, the whole number of these colored people having been at the outset seventy-five; the wanting five had died of some distemper during the passage.

In company with Health Officer Dr. Ramsey and Mr. Tsuchiya, of Japan, I visited the ship and found that ten of the seventy survivors lay sick in the hold. One lay dead, having died after reaching port; across his chest lay another dying; two others whom I examined were also dying; seven others were in various stages of the same distemper. I examined them all, and found that the distemper was beriberi. One of the ten sick men had acute pernicious, four of them moist, and five, dry beriberi. These seventy five men, who had worked in the phosphate quarries at Navassa, had been shipped by the company, in a space less than five feet high, thirty feet wide, and fifty feet long. This space had no port-holes. Two hatchways, each four feet square, were the only ventilation. The hatchways had no sail, nor pipe appliances for ventilation. A considerable part of the space was taken up by straw mattresses, baggage, ship stores, and a large quantity of red phosphatic earth, the cargo of the ship.

It appears that in a space of less than seven thousand five hundred cubic feet seventy-five men, at any rate seventy men, lived for thirteen days and thirteen nights, with the least possible ventilation, with four lanterns consuming part of the oxygen necessary for life, with all the foulness engendered by breathing, defecation, and urination; these seventy-five men being poorly clad, and coming from many hardships suffered in a tropical clime, who were so apathetic that nothing could have induced them to go on deck for fresh air, or for any care of health or cleanliness.

The crew was composed of eleven Europeans, none of whom was, or had been sick; they occupied a part of the ship which was thoroughly ventilated.

I am informed by a leading manufacturing company of this city that phosphatic earth, at which these negro passengers had been employed, and which composed the ship's cargo, is made up of sixty per cent. of bone phosphate of lime, silica, alumina, and iron, and is a natural fertilizer.

Here is another instance to strengthen the theory which I have so often maintained and illustrated by a great variety of facts: charcoal fumes in Japan, carbonized unripe coffee cargoes from Java (the immature coffee is more liable to fermentation), fermenting sugar and grain cargoes, overcrowding in hospitals (Richmond Insane Asylum, Dublin), disintegrating graphite (pure carbon) cargoes from Ceylon, etc.

It was evidently in this case, too, carbonic poison that was the cause of the outbreak. It could not have been the diet. Even if this had been much worse than it seems to have been they could have borne it for thirteen days. The disease broke out five days after leaving port, that is at a time when carbonic poison could have produced its effect while the diet could not.

I do not even admit the joint operation of carbonic poisoning and insufficient diet to produce the outbreak on the Robert S. Patterson. In corroboration of this opinion of mine, I quote Dr. J. A. Wetherill,[1] speaking of the outbreak at the Richmond Asylum, Dublin.

"Whilst medical officer at Wyndham, East Kimberley, Western Australia, I had under my care sixty aboriginal native prisoners. These were chained up at night in a galvanized iron one roomed building 30 by 14 by 12 feet. The only ventilation was by means of four small barred open windows. The floor was of jarrah-wood. Two iron buckets were allotted to every three or four men—one into which the excreta were passed, the other containing drinking-water. The jail was built on piles on the edge of a marsh not twenty yards from the water of Cambridge Gulf. The external night temperature was never below 75° F., and frequently up to 90° F. During the day they had as food, per man, one pound of bread, three-fourths pound of meat, generally salted, one-half pound of rice, with three pints of sweetened tea without milk. Occasionally broth was served and the rice was supposed to act as a substitute for fruit and vegetables, which were not procurable. It must be remembered that the natives had been accustomed to roam unclothed, wild in the bush, free and unrestrained, living on kangaroo, iguana, honey, fish, roots, barks, etc, sleeping on the ground with nothing but the canopy of heaven as a roof.

"Under these conditions a number of them—I regret I did not retain the details—developed beriberi; the principal feature of which was the extensive œdema, and liability to sudden death apparently from syncope.

"The white inhabitants of the town, none of whom were affected, called the disease scurvy, but scorbutus it was not, for there were none of the classical symptoms of that disease, such as hemorrhage into joints, from the gums, etc., nor would it prove amenable to the administration of citrate of potash, vinegar, onions, etc. Beriberi could not have been introduced among the niggers from without, for there was no one either entering or leaving the place, a steamer calling but once every two months. It must, therefore, have had a *de novo* origin, and is, so far as I know, the first time beriberi has ever been seen in the aboriginal natives of Australia.

"From what I have read of the epidemic in the Richmond Lunatic Asylum, Dublin, and judging from my experience abroad, I should undoubtedly say the disease in the asylum is beriberi."

In the case of the Robert S. Patterson the poisoning was not the result of the fermentation of the cargo, as I have no doubt it was in several former instances studied by me. The overcrowding caused the presence of an excess of carbonic gases, the cargo had nothing to do with it. This is the conclusion which I draw from what President John H. Fowler of the Navassa Phosphate Company of Baltimore writes me: "There have never been landed at Baltimore (whither most of the phosphate is shipped), coming from Navassa Island, any cases of sickness similar to those on the Robert S. Patterson. In regard to the substance contained in the cargoes from Navassa, we sell our phosphates on the basis of the contents of bone phosphate of lime, and therefore do not have full analyses made of the different lots as received. We, however, find upon referring back to our books that in 1891 one of the cargoes sent abroad contained 3.98 per cent. of carbonic acid out of one hundred component parts."

I have had a sample of this phosphate analyzed; there were found only three to four per cent. of carbonates.

Dr. Daland asks me "What was the condition of the pork eaten by the beriberi cases that landed at Perth Amboy? Was there any evidence of decomposition?"

It is Dr. Daland's opinion that pork, in a decaying condition, is a cause of beriberi, he having examined a ship in Philadelphia, the Lanark, on which a beriberi outbreak had taken place, attributed the disease, not to the carbonic cargo, 5,000 tons of sugar, but to the pork. Strange to say, all these cases were Mohammedans, who, as everyone knows, abstain from pork. In answer to Dr. Daland, I have to state that if the pork on the Robert S. Patterson was bad, it was eaten as well by the European crew, who escaped the disease, as by the negroes who caught it. I have said in the above article that this European crew slept in a well-ventilated room. Why, should I ask Dr. Daland, again, have they so much beriberi or kakke in Japan, where no pork is eaten at all?

[1] British Medical Journal, October 27, 1894.

That diet has very little, if anything to do with this matter, is sufficiently shown by Wetherill's cases, which I have already quoted. His prisoners were very well fed, and yet contracted the disease from being confined in insufficient space.

As to the surprise which has been expressed at finding that beans were the principal article of diet of these Navassa negroes, when Dr. Simmons (as well as every other doctor in Japan) avers that the Japanese bean (adzuki, phaseolus radiatus), is the very nutriment to give to beriberi patients, I call attention to the fact, that the Japanese bean is used in this case simply as a diuretic, it having extremely powerful diuretic virtues.

Progress of Medical Science.

The Signs of Heart Failure in Fevers. — M. Huchard has made an important statement to the Société Médicale des Hôpitaux regarding the signs of heart failure, which, he thinks, should not be limited exclusively to the determination of the weakening or the disappearance of the first sound. There are, beside this weakening, two other symptoms which he has observed; these he has named the embryocardiac and the bradydiastoliac, or prolongation of the cardiac diastole (*The Sanitarian*). This last symptom was studied some time previously by M. Huchard as a new prognostic symptom in diseases of the heart. He insists upon these facts, and advances proofs to support their correctness, and to show that there are often great errors committed in the diagnosis of acute myocarditis in fevers, and especially in typhoid fever. In this disease the autopsies he has made have proved to him satisfactorily that often, in very grave symptoms of heart trouble, there were hardly any appreciable lesions of the muscular constituents of the heart, and reciprocally. On the other hand, there may often appear in cardiac sclerosis considerable myocardiac lesions, and that even while life may last for a great length of time. In emphasizing these conditions, the results of his personal observations and of the previous observations of Bernheim, of Nancy, in 1882, he has shown that many of the symptoms attributed to myocarditis of typhoid fever must be referred to the effect of functional disturbance, or to lesions of the cardiac nervous system. In all these cases it is certain that the symptoms of myocarditis of infectious conditions, admitted by the greater number of authors, do not exactly reproduce those which he has studied since 1870, with Desnos, in cases of variola. This latter disease may produce myocarditis; typhoid fever causes myocarditis with cardiac nervous troubles, which exert a preponderating influence, and the grippe, which resembles typhoid in this respect, as determining myocarditis, but causes other disturbances of cardiac innervation which he studied four years ago,[1] long before Sampson, of London, who has made a report on the subject to the Medical Society of that city. These researches and these considerations have a great practical importance; they show clearly that the poison of typhoid acts on the heart like digitalis; this agent should not be employed indiscriminately in the treatment of a case of typhoid fever complicated with cardiac symptoms. Injections of caffeine, of ergotine, and even cold baths, should be employed in preference.

M. Hayem described, in 1886, symptomatic myolitis, after having examined the hearts of a great number of patients who had died from varioloid and from typhoid fever. He attributed the alterations of the muscles to changes in the blood and in the blood-vessels. Myocarditis is much more marked in typhoid fever than in variola, which is contrary to the statement of M. Huchard. Sometimes even a vitreous degeneration of the muscular fibres is found in typhoid, a condition which does not exist in variola. It is difficult to attribute death to alterations of the muscular fibres, for it seems due rather to a toxhæmic condition, the effects of which are directed as much to the vessels as to the muscles and the nerves of the heart and other organs. M. Siredey has also found that myocarditis was more frequent in typhoid fever than in variola. In typhoid, the changes in the heart are often limited to the arteries. M. Huchard has, on the contrary, always observed that the fibres in myocarditis were much more deeply changed in variola than in typhoid. The following consideration goes to prove that in typhoid the nervous element should be added to the myelitic. In proportion as sudden deaths are relatively frequent in the cardiac complications of typhoid fever, they are rare in variola. If the cause of death is of equal force in the two affections, why are the results so different?

Milk Diet and Micro-Organisms in the Alimentary Tract.—In the *Dietetic Gazette* are given the results of some recently published work by MM. Gilbert and Dominici (Action du régime lacté sur le microbisme du tube digestif, Comptes Rendus de la Société de Biologie) on the number of bacteria in the alimentary tract after the ingestion of milk. A milk diet exercises a remarkable influence on the number of bacteria present in the fæces of man and of animals. A healthy adult man submitted for five days to a diet consisting in part of 2.5 litres of milk daily. The fæces after ordinary food contained 67,000 bacteria per milligramme. At the end of two days under this new diet they contained only 14,000 bacteria; at the end of three days, 5,000; after four days, 4,000; after five days, 2,250. The weight of the fæcal matter, which ordinarily amounted to 175 gm. per day in this individual, was reduced to 73 gm.; accordingly the number of bacteria daily excreted by way of the rectum was reduced from 11,725,000,000 to 164,250,000, *i.e.*, the milk diet thus had the effect of reducing the bacteria of the fæces to one seventy-first of the normal number.

The above results were obtained after the use of non-sterilized milk. In the case of a patient suffering from ulcer of the stomach, who had been nourished on an exclusive milk diet for twenty days and had received nothing but sterilized milk for ten days, 3,000 bacteria per milligramme were found in the fæces. This number is in close agreement with the lowest figure previously recorded. Similar modifications were produced in the fæces of the dog by a diet of sterilized milk, the number of bacteria decreasing from 25,000 or 21,000 to 1,000 or 500. In rabbits, non-sterilized milk caused an increase in the relative number of bacteria and a decrease in the absolute number. Two animals whose fæces normally contained thirty-five and forty-eight bacteria per milligramme were fed for twenty days on non-sterilized milk—one litre daily—containing 125 to 150 bacteria per milligramme. From thirty five, the number of bacteria increased to fifty seven, and from forty-eight to eighty-nine. Before the feeding of milk, the daily quantity of fæces was, in the case of the first animal, 175 gm.; in the second, 111 gm.; the total number of bacteria, 6,125,000 and 5,328,000 respectively. Since the milk diet reduced the daily amount of fæces to 5 gm., it is evident that the total number of bacteria was diminished to 285,000 and 445,000. Sterilized milk, however, decreased both the relative and the absolute number of bacteria. After being submitted to a diet of non sterilized milk for twenty days, the two rabbits above referred to were nourished upon sterilized milk. From fifty-seven and eighty-nine, respectively, the number of bacteria in the fæces fell to seven and ten per milligramme. The total per day thus fell to 35,000 and 50,000, or one one-hundred and-seventy-fifth and one one-hundred-and sixth of the normal number. In the case of man, the dog, and the rabbit, the absence of those species of bacteria which liquefy gelatine, and of moulds was noted during milk diet.

Milk diet exercises its peculiar action not only on the

fæces, but on the entire gastro-intestinal contents, putting the alimentary canal in a condition of partial asepsis. This does not result from any antiseptic power of the milk, since, as is well known, it forms a good nutrient medium for many species of micro-organisms and the coli bacillus readily grows in it. The true explanation is, perhaps, rather to be found in the character of the changes which milk undergoes in the digestive tract. It is readily attacked by the digestive ferments, the products formed are readily absorbed and but a small residue remains, consisting of nuclein. In this connection it is to be remembered that Dr. Vaughan has lately called attention to the germicidal action of the nucleins outside of the body. The failure of bacteria to multiply in the intestinal canal during milk diet may then be due to the lack of nutrient materials suitable for their development, and, further, to the antiseptic action of any nuclein present. From a dietetic standpoint, the value of milk as an accessory food, at least, is apparent in certain gastric disorders attended with the growth of micro-organisms, in acute or chronic enteritis accompanied by diarrhœa, in typhoid fever, dysentery, and a large number of diseases in which the toxic products of intestinal putrefaction are the ultimate causes of the particular symptoms manifested.

Apocynum Cannabinum in Heart Disease.—Dr. Glinski after having proved by experiments on cold-blooded and warm-blooded animals that the root of the apocynum cannabinum contains a strong poison which in large doses paralyzes the heart, and when given in small quantities retards and strengthens its beats, decided to take it himself, as he is suffering from hypertrophy of the left ventricle, with intercurrent attacks of dilatation of the organ, mitral murmur, dyspnœa, etc. (*The British Medical Journal.*) The dose was fifteen drops of the fluid extract three times a day. As he found that all his symptoms disappeared in two days, he gave it also to other patients in the same quantity in cases of palpitation, disturbed compensation, in which strophanthus, and adonis vernalis had failed and digitalis seemed contraindicated. He gives a full account of some of his cases, and summarizes his experience in the following conclusions: 1. The action of the root of apocynum cannabinum is similar to that of digitalis, without being cumulative. 2. In cases of dilatation the fluid extract rapidly diminishes the area of dulness. 3. It increases the daily amount of urine, stops the palpitation, and promotes the absorption of transudations. 4. With the exception of increased pulsation of the arteries of the head, it has no bad secondary effects. It was used either in the form of a decoction (℥ j. to ℥ viij), 3 to 4 tablespoonfuls a day, or tincture (1 in 10), 5 to 10 ♏, three to four times daily, or fluid extract in doses of 10 ♏ to half a teaspoonful three times daily.

A Rare Tumor of the Parotid Gland.—Dr. Schüller, of Berlin, reports the following interesting case in the *Ärztlicher Praktiker*, No. 32, 1894. A lady, twenty-three years of age, had a hard swelling in the region of the right parotid gland. As she said, there had been removed, nine years previous, a glandular swelling at the same place. The new swelling had first developed rather slowly, and only later had it grown rapidly. When she came to Dr. Schüller, March 30, 1894, the tumor was the size of a pigeon's egg, was hard, and apparently blended with the surrounding tissue. It was immovable from its base, and felt like a soft elastic mass imbedded in a tense sac. Close to it and below, could be felt a second, smaller tumor, of the size of a bean. Dr. Schüller operated on April 4, 1894. He found the main tumor situated between the origin and the anterior ascending ramus of the sterno-cleido-mastoid, below, and close to the ear. It was blended with the surrounding tissue. At the base it appeared to be a continuation of the parotid tissue, where it could not be separated from the gland, and entered deeply into the retro-maxillary fossa.

The tumor was carefully dissected from the nerves, vessels, and muscles; unavoidably a part of the parotid had to be extirpated. Besides the main tumor there were removed nine to ten glands, from the size of a bean to that of a cherry. The main tumor presented on transverse section the appearance of a dense fibro-sarcoma similar to those found occasionally in the testicle. The microscopical picture, however, was not that of a sarcoma. There was found an exceedingly dense granulating tissue, rich in cells, which enclosed centres of shrunken and partly fatty-degenerated cells, here and there with isolated giant cells. Cheesy degeneration was nowhere present. The granulation tissue is traversed in some places by extraordinarily thick-walled blood-vessels. Metamorphoses of tissue such as this tumor presented are (according to Virchow) characteristic of gumma formation. The main tumor consisted in its periphery, apparently, of a lymphatic gland which had undergone gummatory change, and the parotid gland itself was gummatory. The other glands showed nothing but hyperplasia caused by simple chronic inflammation. The process was evidently one of hereditary syphilis.

Treatment of Phthisis.—Dr. C. Theodore Williams has presented in *The Lancet* some practical recommendations from thirty years' experience in the treatment of phthisis. After placing sunlight and fresh air as the first and most essential things in the treatment of phthisis, he adds a number of practical recommendations for the relief of symptoms. Cough, he says, should always be treated by promoting expectoration, one of the best forms of expectorant being the effervescing carbonate of ammonia draught night and morning, which will generally clear the bronchial passages for several hours. If there be a good deal of fruitless hacking before expectoration, causing annoyance to the patient, the addition of a few minims of dilute hydrocyanic acid and half a drachm of syrup of poppy or codeia, will do no harm and considerably allay the reflex irritation. Where the cavities are large, or deep, or basic, and consequently require great expiratory effort to clear, combinations of sal volatile and spirit of ether with camphor water, as in the form of the pharmacopœia of the Brompton Hospital, answer admirably, while for old or feeble persons champagne will often serve the same purpose. But the most satisfactory way to reduce the cough of chronic phthisis is by counter-irritation to the chest-wall—best by blistering. It will be found that relief will follow in proportion to the amount of serum drawn by vesication, and fly-blisters or acetum cantharidis, or the strong but very efficient liquor epispasticus, answer the purpose. Night sweats, when they are a mere flux from the vessels or lymphatics, and not a relief of pyrexial processes, ought to be checked, and this can generally be done by arseniate of iron, 1/6 gr. to 1/3 gr., at bedtime, or picrotoxine, 1/60 gr. to 1/30 gr., or nitrate of pilocarpine, 1/16 gr., or the old-fashioned oxide of zinc in from 3-grain to 5-grain doses, which generally succeed and do no harm. Preparations of belladonna and atropine, though they are effectual controllers of night sweats, are less satisfactory, because their continuance for a long period often induces dryness of throat and mouth, dilatation of the pupils, and disturbance of sight accommodation. The treatment of pyrexia depends very much on its cause. Where it accompanies tuberculization it probably will subside of itself when the tuberculous process quiesces, and even if persistent will only prevail in the afternoon. An effervescing saline, with a few drops of tincture of aconite or a few grains of quinine, is all that is then wanted. But pyrexia accompanying acute excavation, or acute excavation and tuberculization, is very troublesome and sometimes quite intractable. Antipyretics, of which there are any number, according to my experience only give temporary relief, and often do harm by depressing the patient's constitutional powers and producing collapse. I have seen the temperature depressed from pyrexia to a subnormal reading by doses of antipyrin or phenacetin, but always with bad results, and after the use of the medicine has been omitted, the temperature has risen as high

as ever before. The great object in the treatment of this form of pyrexia is to keep the patient quiet in bed or lying on a couch, and, if possible, in the open air, *à la* Dettweiler; to feed him frequently; and to supply alcohol to repair tissue waste, while administering only sufficient antipyretics to keep the temperature within moderate bounds. Quinine in small doses, in effervescence, before the rise or during the rise of temperature, will often suffice, or Henn's well-known pill twice a day. Anyone who studies the phenomena of fever knows that temperature rise is only a small portion of the process, and that by lowering the chart we do not get rid of the factors of heat production or of the wear and tear of the tissues; and so our best line is rather to keep up strength and weight by a frequent supply of food. The diarrhœa which accompanies tuberculous ulceration may be checked by sulphate of copper and opium, if the ulcerative process be limited in extent; but if there is much ulceration, and it is the ileum and large intestine which are involved, injections are best. The enema opii of the British Pharmacopœia is excellent under these conditions, but I have seen a few of the most obstinate cases yield to large injections of linseed tea, which has a most soothing influence on the irritable ulcers.

Clinical Department.

VARICOSE ULCERS SUCCESSFULLY TREATED BY A NEW AND PAINLESS METHOD.

By J. WILL SUMMERS, M.D.,
HAMMOND, ILL.

Mrs. B——, aged fifty-six. History of struma during childhood. Is the mother of two children. General health fair. Veins much dilated from knees down, with very poor cutaneous circulation. Has suffered from chronic ulcers for many years.

Was first seen by the author December 8, 1893; at that time she presented one or two ulcers that had not been healed for five years, and others of more recent date. The manner in which these ulcers appear is as follows: First, a macule which soon becomes papular, and later capped by a vesicle which soon ruptures, liberating a bloody serum. The mass continues to enlarge, forming an ulcer the size of a quarter of a dollar or even larger. During the formation and growth of this ulcer it is highly sensitive and constantly painful. At the time of my first visit, after cleansing the ulcers with a solution of soda bicarbonate, I applied a solution of methyl violet—care being taken to bring it in contact with the entire area of the base and margins. After allowing it to dry, each stained ulcer was covered by a small bit of absorbent cotton. Mechanical support was furnished by Martin's elastic bandage. This entire procedure was repeated every morning. On the second or third day it was evident that the healing process had begun.

At my first visit a new and very painful ulcer was forming on the left leg. This I treated for a few days with subnitrate of bismuth, boracic acid being tried and found too painful. No benefit was derived from either. Pain was constant; on the third or fourth day I painted it with methyl violet, and to my great surprise and the patient's comfort, the pain at once ceased.

After two or three daily applications the sensitiveness had so far subsided as to render bandaging of that part of the leg possible. All of the ulcers were thenceforth dressed daily. At the appearance of any new vesicle I applied methyl violet, which prevented further development. Internal treatment consisted of potassium iodide, grs. x. to xv. t.i.d.

The patient continued her duties as housekeeper, and at the end of six weeks only cicatrices remained to mark the site of her former ulcers.

An ideal solution, as used by Dr. M. F. Coomes, of Louisville, Ky., in the treatment of lupus, is made by using Merck's methyl violet, grs. v., aqua destillata, ℥ ij. This forms a harmless and entirely painless application. I would not hesitate to use it on any chronic ulcer.

The bandage has been worn most of the time, and to this date there has been no return of the ulcers.

To put at ease the mind of anyone who may think the internal treatment and bandage are deserving all the credit, I will state that both had been used, with the accepted local treatment, with but little success by other physicians, at intervals, for several years. Also ulcers that began forming under the bandage were invariably arrested in their course by methyl violet. Its action we believe to be germicidal and highly astringent.

October 6, 1894.

PASTILLES AS A SUBSTITUTE FOR GARGLING TO PREVENT DIPHTHERITIC INFECTION.

By A. ROSE, M.D.,
NEW YORK.

We have to confess that the control of the course of diphtheria is very limited. In view of this fact we are reminded of the noblest of our duties, the duty of prophylaxis. It is true we are experimenting with antitoxin, and it is to be hoped that we shall succeed in securing immunity against diphtheritic infection by means of inoculation of this new serum, but as long as this, our sanguine hope in regard to antitoxin, is not yet realized, we have to welcome every proposition to guard against diphtheritic infection.

It is generally understood that a healthy pharynx is of as much importance in regard to diphtheria as a healthy stomach is in regard to cholera. All writers on prophylaxis against diphtheria speak of the importance of keeping the mouth and throat in aseptic condition. Among the measures to this end gargling "the throat" has always been considered to be a prominent part. As everybody can convince himself by experimenting with some colored syrup, gargling is an illusory measure as far as the disinfection of the pharynx is concerned; except when it is done in a certain skilful manner, as only adults can do it after having been well instructed, not one drop of the gargle enters the pharynx, not even reaches the tonsils.

Dr. A. Szara[1] recommends therefore to disinfect mouth and throat with lozenges composed of resina guajaci, saccharin, etc. He experimented with these and found that they possessed germicidal power, that they actually did disinfect the mouth and pharynx, that the aseptic condition lasted for one hour. He does not give the proportion, at least I did not find them given in the extract of his paper which came to my view. Messrs. Eimer & Amend, the drug firm, made lozenges for me which have the following formula:

℞. Resinæ guajaci	0.75
Saccharine	0.01
Sacchari et succi liquiritiæ	0.75

They are agreeable to take, and may also serve in all cases of pharyngitis where tinctura guajaci is generally given. They are certainly more palatable than the tincture, and much more serviceable than those lozenges of the London Throat Hospital made with red and black currant jelly and containing only a small part of resina guajaci. Dr. J. Bergman[2] recommends lozenges which he calls diphthericidium pastilles, which have the following formula:

℞. Thymol	0.002
Sodæ benzoit	0 02
Saccharin	0.015
And some gum-like constituent.	

Either of these pastilles recommends itself to be given to our little ones going to school in place of candy or chewing-gum.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 24, 1894.

SOME MINOR MEASURES IN THE DIAGNOSIS AND TREATMENT OF DYSPEPSIA.

No doubt the conscientious general practitioner feels that he is often very much behind the times in his diagnosis and treatment of some gastric disorders. Medical literature is full of elaborate descriptions of the different kinds of dyspepsia, of hypoacidity, hyperacidity, motor disturbances, catarrhal disorders, etc. The methods of investigating the stomach have also become greatly refined, the test meals, the washings, syphonings, and electric explorations appear very formidable to the doctor, and still more to the patient. We do not in the least wish to deprecate the use of all the methods of modern research and treatment. It is always best to know exactly the facts, and not guess at them from data furnished by the tongue and descriptions of subjective states. Still Dr. Dujardin Beaumetz has struck a fruitful topic in a recent lecture on "Minor Methods of Diagnosticating and Treating Dyspepsias" (*Bulletin général de la Thérapeutique*). Exact science cannot always be applied, he says, and there exist a number of minor measures which are always useful and often sufficiently effective. In order to determine the kind of dyspepsia from which a patient suffers, he should be made to take a few "test meals." The best meal for this purpose is the breakfast. This should consist of coffee or tea, with milk and a little sugar, and one or two rolls or slices of bread without butter. The quantity of liquid should always be the same and never over a pint. With a normal stomach the repast will be digested unnoticed. If, however, two hours after eating there is a sense of heat in the stomach, and a burning and acidity, then the patient is suffering from hyperacid dyspepsia. If, on the other hand, there is abundance of gas, a sensation of weight and fulness, and of food being still in its place, then there is hypoacid dyspepsia. When there is at the end of a quarter of an hour a sensation of epigastric pain, which gradually increases, then there is probably some gastro-duodenal irritation or inflammation. Finally, the patient may suffer from cramps, pains, and even vomiting, and then there is probably some muscular and nervous disorder of the stomach.

Beaumetz insists that in hyperacidity the heat and burning are most severe three or four hours after a meal, and are oftener felt at night between 11 P.M. and 1 A.M. In hyperacidity, also, the ingestion of food often relieves for a time the disagreeable sensations. A knowledge of the occupation and habits of the patient naturally helps greatly in diagnosis. Beaumetz thinks that dyspeptics ought to sleep on the right side, because this facilitates the passage of food from the stomach into the duodenum. To promote the same end he advises the drinking of a cup of very hot water, or preferably, some aromatic infusion, such as chamomile or anise, etc., an hour or an hour and a half after eating. He does not recommend mineral waters charged with carbonic-acid gas, but does advise still alkaline waters taken half an hour before meals in small doses. Finally, massage of the stomach is recommended, both to stimulate the stomach walls and the secretion of gastric juice.

THE OYSTER AS A TYPHOID FEVER CARRIER.

A YEAR ago or more, reports were rife of cases of typhoid fever in Berlin, due to eating raw oysters. Not much attention was paid to the story at the time, because no positive verification of it was made.

Quite recently the matter has come up in a most striking way, through the development of an epidemic of typhoid fever among the students at Wesleyan University, Middletown, Conn. We give elsewhere a report of this epidemic which was published in *The Evening Post* of November 19th. While we do not, as a rule, place much confidence in newspaper accounts of medical investigations, the present one bears the marks of being carefully written and authoritative. Thirty cases occurred altogether, with one death. All were among college students who had attended certain society suppers where raw oysters were served. Among the students who attended other suppers, where the oysters were cooked, no typhoid developed. The oysters had been placed by the oysterman in the tide-water shallows of a river near New Haven. Typhoid fever had been present in the family of the oyster-grower, his house was near the river, and his sewage drained into it. This is the extent of the evidence so far as we can learn. No typhoid bacilli have yet been found in the oysters still present in the river, but this branch of the investigation is unfinished.

On the other hand, it is known that typhoid fever germs do not live in salt-water, and furthermore, it is a fact that just now typhoid fever is unusually prevalent in certain parts of New England. Thus, for the week ending November 8, 1894, the percentage of deaths from this disease on the total deaths was, in Springfield, Mass., 7.69; in Newton, Mass., 25; in Pittsfield, Mass., 33.33; in Newburyport, Mass., 25; in Brockton, 12.50, and in New Bedford, 11.76. The percentage in New York was only 3.00, and in Philadelphia, 1.62. There is perhaps, therefore, some unusually important epidemic influence that must be taken into consideration.

If one looks over the mortality lists for the different large cities of this country, he will find that there is no excessive prevalence among the seaboard cities, where the raw oyster is consumed in enormous quantities.

The consequences of establishing the fact that the raw oyster may be a means of propagating typhoid fever, would be very far-reaching and would affect not only consumers, but would destroy in a measure an extensive and important industry. The matter should, therefore, be investigated with the greatest care.

THE SUNNY SIDE OF PHYSIC.

We have discovered in *The Lancet*, and published elsewhere, "The Song of the General Practitioner." Our readers will find it a rather lugubrious refrain, yet they will probably say that it tells the truth. Nearly all poems on the medical art are written in the same pathetic key. It is always the poor doctor who works hard and continuously, who never rests or sleeps, or gets paid for his trouble.

There must be some truth in it all, but the public who read might legitimately ask why, if the doctor's life is such a depressing one, do the doctors' ranks continue so crowded? The more we deplore our lot, the more do the youth of the land select it. Is it the spirit of altruism, or is it that in the halcyon days of youth such things as hard work and poor pay and no final rewards, furnish no terrors?

Or is it that the public and the doctor know the picture to be overdrawn? We suspect that the latter element is a very potent one in directing young men into the rugged ways of medical life. Some doctors work hard all the time, and all doctors work hard some of the time, but all doctors, he thinks, do not work hard all of the time. Besides, he sees that many of the profession get comfortable incomes and live in comfortable homes. They are not waked up every night to drive ten miles in the darkness and cold. A great many of their bills are paid; a great many patients are grateful and loyal, and sound their favorite physician's praises in a way that is solacing to vanity and provocative of larger practice. The average duration of life of the doctor is not quite as long as that of the clergyman—the good die young, or at least younger; but still, if he has good luck, he may grow old, for some doctors do reach a green age. There are, in fact, a great many pleasant things in the doctor's life, and we trust that some time a school of more cheerful medical poetry will arise than that which exists at present.

THE REFRACTING OPTICIAN.

The optician has given a great deal of trouble to our medical brethren of Philadelphia. At rather frequent intervals in the past we have read most denunciatory accounts of his demoralizing and unethical work. Our esteemed contemporary *The Medical News*, which generally discusses the problems of human life with great philosophy, has little patience with the optician—that is to say, if he refracts. For it is the so-called R. Os., or refracting opticians, who are really to blame. We have been receiving circulars from this class of practitioners in New York recently and have learned some particulars of their deadly work. It seems that the R. O. makes the following examination:

"For hypermetropia, myopia, astigmatism, presbyopia, heteraphoria, corneal opacities, lens reflex, vitreous, fundus oculi, and visual acuity."

This really does seem to go beyond the simple limits of refraction and physics. The R. O. offers to determine the condition of the cornea, of the vitreous, of the retina, and of the eye-muscles. He offers rather too much for the price of a pair of glasses, particularly when the doctor's own family gets them at half-rates.

It may be seriously questioned whether the R. O. is not practising medicine if he diagnosticates a corneal opacity or an optic atrophy. He must draw the lines much more closely or be put in the lists of the unlicensed.

There is no reason, however, why a modest and genuine refracting optician should not perform a useful service to society. Many people suffer from hypermetropia, myopia, and astigmatism who cannot afford to go to a specialist. They must, therefore, either rely on their family physician, go to a dispensary, or to the R. O. Now we advise such to go to their family doctor and let him decide whether the optician is sufficient, and we advise the family doctor never to send his patient to the refracting optician who proclaims his ability and readiness to diagnosticate almost every chronic abnormality of the eye.

News of the Week.

The Moxon Medal of the Royal College of Physicians.—The Moxon Medal of the Royal College of Physicians, for distinguished services in clinical medicine, has been awarded to Sir William Jenner.

Dr. Timothy M. Ingraham, one of the best-known physicians in the suburbs of Brooklyn, died at his home in Flatbush, on November 4th, of cerebral apoplexy. He was born in Amenia, Dutchess County, in 1821. He received his collegiate education at Wesleyan University, Middletown, Conn., and the degree of M.D. from the Vermont Medical College, in 1847.

Typhoid Fever from Oysters.—There is an outbreak of typhoid fever now at the Wesleyan College in Middletown, Conn., in which the contagion appears to have been carried in oysters. According to a despatch in the *Evening Post* the story of the disease is as follows: The first case developed on October 22d, the student being the son of a physician in Vermont. The patient was taken home and died. This case was followed rapidly by others—one fatal—until they now number about thirty. They began to develop about ten days after the initiations of six societies at Wesleyan, a supper being given by each. As all the sufferers had attended these suppers investigation was turned in that direction. The Middletown city water and also the water from a well on the campus were examined and both found to be innocuous. The milk used at the initiation suppers was next looked into and was found to be perfectly wholesome and obtained from farms where the conditions were healthful. It was next found that, while at all six of the suppers oysters were used, at three only were raw oysters supplied, and that all the victims had partaken of them. These oysters were bought from a Middletown dealer, who obtained them from an oyster grower living on the east shore of the Quinepiack River, near New Haven. He, like the many other growers owning oyster establishments on the Quinnipiack, is accustomed to take the oysters from the deep waters of the Sound and lay them down before opening for some twenty-four hours in the shallows of the river. This makes the oysters absorb the fresher water of the stream, swells and

whitens them, the technical phrase among the oystermen being "giving the oysters a drink." The next discovery was that the oyster-grower's wife had died of typhoid fever about the time of the outbreak at Wesleyan, and his daughter also has been ill of the disease. His house stands not far back from the river, and its short drain empties into the latter near the place where the oysters are bedded temporarily. In addition to the Wesleyan students there were visitors from Yale and Amherst, and two of these, one from each college, are also ill with typhoid. The same paper from which we have quoted reports that a gentleman in New Haven recently gave an entertainment at which raw oysters were served, and six of his guests are now suffering from typhoid. The bed of the Quinepiack River is extensively used for oysters by the growers of Fair Haven and East Haven, which for many years have been centres of the Connecticut oyster trade. Many sewers empty into it, and it is to be hoped that the discovery of the source of the Wesleyan outbreak may lead to the discontinuance of the custom of temporary bedding and to taking the oysters directly from the main beds in deep water.

Dr. Zacharin's Future.—Dr. Zacharin, the eccentric Russian physician who attended the Czar Alexander III. during the greater part of his illness, has not a very cheerful future to look forward to. The present Czar Nicholas is said to be so displeased with Dr. Zacharin's conduct that he has suggested that he confine his practice henceforth to Siberia.

A Bon-mot of Dr. Holmes.—Dr. Arthur P. Perry writes to the *Boston Medical and Surgical Journal*: "A *bon-mot* made by Dr. Holmes at the time one of his sons was born, was lately written out for me by a physician who was a student at the time; and, as it is as good as all Holmes's sayings were, and I think has never been in print, I thought it might appear in the *Journal*. I give it *verbatim* as it was sent me. 'In the forties Dr. Holmes was one of the instructors in what was known as the Tremont Medical School, which gave instruction to quite a large number of students between the lecture terms of the Harvard Medical School. Usually prompt, we were one day surprised by his non-appearance at the beginning of the lecture-hour, but we waited. Finally he entered the room, hurriedly glanced around with a smile and said, "Gentlemen, I know I am late, but there is a little stranger at my house." And then with an expression such as only Holmes's face could assume, he continued, "Now can any one of you tell me what well-known business firm in Boston he is like?" There was no answer. "He is Little & Brown," said the doctor, with a twinkle in his eye.'"

New York State Medical Examinations.—At the September examinations for State medical license by the board representing the Medical Society of the State of New York, the number of candidates was seventy-six, of whom fifty-one were successful and twenty-five unsuccessful.

Tuberculous Infection in a Laboratory.—We regret to hear the report that Dr. John M. Byrom, Director of the Bacteriological Department of the Loomis Laboratory, is suffering from tuberculosis which he contracted by inhaling its germs while engaged in his professional work.

A Successful Operation.—Dr. Pulser: Did you remove old Bonder's vermiform appendix?

Dr. Cutter: Yes.

Dr. Pulser: And was there anything in it?

Dr. Cutter: A cold two-fifty for me.

The Ceremony of Unveiling the Statue to Claude Bernard took place on October 28th. Many members of the Academy of Sciences, and all the professors and students of the Lyons Faculty, besides many notabilities, military and political, were present. The statue, the work of Aubert, a sculptor of Lyons, represents Claude Bernard in a standing position, holding a lancet in his hand and inoculating a frog with curare.

Anxiety as a Cause of Granular Kidney.—It is interesting, in relation to the ailment of the Czar, to recall a paper read by Professor Clifford Allbutt at the annual meeting of the British Medical Association, at Sheffield, in 1876. The subject he took up was "Mental Anxiety as a Cause of Granular Kidney," and by an analysis of his case books he showed what an abnormally large proportion of the patients showing symptoms of granular kidney had been subject to the depressing influence of prolonged anxiety. He says: "During the last two years I have made notes of thirty-five cases of granular kidney occurring in private practice, and I find a marked history of mental distress or care, or both, in twenty-four of them." This is a large proportion, even if we admit that the pushing inhabitants of West Yorkshire worry abnormally concerning this world's goods. Several illustrative cases are given, and one especially in which as a consequence of an unfortunate investment, a man, in a good position, for three years "went to bed night by night ignorant whether he might not be gradually drained of his all." Dickinson is in some sense in accord with Allbutt on this question, although not so positive. Prolonged mental disturbance, anxiety, or grief as a cause of granular kidney is, he says, "perhaps problematical; the mode of its operation is not obvious, but must be surmised as through the nervous system. A lowering of nervous force is to be recognized at least as predisposing to every form of albuminuria. I have seen so many instances in which granular degeneration has been immediately sequent upon trouble that, in the absence of other causes, I am fain to conclude that mental conditions are sometimes concerned in its production."—*British Medical Journal.*

A New Method of Producing Local Anæsthesia.—At the meeting of the Hufeland Society, on October 25th, Professor Oscar Liebreich presiding, Dr. Schleich read a paper on, and demonstrated, what he terms a new method of anæsthesia, called "Infiltrations-anæsthesie." Dr. Schleich has for some time made use of this new form of local anæsthesia, not for trifling operations only, but for complicated ones, such as laparotomy, etc. He uses a very weak solution of cocaine—1 per mille. The cocaine is not dissolved in distilled water, Liebreich having shown in his inquiry on "anæsthetica dolorosa" that distilled water injected subcutaneously has a toxic effect; the solvent used is the physiological salt solution of about half the usual concentration, that is, about 0.2 to 0.3 per cent. of common salt. Schleich's method is as follows: A small spot of the skin near the field of operation is rendered insensible by chloride of ethyl, and here a few

drops of the cocaine solution are injected. At the spot of infiltration a bulla immediately arises, which is absolutely without sensation. Pushing the point of the syringe through this area of insensibility, Schleich again injects a few drops; another bulla arises close to the first, and proceeding from bulla to bulla round the field of operation the whole is infiltrated and rendered quite anæsthetic. This is done extremely quickly, as Schleich showed in the case of a man with a large syphilitic abscess on his arm, who was operated on before the meeting. The man felt absolutely no pain; and the duration of the operation, including the anæsthesia, was only eight to ten minutes. Dr. Schleich said that he had employed his method of anæsthesia for about three thousand operations with unvarying success, and without any bad after-effects. It does not seem to us that the method presents any great elements of novelty.

A French Congress of Internal Medicine was recently held at Lyons, October 25th to 29th. The organizers were MM. Potani, Lépine, and Bard. This is the first national medical meeting ever held out of Paris, though Congresses of Surgeons and of various specialists have had successful meetings for several years. The French physicians are trying to get away from the complete dominance of Paris in medical matters.

Massage Establishments and Prostitution.—The *British Medical Journal* presents a report on London massage establishments couched in words of what it evidently considers "decent plainness." One part of the report is as follows:

"In the summer months the establishments are closed for the most part. When London fills up again they become active. We will leave for another article the explicit statements which we have to make as to the nature of the practices which go on in many of these places; but for the present it may be sufficient to state shortly what kind of place the casual inquirer will find if he goes for the first time to some of the addresses we refer to. He will find probably a flat of four or five rooms, in a fashionable West End locality. In many cases the establishment is on the first floor over business premises. The approach to it is guarded by various arrangements for privacy. As the visitor enters, an electric bell rings automatically and he will find himself received in a well-furnished room by a lady of middle age, with a certain capable air of respectability. She will make no inquiry as to his name, and probably none as to his complaint. He will be invited, with little loss of time in preliminaries, to adjourn to a room luxuriously furnished, where he will find a bed or couch spread with blankets. He will be informed, unless it is assumed that he knows it already, that the terms are for an hour a guinea, but that he can stay as long as he pleases by the same rate. In some instances it will be suggested to him that it would be a good thing to have a bath first and massage afterward. It will be assumed, as a matter of course, that he intends to have 'general massage,' that he will want a young lady to do it, and that he will undress completely. Madame will then leave him to his own devices. In two or three minutes the lady assistant will appear, and the 'treatment' will be duly administered. He will not be interrupted, nor, in fact, will he see 'madame' again until he pays her as he leaves the house. This state of things in itself will be admitted by everybody to be sufficiently risky. What it leads to we shall feel it our duty to indicate with decent plainness in another article."

It does not seem as though any sequel to the above was really needed. Such establishments are freely advervised in Chicago daily papers, especially since the Lexow Committee's work.

New Medical Colleges.—A new medical college was organized the other day over in Alabama. Also a new one at Fort Worth, Tex. About one month ago two members of the faculty of one of the Nashville schools resigned their chairs on account of personal differences, and are now industriously at work "organizing another school." More schools than this have been established from no better motive. Out in St. Louis the opening of a new medical college has gotten to be almost a joke. In a word, there is absolutely no need for these colleges. There is every need, God knows, for better medical education, but the way to accomplish it is not by increasing the number of colleges. Since 1880 there have been more than fifty medical schools chartered in this country, a great many more than there was any necessity for. Fortunately several have died. There are 110,000 doctors in the United States. More than 3,000 belong to the faculties of medical schools. Of this number Ohio, with 16 schools, contributes 408; New York, with 12 schools, 540; Missouri, with 16 schools, 405; Maryland, with 7 schools, 170; and Tennessee, with 8 schools, 160, etc. In all we have one medical school for every 430,000 of our population, or one for every 730 physicians.—*Atlanta Medical and Surgical Journal.*

Safeguards against Small-pox.—Dr. J. M. Worthington, health officer of Anne Arundel County, says the county has adopted a complete system to detect the approach of small-pox and to prevent the spread of the contagion. He said: "To provide against an epidemic of small-pox the county commissioners, at a recent meeting, appointed two vaccine physicians for each election district, making fourteen for the county. With this wise provision it would be difficult to have a case in the county without its being at once known and attended to. Isolation, disinfection, and vaccination are the best-known means to lessen the disease. The family physician is the man of all others to commence the work, and if he does his duty there will be little occasion for panic or alarm. As a rule, he knows what to do and how to do it. In some special cases he may need the assistance of the district vaccine physicians for the poor and unprotected. He should at once notify the health officer of his county, whose duty and pleasure it would be to report to the State board of health. It should be a rare case of emergency or necessity to appeal for aid or comfort to the Surgeon-General's office at Washington, D. C. A recent notable small-pox scare, affecting the family and their physician, a man of ability and high personal character, could have been nipped in the bud. A messenger on foot or horse, a railroad, double track, all-steel rails, United States mail, telephone, and telegraph, all should have been exhausted to reach the doctor and ascertain the facts before the slander was spread upon the wings of the wind."

Errata.—Dr. R. Abrahams writes: Will you kindly correct the following misprints in the RECORD of Novem-

ber 10th. Page 604, first column, fifteenth line from top, read "tubular" for "tubercular." On the same page, twentieth line from bottom read "observers" for "observer." Page 599, second column, ninth line from bottom, read "grave" for "great."

Randall's Island Hospitals, New York.—Dr. Charles W. Allen has been appointed Visiting Dermatologist to the Randall's Island Hospitals.

Professor Dr. Klebs, of bacillus fame, is on a visit to this country, and is at present the guest of Dr. Karl von Ruck, of Asheville, N. C.

Longevity.—Our esteemed contemporary *The Annals of Hygiene* makes the astounding assertion, in its issue for July of this year, that one person out of every four thousand born reaches the age of one hundred years. This may be so in the home of our contemporary, but elsewhere life is too rapid for any such blissful extension of it as this.

"The Burst-up of Listerism" is the way Dr. Donald Campbell Black, of Glasgow, speaks of the modifications which have taken place in the practice of antiseptic surgery. He apparently harbors no kindly feelings for Sir Joseph Lister, though at this distance we are unable to guess the cause of his enmity. He relieves his mind in a long tirade against the one to whom, more than all others, the world owes the principle of antiseptic surgery, and closes with the following splenetic deliverance:

"I read in a recent number of an influential medical contemporary that Sir Joseph Lister had been awarded the Albert Medal of the Society of Arts 'for the discovery and establishment of the antiseptic method of treating wounds and injuries (what is this?), by which not only has the art of surgery been greatly promoted and human life saved in all parts of the world, but extensive industries have been created for the supply of materials for carrying the treatment into effect.' If it be 'science' to give a transient impulse to the manufacture of 'putty' and calico, then I have certainly misinterpreted the term 'science' during all the years that I have lived."

A Medical Library Association has been recently organized in Grand Rapids, Mich. The purpose of the Association is the formation of a reference library upon medicine and allied sciences. The new organization starts out with a membership of about fifty. One of the features of the Association will be the admission of non-residents to membership, whereby for a small annual fee, physicians outside of the city may avail themselves of the advantages of the library. A competent librarian will be secured, and the most approved methods of cataloguing and indexing will be made use of. Books and journals are being liberally donated by those interested in the project, and the success of the enterprise is assured. The following officers have been elected: Dr. G. K. Johnson, *President;* Dr. S. G. Milner, *Vice President;* Dr. W. A. Dorland, *Treasurer;* Dr. Reuben Peterson, *Secretary.*

South Carolina State Medical Examining Board.—The second meeting of this Board, created by act of the Legislature in January last, was held at Columbia, October 9th and 10th. Of fourteen candidates four were rejected. The next meeting of the Board will be on the fourth Tuesday in April, 1895. Anyone wishing to enter the State to practise, between the meetings of the Board, must appear before the chairman and secretary to be examined, and upon their being satisfied as to his qualifications will issue to him a temporary license, which license is only good until the next meeting of the Board. The Secretary of the Board is Dr. C. F. McGahan, of Aiken, S. C.

Cannot Experiment on the Body of Wilson, the Murderer.—Attorney-General Hancock has written an opinion in answer to an inquiry from Governor Flower in regard to the resuscitation of Wilson, the murderer. The opinion says: "In my judgment neither the Governor of the State, the Superintendent of State Prisons, nor the Warden of Auburn Prison has authority to deliver the body of a convict, after the execution of the death penalty and a post-mortem examination, to Dr. Gibbons or any other individual not a relative of the person executed. If the body is not claimed by a relative, it becomes the duty of the authorities in charge to bury it, and not to deliver the same to any individual for the purpose of experiment."

The New York Society for the Relief of Widows and Orphans of Medical Men elected these officers lately: *President,* Dr. Ellsworth Eliot; *Vice-Presidents,* Drs. David Webster, J. H. Emerson, and Charles H. Teale; *Treasurer,* Henry Tuck. President Eliot said that the funds of the Society had been increased almost $60,000 in the past year.

The New York Pharmaceutical Club.—Fifty members of the Pharmaceutical Club sat down to their first Club dinner at 7 P.M., November 21st, in their pretty new rooms at 37 East Nineteenth Street. No papers were read nor speeches made. The Club was incorporated in August, and has now one hundred and sixty-five active members. Its membership will be limited to the number of pharmaceutical men in good standing in the drug business who care to join.

Papers on scientific subjects connected with the drug business will be read every Thursday. The officers are as follows: *President,* Robert J. Bell; *Vice-President,* John W. Bachelder; *Treasurer,* Frank A. Barnes; and *Secretary,* Velie A. Wood.

The Proportion of Successful Candidates in the Medical Staffs of the Army and Navy.—During the year ending June 30, 1894, thirty-seven candidates for the medical staff of the army received permission to appear for examination before the Medical Board; of this number five were found qualified. In the navy, thirty candidates were invited to come up for examination, of which number three only were found qualified physically and professionally for appointment to the rank of assistant surgeons. There are eight vacancies in the naval medical staff; in the army medical staff there are none, owing to the action of Congress in reducing the number of assistant surgeons to one hundred and ten.

Dr. Reid Alexander, of Topeka, Kan., died in that city, in October, of perforation of the bowel. He was a graduate of the Medical Department of the University of Pennsylvania, in the Class of '85, and at the time of his death was President of the Topeka Academy of Medicine and Surgery.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 1, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Perkins's Tractors.—Mr. Isaac Wood, of Rahway, presented to the Academy, through the Chairman of the Library Committee, Dr. Grandin, a set of Perkins's tractors, an instrument at one time in use for the cure of disease.

Wanted, $100,000; Half of it Immediately.—Dr. Grandin reported gifts of books to the library since last spring. He then added that the term of office of the present Committee on Library was about to expire, and they wished before retiring to make another urgent appeal to the public for an endowment fund. The library was as free to the use of the public as to the profession, yet the latter had out of their own pockets erected the best stack-room in the country, and the public, especially the wealthy portion, were now urgently invited in their own interest to contribute before the first of January $50,000 of the much needed endowment fund of $100,000 dollars.

Library Hours Lengthened.—The library will hereafter be kept open until 10.30 P.M., until time shall show whether use after 10 P.M. will justify the added expense.

Question of Dues.—Dr. A. M. Jacobus gave notice on the part of the Council of an amendment to the by-laws, providing for reduction of dues of members residing in the State, but outside of the counties of New York, Kings, Queens, and Westchester, to $5 a year, the dues in the counties named remaining as at present, $20 a year. The unfairness of taxing the more distant members equally with those residing near the Academy, with its library, was self-evident.

The President announced that the anniversary discourse would be delivered by Dr. Charles L. Dana, Wednesday evening, November 28th. The profession who have friends among the public who may feel some interest in the Academy are requested to send their names to the Librarian, Mr. Browne, who will forward them cards of invitation. This, the President said, was one means for making the public acquainted with the work of the Academy and with its invaluable services to it. It was wonderful how little most of the sixteen or eighteen thousand citizens who, out of the total two millions, constituted the generous donors to worthy public purposes, knew about the Academy. If they were informed of its catholic spirit, of the fact that it was not a private medical school, that it was established in the interest of the public welfare, and opened its library to the use of all, he thought the endowment fund for which the Chairman of the Library Committee had made so eloquent an appeal would be forthcoming at once.

Intra-lobular Occlusion Jaundice.—Dr. William H. Porter read a paper with this title, which implied that the jaundice was due to occlusion, but not to a form of occlusion, such as pressure by a tumor, after the bile had entered the bile-ducts. In order to elucidate the subject he outlined the minute anatomy of the hepatic lobules, the mechanical processes connected with the secretion of the bile, and also his views of the chemical and physiological processes involved in the same act. To start with, he rejected the old explanation of jaundice, based on the view that the constituents of the bile were reabsorbed into the blood.

The mechanism connected with the production of bile was based on the minute anatomy, as already suggested. Masses of protoplasm in the form of epithelial cells in the acini by virtue of a function peculiar to themselves secreted the bile from the blood brought to the locality through the portal system, the bile thus secreted entering the radicles of the bile ducts, and being finally carried to the duodenum. The bile was made from proteid compounds, during which oxygen brought from the lungs consumed carbohydrates and evolved heat, and it was by the influence of the heat that the nerve-terminals were stimulated and enabled to perform their function. During the act the cells were alternately swollen and relaxed, but when abnormally irritated by toxic agents, such as might gain entrance to the portal circulation in the form of chemicals or bacterial products, they remained unnaturally congested, their nutrition was impaired, their function interfered with, and they underwent retrograde metamorphosis. In this abnormally swollen state the masses of protoplasm were forced into the primary radicles, which thus became occluded. As it had been proven that the blood-vessels could not absorb the biliary constituents, there remained but one channel through which they could enter the circulation, namely, the lymphatics. Passing from the hepatic lymph-channels into the thoracic duct, they finally reached the general circulation and were carried to the different parts of the body, and unless eliminated they stained the tissues and caused jaundice and pathological changes in other organs. The kidneys took a principal part in the elimination of the bile constituents. There might be various degrees of intra-lobular occlusion jaundice, depending upon the amount of toxic agents absorbed from intestinal indigestion and decomposition, etc., and the chronicity of the case would depend upon the continuation of the active cause and the change induced in the liver-cells. There was never complete occlusion of all the biliary radicles, but often sufficient to cause various degrees of jaundice. The diagnosis of this form of jaundice was to be made by excluding other forms of mechanical obstruction lying between the biliary radicles and duodenum. The prognosis was usually good in acute cases, especially in persons of good general health whose attack had been brought on by temporary indigestion. Where the kidneys were badly damaged, the prognosis was unfavorable. Much depended upon the treatment.

The author followed the circle of injurious results of intra-lobular occlusion jaundice, a chief one being the depriving of the intestine of a fluid necessary to perfect digestion and antisepsis—the bile. The nutrient pabulum going to the various organs of the body became intermixed with a toxic principle which interfered with their proper nutrition, a fact which gave one indication in treatment. One must look to the diet, to artificial digestives, to intestinal antisepsis, to sunlight and exercise, to hepatic stimulants, to the excretory functions. The digestive system must not be overtaxed by either too much food or food of wrong quality. The author had found by experience the following diet suitable to many cases, according to their severity: For breakfast, two ounces of wheat bread, two eggs, eight ounces of milk, with a little butter, making a total of fourteen ounces. For the mid-day meal, three ounces of wheat bread, a little butter, seven ounces of meat. In the evening, two ounces of wheat bread, a little butter, eight ounces of milk, seven ounces of meat. Before retiring, eight ounces more of milk. If milk could not be tolerated, use a fermented milk. Fruits and vegetables should be avoided because they were prone to excite, by their fermentation, abnormal decomposition of proteid compounds and development of toxic substances.

Artificial digestion for a time within the alimentary canal was best aided by ox-gall and pancreatic extract given before meals, and hydrochloric acid and pepsin after meals. In some cases an additional intestinal antiseptic might be called for. Give some laxative or cathartic to overcome constipation and prevent toxic absorption. Sluggish action of the heart and circulation was to be met by muriate of caffein and strychnia. The biliary radicles were best reached by calomel or bichloride of mercury and arsenic.

Dr. Alfred L. Loomis was called upon to open the discussion. He believed Dr. Porter had presented to us the more advanced, the more recent views with re-

gard to the histology and physiology of the hepatic lobules, and he had no criticisms to make on that part of the paper. When it came to the general question of jaundice, of course we were entering upon a subject which had been discussed from very different stand-points and with very different ideas in the minds of those who had taken part. From the time that he began its study as a medical student, it remained obscure to him until he came to take the position, as he did long ago, that there was no jaundice which was not obstructive. He believed that was the position which we were compelled to take even to day. The question then arose, just where was the obstruction in any given case? It might be outside the liver, it might be internal, along the larger ducts, and it was difficult to exclude obstruction at times along the smaller ducts. For instance, there might be a catarrhal jaundice without evidences of catarrh on the intestinal side of the duct, in which event it would be difficult to say just where or how far up the catarrh existed.

Regarding infectious jaundice, it had seemed to him for a number of years that the only satisfactory explanation lay in the hypothesis that the function of the liver-cells was interfered with in some way. He need only mention the different forms of degeneration of the liver-cells, and would say that the author's explanation of the manner in which these cells obstructed the radicles seemed clear and satisfactory; that is, that the cells themselves became the obstructive cause of the jaundice, and that when such obstruction arose jaundice was brought about by the entrance of bile products into the circulation through other channels than the hepatic ducts, and by other means than reabsorption into the blood. The symptoms of such obstruction were made evident by influence on the nervous system and in icterus before local changes took place in special organs, as in the kidneys.

While listening to the reading of the paper the query had suggested itself to his mind whether in all forms of obstructive jaundice, including cases in which the obstruction was in the larger ducts, the icterus was not primarily due to obstruction at the radicles of the hepatic duct. He had noticed that in chronic jaundice, jaundice which had continued for years, the chief change, according to his observation, had related to connective tissue development shooting down from the surface into the centre of the lobules like a framework, and attended by corresponding changes in the liver-cells. He was, therefore, of the impression that in jaundice occurring in connection with interstitial hepatitis or some other diseases of the liver, the change leading to the jaundice began in the radicles and that the secondary changes were in the connective tissue.

Dr. Loomis could confirm all Dr. Porter had said with regard to diet being the most important factor in the treatment of these cases, yet it seemed to him that hardly sufficient stress had been placed on oxidation. He believed from clinical observation that all patients with jaundice did best when most in open air and sunlight. As to diet, he thought quantity as important as quality. He did not like plain milk, as a rule, but buttermilk or milk which had been made to undergo some fermentative change. Patients had not digested plain milk so well. With life in sunlight and open air at a moderately high altitude, say from fifteen to twenty-five hundred feet, and away from the sea, it was wonderful how rapidly some cases of jaundice would improve.

The Theory Insufficient.—Dr. Andrew H. Smith was unable to explain certain cases of jaundice which he could recall on the theory advanced in the paper, that it was entirely intra-lobular. In fact he could not recall a case of considerable intensity in which he was able to accurately limit the process intra lobular, or to differentiate between other forms of jaundice and that which was supposed to be strictly intra lobular. Perhaps he might in the future, since his attention has been specially directed to it. It was difficult to him to grasp the two ideas at the same time, that the bile was formed in the hepatic cells, and that jaundice was due to disorganization of those cells. We saw in yellow atrophy of the liver, for example, very rapid destruction of the liver-cells and substance, and yet a great degree of jaundice, as if bile production was very active at the very moment that it was destroyed. It seemed to him that in many instances the question was chiefly one of nervous influence, one which a chemical formula would hardly reach. A large amount of bile, say a pint and a half, was secreted by the liver every twenty-four hours, and while much of it passed out with the fæces, yet not a little entered the circulation. Notwithstanding this, the coloring matter of the bile did not appear in the urine under ordinary circumstances. There must be some process by which the bilirubin and biliverdin were rapidly destroyed. It seemed to him that there was as much opportunity for the production of jaundice, the appearance of bile at the surface, from some interference with the destruction of the bile after it had entered the circulation as by some change taking place in the hepatic structure. It was difficult to account for the sudden occurrence of jaundice under certain circumstances, as mental emotion, on the theory advanced in the paper. There was a very marked nervous impression, and this, perhaps, caused some disturbance of the vasomotor system of the liver, with less degree of tension in the blood-vessels of that organ than in the bile-ducts, under which circumstances there might be transferrence of bile from the ducts into the capillaries. This, however, was mere supposition, and was difficult of absolute demonstration. If the rules offered with regard to diet and medication were intended to apply only to cases of what we had been accustomed to consider catarrhal jaundice lasting some weeks, Dr. Smith had no criticisms to make, but he thought more latitude could be allowed in jaundice of less degree, and especially in so called biliousness.

Heptogenous versus Hæmatogenous Jaundice.—Dr. R. C. M. Page said jaundice was usually described as of two forms, heptogenous and hæmatogenous. The latter was claimed to be due to disintegration of blood-corpuscles and the transformation of their coloring matter into bile pigment. Now, bile is formed in the liver, and as it exists there in health there is no jaundice, but if from any cause it is retained in the liver it is absorbed by the lymphatics, passes along to the thoracic duct and general circulation and produces jaundice of most of the fluids and tissues of the body. This retention of bile is due to obstruction. The mode of obstruction in many cases is very readily understood—for instance, in catarrh of the bile-ducts, in the presence of gall-stones, of neoplasms. But the cause is not so apparent in some other conditions, as in suppurative pyelophlebitis, icterus neonatorum, acute yellow atrophy, phosphorus poisoning. But even in these cases there is probably obstruction to the escape of bile from extension of inflammation to the bile-ducts, or else the ducts become stuffed with desquamative epithelium, or both conditions may act, for the expulsive forces of the liver are so very feeble that it requires but a slight amount of resistance to produce retention. True jaundice depends upon coloring matter of the bile which has entered the circulation, and this entrance into the circulation is probably due in all cases to obstruction, although the obstruction may not be fully apparent in rare instances. If this be so, it is manifest there is no such thing as hæmatogenous jaundice.

Some closing remarks were made by Dr. Porter.

Women in the Scotch Universities —By a recent ordinance of the Scottish University Commission the universities are empowered to throw open to women such open bursaries, scholarships, and fellowships as they may see fit.

The Mecca Pilgrimage in 1893 was much larger than usual, aggregating over 250,000 souls. Of this number 25,000 died, most of them from cholera.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 10, 1894.

GEORGE C. FREEBORN, M.D., PRESIDENT.

Typhoid Fever with an Unusual History.—DR. GEORGE P. BIGGS presented specimens from a case of typhoid fever, which was chiefly interesting on account of the peculiar clinical history. The subject of the report was an Italian woman, aged nineteen, and married, with a negative family history. About two weeks previous to her admission to the hospital she had been taken with prostration, headache, pain in the back and abdomen, and was so ill as to be confined to bed. She felt feverish and constantly hungry. Four days before admission there was quite a profuse hemorrhage from the bowel, and two days later she aborted at the third month. A few days after entering the hospital the physician who had attended her previously called at the hospital, and said that one week before the abortion an attempt had been made to produce abortion, under the impression that the chill that she had had was a convulsion. It had been so reported to him by the friends. At the time of her admission her temperature was 104.6° F., the respirations were 28, and the pulse 128. Physical examination revealed nothing but a few râles over the lower lobes posteriorly. The heart sounds were normal, and the heart action, though rapid and feeble, was regular. The spleen did not appear to be enlarged. She was excessively anæmic. The urine had a specific gravity of 1,018, and contained five per cent. of albumin, but no casts. On the day following her admission there was a decided chill, and a subsequent rise of temperature to 106° F. An intra uterine douche was given, and a number of old blood-clots removed from the uterus. On the following day she was curetted, and a portion of tissue, supposed to be the remains of the placenta, also removed. The discharge from the uterus was moderate, and was without odor; but with the history, and with the chills and fever, it was thought probable that her symptoms were due to sepsis. On the third day of her stay in the hospital there was a hemorrhage from the bowel, similar to that which is observed in typhoid fever, and that night she had a severe chill. She was more than ever prostrated the next day. The urine had a specific gravity of 1,009, and contained two per cent. of albumin and granular casts. She died one week after admission, and just three weeks from the onset of the first symptoms.

The lesions at the autopsy were found to be those of a typical case of typhoid fever. The spleen was about three times its usual size. The intestinal glands were greatly enlarged. The typhoid ulcers were limited to the lower two feet of the ileum, and were particularly prominent in the last nine inches. There were also a few typhoid ulcers in the ascending colon, and these were quite superficial. The mucous membrane at this point was much congested, and there were small hemorrhages. Some of the ulcers in the small intestine were quite deep. The body of the uterus was cauterized with a hot iron, and a culture taken from the interior of the organ. The result was a pure culture of a bacillus which appeared to be identical with those obtained from the spleen. The uterus was about ten centimetres in length, and six centimetres in breadth at the middle. Its interior surface was covered with a whitish fibrinous material. The cavity was entirely empty. The peritoneum was normal, as were also the ovaries and Fallopian tubes, showing clearly that there had been no septic process originating in the uterus. A very marked atheromatous patch was noted in the aorta. The other organs showed well-marked parenchymatous changes, passing into fatty change. This was particularly noticeable in the heart and liver. In the latter organ there were also some peculiar yellowish areas, the exact nature of which had not yet been determined. They were located in the centre of the lobules, and from an examination of a frozen section they appeared to be composed of a few fat globules and of granular detritis.

General Tuberculosis.—Dr. Biggs then presented specimens from a case of general tuberculosis. The specimens were removed from a woman, forty-seven years of age, who had been admitted to the New York Hospital on May 16, 1894. For one year previous she had had constant pain in the left hip with a sense of numbness of the left thigh. For six months the severity of the pain had steadily increased. Examination under ether showed a mass about the size of a duck's egg in the left iliac fossa. It was quite tense and immovable. On admission the temperature was 98.4° F., the respirations, 24, and the pulse, 76. The urine was alkaline, had a specific gravity of 1,016, and contained a trace of albumin and a few leucocytes. Under ether a four-inch incision was made just above and parallel to Poupart's ligament on the left side. This led the way to an extra-peritoneal collection of fluid in the left iliac fossa. On incision six ounces of a dark-greenish fluid escaped. The cavity was washed out and packed with gauze. No connection between the cyst and the other parts could be detected. The fluid was not examined, The pain was relieved by the operation. On June 25th she menstruated. By the time the wound had nearly closed, July 5th, she was again complaining of much pain. The wound was re-opened, and with the finger in the rectum another mass was felt quite low down. A similar collection of fluid was evacuated, and the same treatment adopted. The first cyst had apparently disappeared by this time. The urine was then found to be free from albumin, but it contained hyaline casts. The pain was once more relieved by the operation. On July 30th another accumulation of fluid was evacuated. On August 4th it was noted that the left leg was quite markedly adducted and rotated inward, and that it was partially flexed, with a shortening of the limb on that side of one inch. The pain was now worse, and the discharge from the old sinus quite profuse. On August 11th this sinus was explored, and a distinct, harsh crepitation felt on moving the thigh. The finger could be passed into the hip joint. The head of the femur was found to be bare, and considerably eroded. The patient's temperature at that time was as high as 103° F. in the evening. On August 19th some œdema of the right leg and foot was noted. The œdema increased, and she finally died on October 9th.

The first specimen presented, the hip-joint, showed that the floor of the acetabulum had been entirely destroyed, and that the opening so made communicated with a large collection of pus. The lining of the acetabulum was extensively infiltrated with partially necrotic tubercular tissue. The head of the femur was also exhibited, and was shown to be deeply eroded. There was a large abscess extending up behind the peritoneum as far as the diaphragm on the left side, and as far as the spinal column on the right side. Another abscess extended down on the inner side of the pelvis between the layers of the broad ligament. Then there were abscesses burrowing down into the thighs. The pus was rather thin and mixed with blood. There was another collection of about two ounces of thick cheesy pus in the median line in the pre-vesical space. The mucous membrane of the bladder was considerably thickened and congested, and there were a few points of hemorrhage. Its whole surface presented a more or less granular appearance. In the trigone were two perfectly distinct tubercles. The uterus was of about the normal size, and contained three perfectly characteristic fibroids about the size of hickory nuts. The mucous membrane of the upper two-thirds of the body of the uterus was covered with a yellowish-white cheesy layer characteristic of tuberculosis of the endometrium. The posterior wall of the vagina contained one small nodule about three millimetres in diameter, and this, on incision, was found to contain some material apparently tubercular, although the presence of tubercle bacilli had not yet been demon-

strated. The tubes were larger and harder at a distance from the uterus, and were filled with cheesy matter. The ovaries were distinctly atrophied, and while the tubes were adherent to them there was no evidence of tubercular matter in the substance of the ovaries. There were no symptoms referable to the condition of the genital organs. There were typical tubercular deposits scattered through both lungs. The bronchial glands were deeply pigmented, but contained neither cheesy nor calcareous matter. The liver was extremely fatty. In spite of the rather prolonged suppuration, none of the organs gave a reaction with iodine. A nodule was found in one of the suprarenal capsules, which was probably tubercular in its nature. It was fibrous rather than cheesy, and was situated superficially in the suprarenal capsule. The intestines showed no tubercular lesions. The peritoneal cavity contained no fluid, and the pericardium and pleura were perfectly normal.

Marked Atheroma of the Aorta.—Dr. Biggs also presented a specimen of marked atheroma of the aorta. The specimen had only been removed late that afternoon by autopsy from a man dying with uræmic symptoms. The kidneys showed rather advanced chronic diffuse nephritis. No special lesions were found except in the aorta, which, in the lower portion, showed a large number of greatly softened areas, some of them measuring as much as 2 ctm. in diameter, and apparently on the point of rupture.

Dr. Biggs, in answer to a question from Dr. H. P. Loomis as to what he considered the primary lesion in the case of tuberculosis, replied that the lesions in the hip and genital organs appeared to be of longer standing than those in the lungs. Personally, he thought primary tuberculosis of the genital organs was not very rare.

Dr. R. H. Savre said that the lesions in the lungs and genital organs seemed to him much more recent than those in the hip, and certainly the clinical history seemed to point to primary disease in the hip.

Dr. Biggs asked what would then be the explanation of the tuberculosis in the hip.

Dr. R. H. Sayre said he did not think anyone had offered a satisfactory explanation of the common clinical fact of tuberculosis of the joints without apparently any prior tubercular lesions. There were various autopsies on record where, so far as the gross appearances went, there were no evidences of tubercular processes in the lungs, yet there were quite well marked tubercular processes in the organs. Virchow had reported several such autopsies. He saw no reason for assuming that tuberculosis must come through the lungs.

Dr. J. S. Ely thought there was another way of explaining a primary tubercular process in the internal organs where it occurred in relatively young persons, and that was by direct transmission of the tubercle bacilli from the mother to the fœtus. It had been demonstrated experimentally, and inferred from these experiments, that the lesions might lie dormant for four or five years. It was known that under certain circumstances, germs might remain quiescent in the body for a long time, and then become active. Fraenkel had reported a case several years ago, in which a deep abscess had developed a year after a typhoid fever, and in which the typhoid bacillus was found by cultivations. In Vienna not long ago a case of osteo myelitis had been reported where careful search revealed no fresh source of infection, but where thirty-five years after a previous osteo-myelitis there was a fresh outbreak in the same spot. On chiselling away the bone a layer of fresh pus was found containing the staphylococcus pyogenes aureus. It was surrounded by dense bone, which had probably encapsulated the bacteria thirty-five years before. Now, it was possible that the hip, in the case under discussion, had become infected many years before any real outbreak of tuberculosis had been manifested by physical signs. It seemed to him that the hip was the primary source, but he also believed that the point of entrance of the tubercle bacilli was the lungs. A strong argument to him was the much greater frequency with which the bacilli entered the lungs than elsewhere.

The President said that not long ago he had had sent to him for examination a portion of tubercular tissue taken from a female nurse's arm. During labor, her arm had been gripped very strongly by the patient, and some time afterward small nodules had developed subcutaneously at this spot. On examination, he had found the typical lesions of tuberculosis, as well as tubercle bacilli in the lesions. Three or four specimens were taken. More recently he had learned that there had been a diffuse tubercular inflammation of the cellular tissue of the arm. The patient appeared to be perfectly healthy. It was thought that the lymph nodes in the arm had contained some of these bacilli, and that the gripping of the arm, by rupturing these nodes, had set free these germs, and had enabled them to become active as a result of this traumatism.

Dr. H. P. Loomis recalled an autopsy made about three years ago on a prize-fighter. He had died of acute pneumonia. The autopsy showed the lungs normal, with the exception of the pneumonia, but there was a large bronchial gland which contained typical tubercle bacilli in large numbers, and also typical tubercular lesions, showing that these germs might be stored up in the body for a long time without manifesting themselves.

Dr. W. G. Hudson presented a microscopical specimen for an opinion as to its nature.

Dr. H. P. Loomis expressed the opinion that the specimen was undoubtedly one of tuberculosis.

Tumors from Dogs were presented by Dr. J. S. Ely. The first tumor was an ecchondro-osteo-sarcoma of the mamma of a bitch. The specimen was taken from a thoroughbred Irish spaniel belonging to Dr. Furman. Last March this animal had a litter of seven pups. One of them nursed persistently on the left nipple. Shortly afterward several lumps developed in this mamma, which were lanced by Dr. Furman, and pus evacuated. Three months before the tumor was removed it had become so large as to be troublesome.

The second tumor, of which a microscopical specimen was also presented, was a carcinoma of the skin, situated on the lower surface of the tail of a dog, about one inch from the root of the tail. These tumors, the speaker said, sometimes developed from the peri-anal glands, but in this case there was no connection with the trunk. The tumor was dense and lobulated.

The speaker said that Bland Sutton, in his introduction to general pathology, had treated at considerable length of tumors, yet he had not mentioned carcinoma as common in the dog. In a recently published article on tumors in some of the lower animals, 38 tumors were described as having been observed in dogs, viz., 16 were adenomata, 9 were carcinomata, 2 epitheliomata containing "pearls," and 11 were sarcomata.

Ovarian Tumor.—The President presented a portion of ovarian tumor showing electro punctures. The growth had been removed from a woman, forty-six years of age. The history of the growth extended over a considerable number of years. She had been under treatment in London for a long time, and while there one hundred and thirteen electro-punctures had been made during a period of a year and a half. The tumor, nevertheless, continued to grow. She entered the hospital service of Dr. Bache Emmet, and on April 10, 1894, he removed the tumor piecemeal. It was attached to the left horn of the uterus. The woman died of shock. The tumor was a large lobulated mass, the central portion of which was a rather large cyst. The greater part of the cyst was composed of fibrous tissue. There were evidences of smaller cysts in the wall. Microscopical examination showed the tumor to be a fibro-sarcoma. The spots, which from their gross appearance were at first supposed to be hæmorrhagic spots, were really areas of necrosis. Scattered through the tumor were calcareous masses. The clinical record was unfortunately very incomplete.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MEETING OF THE COLLEGE OF SURGEONS—REFUSAL TO THANK THE COUNCIL—CHELSEA HOSPITAL AGAIN—COVENTRY DISPENSARY—CLINICAL SOCIETY—SUBDIAPHRAGMATIC ABSCESS COMMUNICATING WITH PLEURA—CHLORAL POISONING.

LONDON, November 3, 1894.

THE annual meeting of the Fellows and members of the Royal College of Surgeons was held on Thursday, and gave one more occasion for a protest on behalf of the members. This protest, however, will no doubt, as usual, be calmly disregarded by the Council. The President opened the proceedings with a few remarks on the Report for the year, which had been already circulated. Then Mr. Joseph Smith, who had given notice of the oft-passed resolution that members should have a voice in the election of the Council, rose and said that he regretted no hope of redress had been held out by the President. His motion had been passed by several successive annual meetings, but it had never been acted upon. This year the notice was pronounced not quite in order, but the President and Council had permitted it to be brought forward. Mr. Smith, however, declined to accept any grace in the matter, holding that the dignity of the members demanded the right to discuss their affairs in a manner consonant with the propriety of public meetings. He therefore withdrew his motion. Thereupon a resolution in somewhat modified terms was moved and seconded. After some discussion it was carried by twenty-five votes to eight. In the course of discussion the President said he was the son and grandson of a general practitioner, and that every Fellow was a member, though how that affected the claims of members who were not Fellows he did not explain. Mr. T. Smith declared it would be ungraceful for the Council to try to deprive Fellows of their privileges. In that objection is the gist of the matter. The Fellows claim the privilege of electing. Of this privilege they have deprived the members, and they refuse to restore a single vote to those who constitute the great majority.

A resolution was proposed thanking the Council for the Report and for their concessions as to separate meetings for Fellows and members. Objection was taken to this on the ground that whatever had been conceded was a right, not a favor, and the motion was rejected by nineteen to six. The numbers show what a falling off there has been in the attendance at these meetings. This is caused by the apathy of despair at obtaining what once seemed possible. The members are absorbed in their daily duties and can hardly spare time to take part in political movements. When, however, they next arouse themselves to appear in their thousands they may effectually assert their rights.

The Chelsea Hospital scandal seems interminable. Lord Cadogan has now resigned the presidency and it is reported that the next development will be the withdrawal of the royal personages who are patrons. Still the committee stick to their position and will not resign. It is suggested that the newly elected staff should resign. But what would be the result? Others would step into their shoes, just as on the last occasion.

An example of the want of unity and the readiness to supplant is also furnished at Coventry. The dispensary of that town has been figuring in a correspondence in which it is asserted that if the staff resigned their neighbors would take their places. I expect this is a fact, though the *British Medical Journal* affects to be shocked at such a suggestion, and pretends it would not accept advertisements of the vacancies. This is really too good when we remember what advertisements are accepted, and that on other occasions the *Journal* has actually more than withheld support from a hospital staff which was resigning. But I turn from these unwelcome disputes to more practical subjects.

At the last meeting of the Clinical Society Dr. Hector Mackenzie and Mr. F. C. Abbott related a case of subdiaphragmatic abscess communicating with the right pleura successfully treated by resection of ribs and drainage, in a boy aged ten. When admitted into the hospital there was an acutely rounded and reddened swelling centrally situated in the epigastrium. The right side of the chest gave the physical signs of a pyopneumothorax, and the epigastric swelling freely communicated with the right pleura, for it became much more prominent when the patient sat up or coughed, and then distinctly gave evidence of fluctuation. It was decided to drain the sub-diaphragmatic abscess and the empyema by a single opening in the pleura. On the second day after admission a portion of the sixth rib was resected just behind the mid-axillary line. Thirty ounces of exceedingly offensive thin watery pus containing some flakes were evacuated. On exploring with the finger the upper surface of the liver was felt through the opening in the fore part of the diaphragm. The whole cavity was well irrigated with warm boracic solution and a double drainage tube inserted. The cavity was washed out daily, but the discharge continued to be offensive for several days. The patient left the hospital on the forty-seventh day cured. The lung expanded well, and the only sign to be detected six months later was a slight relative dulness at the base of the affected side. The history of the illness pointed clearly to an abdominal origin. The presence of air as well as fluid, and the factor of the abscess pointed to perforation of an air containing viscus, most probably of a gastric or duodenal ulcer.

The President, Mr. Hulke, mentioned the case of a lad aged thirteen, for whom he made an opening in the tenth interspace, and, removing a piece of rib, gave exit to much foul pus. It could then be made out that there was an opening in the diaphragm leading down to an abdominal abscess. Drainage-tubes were inserted and the lad made an excellent recovery, the lung subsequently expanding fully.

Mr. F. C. Abbott said he had little doubt at the time that the abscess originated on the upper surface of the liver, thus shutting off the greater sac of the peritoneum. He pointed out that most cases like this occurred on the left side, and observed that a gastric ulcer which had perforated, would, after passing into the lesser sac, naturally affect the pleura on the same side. Perforating ulcers on the anterior surface of the stomach really penetrated the corresponding pleura. He thought the best plan was to attack such abscesses through the thoracic wall, because the lung invariably expanded well after. The danger in any event was certainly less than would result from an opening made in the middle line of the abdomen.

Dr. S. West questioned the propriety of getting at these abscesses through the chest, cutting into what might prove to be healthy pleura, and thus introducing foul septic pus into the pleural cavity, the more so as the abdomen could at present be opened with comparative impunity. He, however, recalled a case in which Mr. Pitts had cut down upon a hepatic abscess through the pleura with every success. Mr. Pearce Gould observed that many of these cases died before the abscess had extended from the region of the duodenum to the corresponding pleura. He saw one case a few days since, a young woman said to have a sarcoma of the liver. There was evidently a large abscess below the diaphragm, and he opened it in the middle line, immediately below the ensiform cartilage, giving exit to a large quantity of gas, to several pints of fluid, and to an enormous hydatid cyst springing from the upper surface of the liver. There was no opening in the diaphragm.

Dr. Lee Dickinson said that duodenal ulcers were very rare in boys of this age, and suggested perforation of the colon, referring to a case of right sub-phrenic abscess described by Dr. C. J. B. Williams, which proved to be due to a perforation of the hepatic flexure of the colon.

Mr. Bruce Clarke said that not long since he had opened a hydatid of the liver through the pleura without any untoward sequelæ.

A case of recovery from poisoning by one ounce of chloral hydrate was next communicated by Sir Dyce Duckworth for Dr. R. J. Colenso. A lady aged thirty-four, deliberately took, on December 12, 1893, one ounce of chloral hydrate in two ounces of water at 8 A.M. At 4 P.M. she was discovered in her bed unconscious. No ordinary rousing measures were of any avail. Medical aid was not procured till 5 30 P.M. The patient was then found to be comatose, with abolition of all reflexes, breathing shallow and stertorous, pupils both small and very sluggish, pulse 130, small and rather firm; temperature 100.5° F. The nature of the poison taken was not found till about three hours subsequently. Atropine was given hypodermically, and the stomach washed out, but the washings revealed nothing as to the poison taken. Strychnine, ether, amyl and other restoratives were employed, and recovery ultimately occurred. The satisfactory result was doubtless due to the robust health and fine physique of the patient, and in no small degree to the persistent and energetic efforts made by a staff of intelligent assistants, who labored for twelve hours to restore animation.

The president alluded to a case of a young woman who was proved subsequently to have taken 320 grains of chloral. The pupils were contracted almost to a pin's point. He washed out the stomach, but they had to resort to artificial respiration several times in order to keep her going. He pumped strong coffee into the stomach and ultimately she came round.

Dr. Churton-Leeds then read the notes of a case of multiple neuritis, fatal on the sixth day, in a rather fragile girl aged fourteen.

MR. BRYANT'S HUNTERIAN LECTURE.

REPORTED BY OUR LONDON CORRESPONDENT.

THE lecture at the Hunterian Society was this year delivered by Mr. Thomas Bryant, ex-president of the Royal College of Surgeons. The topic he chose for his address was "Some subjects of Public and Professional Interest." After some general remarks on the education of the profession, he enforced the necessity of keeping up the standard of preliminary studies, and declared that the Medical Council represented not only the licensing boards but the best views of the profession in the conviction that those young men who have enjoyed the broadest and deepest general education are the best fitted to undertake and master as they ought the many difficulties with which the student of medicine has to grapple. He hoped, therefore, that the time was not far off when for all university men an Arts degree, and for all others an examination of equal standard, will be required before they are allowed to enter the portals of the profession; although, with the view of giving a helping hand to the student who, after taking his arts degree, must now have five years for special medical study—it ought to be so arranged that in his arts curriculum the subjects of physics, chemistry, and biology should be included. Under this new régime the student would enter upon his purely medical work better equipped and with every prospect of success, and would with greater probability than now can be said to exist, have unconsciously acquired in his university training a cultured mind, and with it something of the true "professional spirit," so that he would not only practice in that spirit, but when the business side had to be faced—for there was such a side—and the question of emolument and worldly advantages must be considered—he would recognize and remember that he could only raise himself by raising the profession in the estimation of those who formed his circle, and that he could never do so either by lowering the position of his profession ever so little, or by allowing the "spirit of trade" to master the "professional spirit," and so becoming a "medical tradesman." Where, then, asked the lecturer, "is the room for the old system of apprenticeship, for the restoration of which we every now and then hear a feeble cry? The reply to this could be but one, "Too late, too late. Apprenticeship is as dead as Cæsar." This, he held, need not be a source of regret, for, reviewing the system all round, the master was the only one who, as a rule, derived any certain benefit from its adoption, for he pocketed the premium which went with the apprenticeship—often several hundreds of pounds—and at the same time found a dispenser or useful servant in the unfortunate man who was bound for five years to do whatever was required of him. With the present heavy demand upon the powers and time of the student, he hoped to hear no more of this system, as it is an impossibility and an anachronism. He thought it would be well if the teachers during the last year of study would take some opportunity of leading their pupils' thoughts in this direction, for it was clear that in business questions, business knowledge is essential, and good advice at this time must bring forth good fruit. This might be done by means of a post graduate lecture, this taking the place with advantage of the old "introductory," which had been nearly given up. He believed that the best step a student could take before entering upon a practice was to spend a year as an assistant to a good medical practitioner; by so doing he would learn the business part of his profession as well as acquire much more if the practitioner happened to be of a high class. Medical schools should keep a list of high class men in good practice who were willing to accept qualified students for this end, and both would no doubt profit by the plan.

The subject of professional remuneration, which was now claiming attention, he felt was a difficult one to handle, but it had been the cause of no little recent complaining and heartburning, and there was a great deal of reason for this feeling, since much professional work was notoriously ill paid, and private work was no less so. Not long since an active chairman of a provincial county council told him in conversation he was as chairman ashamed at the smallness of the salaries the poor-law medical officers received, and yet he was alive to the fact that if the present ones refused to continue for that amount there were others who would readily accept the place. He admitted the parish parsimony as regards payments, but with such competition before him, what was he to do. The same complaints might also be made as regards clubs, and more particularly of the so-called Medical Aid Associations. Indeed, rising higher in the scale, and with respect to honorary appointments, men who would wish to stand well with their confrères were at times too ready to accept positions which others had deemed it right to vacate. In such men the "spirit of trade" had mastered the "professional spirit" and was allowed to have its way. This conduct all round was bad and sad; but how was it to be prevented? Some men to put a stop to these practices and other evils called out, "Let the Medical Council or Royal Corporations correct them;" while others looked to defence associations, medical associations acting as courts of ethics, to pass judgments and enforce decisions.

He wished to point out that to look for a sound remedy we must look to ourselves, for "our remedies oft in ourselves do lie." To aid us in this direction by all means let medical defence unions, local societies and medical associations be formed, if we have not enough, and more particularly let these bring before the General Medical Council or Royal Colleges every grave act of professional misconduct of registered practitioners, and in so doing support their causes with evidences which must satisfy their judges; for the functions of these bodies were simply judicial. By so doing the evils of covering, of unqualified assistants, of giving false certificates, of undue or gross forms of advertising and touting for patients would speedily be abolished, and with these evils many others would die. He suggested a Board of Dis-

cipline to whom all medical grievances could by the local societies or associations be submitted, the duties of such a board being much the same as those of our own Royal Colleges of Medicine and Surgery. Such a strong appeal court would have the confidence of the profession and public and would help materially to suppress doubtful acts and check many evil ones before they became grave enough to be pronounced "infamous in a professional respect" and so render the culprit liable to be taken off the register. In practice we should never forget that the patients' interests are those which should be first thought of, and that the public good was its ultimate object; but in so doing let us remember that it was all important for the public interests, as well as for the due exercise and dignity of our profession, that every practitioner should hold an independent but responsible position and that in his professional work he should be left perfectly free from lay control, although amenable to lay censure. It was also equally needful that he should be adequately paid for his services by all classes according to their means. All measures, whether under the guise of charity or termed "provident," and all hospitals which encourage the public to seek professional advice for nothing or next to nothing, were to be discouraged as helping to panperize and degrade the public at large.

The same might be said of the members of the profession who tempted the public to do the same thing by means of private hospitals, touting clubs and associations, or who were ready to accept at a reduced figure, over their neighbors' heads, appointments which had been put up by laymen, as it were, to auction or competition. Medical men by such acts adopted the surest way within their power to lower the position of their profession in general estimation; and at the same time did injustice to themselves and the public by not giving to the latter the best services the profession can supply, while they must, in addition, lose their own self-respect even if they happen to gain cash by their own unworthy actions. For let it be asked, How is it possible for a man who is ill-paid or overworked, or both, to give the attention it is essential for him to bestow on every case he has undertaken to attend; or to maintain, in the interests of the profession, the position to which he is entitled and his own self-respect. Mr. Bryant then passed on to consider the following questions: the working of public provident dispensaries, the conditions under which private ones should be worked and sanctioned; the conditions under which clubs should be worked; the good or evil influences of medical aid associations worked for their own profit by laymen; the duties of unqualified assistants; and how midwives, or, what seemed a better term, "nurse midwives," are to be educated and utilized for the public good. The chief solution of these lay in the hands of the general practitioner; and he expressed his conviction that clearly formed opinions upon each of these, formulated after due discussion by such societies as this, would do more to mould the professional mind for good, and form a better basis for future corporate action than any opinions emanating from the General Medical Council or the two Royal Medical Corporations.

It was likewise an error to look to the General Medical Council or Royal Corporations to give, under existing circumstances, judicial opinions on these and other complicated questions. To ask these bodies to consider and solve ethical questions connected with professional work and professional advancement, and, having solved them, to seek powers to enforce their views, is too much to expect, even if it were desirable. The General Medical Council has done good work in putting down the serious public offence of "covering" and of giving false certificates, more especially of death, by unqualified practitioners. It did good also in expressing decided opinions on gross advertisements and other delinquencies. He assured his hearers that his own college—the Royal College of Surgeons of England—with its present limited disciplinary powers, had not been, and was not idle in the same direction, for there were few meetings held of the council before which some complaint of undue modes of advertising, and of the employment of secret remedies, with other illegitimate methods of carrying on the "medical trade," was not brought. If the offence charged was not serious enough to justify the name being taken off the books, a serious expression of the council's opinion upon the nature of the act complained of, and a decision that the misdemeanor was inconsistent with the declaration made by the delinquent when he was admitted a member "that he would demean himself honorably in the practice of his profession, and do his best to maintain the dignity and welfare of the college," were often enough to induce him to mend his ways and adopt more lawful means of carrying on his work. At any rate, these expressions of opinion did great good and tended to stop ways which lead downward; and he believed that if the attention of the council were more often drawn by the college members to methods which weak men adopted from their weakness and which strong ones know were injurious both to the profession and the public, the action of the council for good would be more frequently repeated, to the great advantage of the profession and the suppression of bad ways. A society could well do what individual men might shrink from. During the last seven years—besides all members of the college who had been convicted of criminal offences—six members have been removed from the list of members for issuing advertisements or practising secret methods of cure which the council regarded as "prejudicial to the interests" and "derogatory to the honor of the college," as well as "disgraceful to the profession of surgery;" and six other members who had offended against our by laws in the same way had simply been let off after they had made "declarations," that they would not so offend again; while one other member was removed for being associated with a disreputable museum. Thus thirteen members had been brought before the council in seven years for having seriously offended against the by-laws of the college, besides many others who had been satisfactorily dealt with by the President for minor offences. But, said the lecturer, "you must not rely on the Royal Corporations for the help which, to be effective, must come from yourselves."

Let such societies as this, and all others like it, exclude men who do such wrongs from their list of members if they persist in their bad ways after they have been warned, and let the excluded members know the reason why they are so excluded; and when the profession as a body has spoken, greater powers may be attained by the corporations; for seven years ago, when the Royal College of Surgeons applied to the Privy Council for some enlargement of its disciplinary powers, its requests were refused, not, however, on account of any objections which were raised by the Privy Council to the powers asked for, but on account of the opposition of certain Fellows and ill-informed members of our own body who had placed themselves in antagonistic positions. If this opposition had not occurred, the disciplinary powers of the college would have been enlarged.

With respect to "public provident dispensaries," such institutions might be made valuable both to the public and the profession. But in order to secure these desirable ends it was all-important that only such members should be admitted to the advantages of the dispensary as were of the wage-earning and poorer classes, and that the scale of admission charges should be calculated in single persons as upon a percentage of their wages, and in families upon the aggregate wages of the family or household and not on that of the member only in whose name the ticket was taken out. Their doors should be opened to registered members, but their rules should be such as to allow of any of the "well-to do poorer classes" being able to obtain speedy help and relief upon well-defined terms from any one of the doctors of the district in the event of any sudden illness or accident taking place. Every doctor of the district should, more-

over, be admitted a member of the staff, should he wish to, and be paid for the work he had done.

With parish dispensaries for the very poor, and provident dispensaries for the "well-to-do poor," the needy classes would be well looked after, and the medical officers of both would be fairly treated. With the existence of these public provident dispensaries, so called "private dispensaries" would not be needed, and consequently should not be allowed; since such dispensaries were too often the mere speculations of needy men who traded upon the poor for their own ends, and degraded the medical officer to the level of a small and unscrupulous tradesman. Again, town and country clubs were institutions to be encouraged, for the same reasons as public provident dispensaries; but it seemed that the scale of charges now required should be somewhat higher than that which has been asked in past years, for wages had been much raised, and the medical club charge should be a percentage on wages. As to what were called "medical aid associations" the lecturer was at a loss to know where, in most of them, good was done, for it was clearly degrading for any qualified man to do professional work as the paid servant of a committee of illiterate or even educated laymen, and consequently to work under their control.

It was likewise a clear wrong both to the public and profession, that members should be admitted to these associations who were not of the wage earning or allied classes, and who were well able to pay the limited charges of a private practitioner. The medical aid association was a growth of a diseased nature, and it ought to be either brought into line with public provident dispensaries or club practice, as sanctioned by and based upon the friendly societies act, or it ought to be rooted out of professional public work. As to the duties of unqualified assistants, all would agree that they should be reserved for home duties, not far beyond those of a dispensing assistant.

Finally Mr. Bryant said a few words about the burning question of midwives. He admitted that in some districts they are necessary. If necessary, it was evident that they should be efficient, for if they were not efficient they must be dangerous assistants and had better be away; and if they were to be efficient, the conclusion was that they must not only be made so, but that their knowledge should be tested by competent examiners before they were allowed to embark on their responsible and serious duties. He wished all "midwives," as they were called, to be regarded as "nurse midwives" and even to be named such—and he was pleased to add that this suggestion had been adopted by the General Medical Council, since the term carries with it the meaning that they were really nothing but skilled nurses educated for special work. He wished it to be undertaken under the direction of the two Royal Medical Colleges of England by means of examining boards, central or district, the curriculum of study as well as scope of examination entirely resting with the two royal colleges.

"MUST THE PARSON PAY?" AGAIN.

To the Editor of the Medical Record.

Sir: As I am asked a question or two or more by a gentleman (I wish he was more of a gentleman) of Pararis, Fla., it brings me forward to trouble you a little to answer. He asks, "Is it not a fact that laboring-men and clerks who receive a salary of $40 per month (some less), pay their medical bills without a murmur?" No, sir: some of them do, many of them murmur, and some do not pay at all. Again, "Is it not also a fact that the vast majority of physicians do a great amount of work for which they receive not a penny, in some instances even furnishing the medicine?" Yes, sir; but how does that tally with the first question, or do other people better off cheat the doctors? No man honors the medical profession more than the writer, nor have I said a word against them and do not propose to, as a class. My objection to C. H. Carroll's letter is his unwarranted inference that the minister merely recites his sermon on Sunday, as if he preached but one, when many of them deliver three, besides week evening work, funeral sermons at any call, and often receives no compensation. His sarcastic sneer of a minister's "repeating a prayer which he has learned by heart," is so utterly unworthy of any man, let alone a professional one, that it really places a stigma on his manhood (if he has any) that no gentleman would have placed there. Does the man imagine that a minister has no brains to think? Does he suppose that ministers have no heart for human suffering, no sympathy for the sick, no regard for God? that they merely repeat parrot-like words without a thought? expressions without a feeling? sentences without a care to comfort the sick, the sorrowing, and the mourner? Does he have the opinion that ministers mock God with lip service, without devotion, when they pray in the presence of human misfortune? Thank God, the medical profession, as such, are nobler-hearted than the few cavillers like this Florida agnostic. If he will read my article he will see that the average salary of the entire ministry is less than the $40 a month clerks. And no minister in the United States gets as high a salary as some medical men. I do not want the services of a man who so undervalues a minister's self sacrifices, and don't expect it. Medical services have been rendered me by men of large souls, not by being asked, but because they appreciated the poorly paid services, as a rule, of the large army of philanthropists in the Christian ministry.

Minister.

Berlin, N. H.

THE MARRIAGE OF SYPHILITICS.

To the Editor of the Medical Record.

Sir: In a letter appearing in your issue of November 10th, entitled "The Marriage of Syphilitics," Dr. Frank E. Maine, of Auburn, N. Y., answers a series of questions propounded by Dr. Burnside Foster, which, if acceptable to the latter, will render any further research on his part quite unnecessary. Unfortunately, Dr. Maine has taken a very positive stand in this matter, and one that is wholly unwarranted by either authorities or facts. The opinion expressed in this letter is opposed utterly to that held by all prominent authorities in the study of syphilis, both at home and abroad, and differs wholly from the teachings of men like Bumstead, Taylor, F. N. Otis, Keyes, Sturgis, and others, who have devoted a large part of their lives to the careful and painstaking study of this disease in the rich fields for research only obtainable in great cities.

While Dr. Maine may have had sufficient practical experience in the study of syphilis, in its relations to marriage, to feel justified in presenting his opinion in opposition to the gentlemen above cited, I must certainly object to his classifying scrofula among the syphilitic sequelæ, and would respectfully refer him to any of the more modern works on general pathology under the heading tuberculosis. As a matter of fact, some of the most healthy persons of my acquaintance have been born of parents, one of whom, at least, had been a sufferer from syphilis before marriage; nor have I observed the slightest trace of the disease in any form passed down to the third generation. In conclusion, Mr. Editor, allow me to refer to the words of Jonathan Hutchinson, F.R.S., the greatest English syphilographer of to-day, who says in regard to the advisability of telling syphilitics that marriage is for them ever to be avoided: "Such a course, or anything near it, would prevent thousands of happy marriages; would swell the ranks of those who adopt concubinage instead of wedlock, and while it would reduce the sum of human happiness, would probably not in the least diminish the prevalence of syphilis."

Very sincerely yours, W. K. Otis, M.D.

5 West Fiftieth Street, New York City.

NUCLEUS OF RED BLOOD-CORPUSCLE OF MAMMALS.

To the Editor of the Medical Record.

Sir: I read Dr. William Moser's remarks, in the Medical Record of October 20th last, relating to the caryocinetic changes in the red corpuscle, with much interest, as I there recognized various appearances of blood which I discovered during examination under the microscope about seven years ago, which interested me greatly at the time.

Up to this date it appears to be a recognized fact, taught in all text-books, that a nucleus did not exist in the red corpuscle of mammals, except in the embyro, and as a consequence, in certain anæmic conditions of the blood. I was always unwilling to accept that conclusion, on account of the admitted importance of all nuclei to cell life, and thus, as the blood corpuscles of birds and reptiles always contained a nucleus at all stages of their existence, it seemed highly probable that they really existed in the red corpuscles of the mammalia, and, reasoning by analogy, it seemed difficult to account for their absence, especially as they had been seen in human blood in the fœtal stage and under certain pathological conditions.

As I considered that the nucleus was composed of protoplasm, it struck me that the stain used by botanists as a reagent for this material in plants would be the best to employ to demonstrate the nucleus of the red corpuscle of animals, if it contained protoplasm.

Acting on this suggestion, I made a large number of human blood preparations in the following manner. Placing a drop of human blood on a slide, 3 × 1 inches, I then took another slide and drew the sharp edge rapidly across it at right angles, using all the pressure possible, and allowing it to dry. This is the best method of obtaining a single layer of blood with the corpuscles evenly distributed. When quite dry I pour over the preparation a strong solution of iodine, and remove after about a minute. It will dry rapidly, and will then be ready for microscopical examination.

I may here state that preparations of blood treated in this manner will remain in good form for an almost indefinite length of time, needing no glass cover or any preservative, and can be examined dry.

This examination of preparations of blood, dry, and without the addition of a glass cover, I consider an important feature of my work, and accounts for my seeing so much which had escaped previous observation, because I noticed that the addition of Canada balsam and other preservatives and a cover, caused most of the special features to disappear.

I was surprised to find on making a microscopical examination of human blood thus prepared, that all the red corpuscles in the field showed in each instance a clearly defined nucleus, some in the centre of the cell, and at the edge in others; in many instances two nuclei were visible in the one cell, and in rare instances they were in a cluster of five or six. In some instances were exhibited what a German authority calls homogeneous cells, having merely a very fine line as an outer ring, and in some cases such cells contained a nucleus.

At the time I made a very fine photograph of this slide showing all these appearances above described in the most clear and definite manner, but I failed to find any specialist who would take the slightest interest in the subject. I was aware that Dr. Osler, late of Canada, and then holding a professorship at the Johns Hopkins University, had given much attention to the microscopical appearance of blood, and I forwarded to him copies of my original photograph and enlarged copies of the same; but he came to the conclusion that because they had failed in their laboratory to find a nucleus in the red corpuscle by any of their methods of staining, that a nucleus did not exist, although he admitted that I had stained and photographed such an object which was optically perfect. I have still the original plate of my photograph, and have shown copies to hundreds of physicians.

However, feeling discouraged at the want of sympathy with my work, I simply let the matter drop, and was glad to find by Dr. Moser's paper that the subject is now claiming attention and has a prospect of being followed up, as I consider it will be an important factor in solving many of the most difficult medical problems of the present day, when systematic and intelligent microscopical examination of the blood is carried on.

John Michels.

THE DISPENSARY QUESTION IN CLEVELAND.

To the Editor of the Medical Record.

Sir: I have noticed that your medical journal has from time to time denounced the "dispensary abuse," but on the other hand I have noticed the apparent apathy of the profession in regard to this question. I would call your attention to the fact that here in Cleveland we have got the profession at large agitated over the question of the dispensary abuse, partly brought about by a trial going on between two homœopathic physicians in regard to this subject, the judges in the case being two trustees of their college.

In my own case the trial was before a jury in a Justice court. I sued the defendant for services rendered. The defendant came to the college dispensary looking for the surgeon who treated cripples. On being questioned he claimed a willingness to pay. He stated that he had a correspondence with Columbus, O., parties who would correct the club-feet of his boy for $500. He said that $500 was too much, but that he could pay a reasonable fee. I agreed to do it for a reasonable fee—less than $500. For personal convenience I very commonly have private patients from in and out of town go to the college building when a plaster-of-Paris dressing is required, but it is not applied in the presence of the class. This is done at the college instead of my office on account of having plenty of help at the college and also that it saves my office from being plastered up.

In this case I applied plaster to the child's feet several times at the college building. The operation was performed at University Hospital. The treatment was continued at the defendant's home and my office, lasting, in all, about four months.

The defendant reassured me over and over that he would pay, and acknowledged indebtedness in the presence of others. Finally when I tried to collect my fee he denied indebtedness, claiming that I treated his child as a clinical case betore the class. My answer to this is that there was no session of the college, and therefore there was no class. I sued for $262.50. The defendant had paid on account, $5. The jury granted $143, with interest for three years.

In discussing the "dispensary abuse" there is no chance for argument in regard to the deserving poor—they are never turned away from dispensaries to my knowledge. The question is: "Is it right for a dispensary to treat the well-to do?" My argument on the subject is as follows:

I hold that the services of dispensaries are maintained solely for the poor. That in return for the services rendered the poor patient may be used for clinical teaching. That the wealthy make donations to the institution on the representation that the money is to be used in this way. That to obtain donations in the aforesaid manner, and then to use the funds so obtained partly for the benefit of the well-to do, is usually called "obtaining money under false pretences," and is punishable by fine and imprisonment.

But we all know that this abuse exists; and what is the cause? As I see it, the incentive is the inherent selfishness of man; it is largely brought about (especially in the great cities of the East) by the men at the top—

those in authority. The Professor says to himself, "The larger the clinic, and the more assistants I have, the more important is my position. Secondly, these middle-class patients do not come from my following—I lose no practice by it." It was from the same motive that one of the Vanderbilts was led to say: "The rights of the public be d—d." In this case it would read "The rights of the profession be d—d."

The dispensary has no rights in the handling of patients further than the treatment and clinical use of the poor. It has no moral right to enter into competition with the outside practitioner.

But what about the rights of the dispensary physician? He is in active outside practice and has educated himself for that purpose. He is in open competition with all other practitioners and has a moral right to increase his practice by any honorable means, *i.e.*, in this case to take what additional practice the dispensary may accidentally or incidentally bring him. What right has a dispensary to say that we as a dispensary acknowledge that we have no right to this well-to-do patient, but we shall not permit you (the dispensary physician) to treat him? What right has a dispensary to discriminate against their dispensary physicians? Certainly the dispensary would admit the right of some other doctor (who might be physician to some other dispensary) to have the patient as a private case.

I am willing to abide by any reasonable rule of a dispensary as to the treatment of the poor, but will brook no dictation from any such organization as to whom I shall treat among the well-to-do.

Dr. Bishop, the defendant in the trial between the two homœpathic physicians, sent out a card to the physicians of the city asking the opinion of the profession in regard to the dispensary abuse. He claims to have over one hundred answers in which they all denounce the abuse, and agree that dispensaries are solely for the poor, with the privilege of using the patient for teaching purposes.

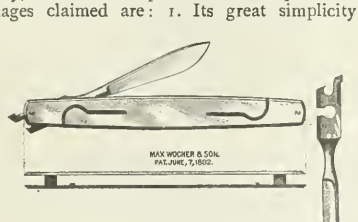
William E. Wirt, M.D.

Cleveland, O.

New Instruments.

AN ASEPTIBLE BISTOURY.

The general desire of physicians to obtain an aseptible bistoury, that resembles in its main features the old shell-handle double bistoury, with slide catch, has been complied with by introducing a new bistoury, of which the above is an illustration. It is the same form and size as the old slide bistoury, its blades open and close just as readily, and have the improvement that they lock automatically, both in the open and closed position. The advantages claimed are: 1. Its great simplicity. (It



consisting only of a plain skeleton steel handle and two blades.) 2. Its blades are locked automatically, both in the open and closed position, and their edges are protected in the handle when closed. 3. Its blades can be removed for sterilization in a simple manner, by holding them at a right angle with the handle. 4. The construction of the handle admits larger blades than any other bistoury, which is in many cases of great importance to the operator.

The accompanying cut shows the form and construction of the instrument. The small spring is pressed outward by the thumb nail, while the middle finger acts as a counter pressure against the side of the handle, at the same time the blade is opened by the fore-finger. The same position is assumed in closing the knife. In this case the fore finger presses against the back of the blade. In readjusting the blade, hold the same at a right angle to the handle, so that the corresponding numbers on the blade and handle are in view.

The instrument is manufactured by Max Wocher & Son, surgical instrument makers, Cincinnati, O.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 17, 1894.

	Cases.	Deaths.
Tuberculosis	86	106
Typhoid fever	28	10
Scarlet fever	72	3
Cerebro-spinal meningitis	1	1
Measles	52	2
Diphtheria	166	27
Small-pox	45	2

Yellow Fever and Mosquitoes.—Dr. Carlos Finlay, of Havana, believes that yellow fever is propagated chiefly, if not entirely, by inoculation, the principal agent of which is the mosquito. In a paper in the *Edinburgh Medical Journal* for October, 1894, he presents the following parallel, showing how closely the vital conditions of the mosquito agree with those which are known to favor or hinder the spread of yellow fever.

Yellow Fever.—Temperatures at which yellow fever has been observed to cease in New Orleans and in Rio Janeiro = 15° to 18° C.

Temperatures which have proved insufficient to prevent a subsequent reappearance of the disease without a new importation = 0° C.

Temperatures which are considered to completely extinguish the infection of yellow fever = severe frosts.

Mean temperatures which admit of a free propagation of yellow fever in Havana = 26° to 30° C.

Coincidence of unprecedented abundance of mosquitoes with severe yellow fever epidemics, in Philadelphia, 1797, and in the Southern States of North America, 1853.—(*Laroche*, ii.)

Artificial heat which has proved efficacious in definitely arresting the transmissibility of yellow fever—several stoves employed to heat the hold of the Regalia.—(*Laroche*, ii., p. 440.)

Altitudes at which epidemics of yellow fever have been exceptionally observed: Newcastle (Jamaica), 4,200 feet; and Madrid (1870), 2,000 feet.

Culex Mosquito.—Temperatures at which the mosquito is completely benumbed by artificial cooling of the air = 15° to 19° C.

Lowest temperature which the mosquito will bear, in a state of apparent death, and after which it may yet revive = 0° C.

Artificial cold after which the mosquito cannot revive = from 1° to 4° C. below zero.

Mean temperatures in which mosquitoes are most numerous in Havana = 25° to 30° C.

Coincidence of a scarcity of mosquitoes in Havana with an unusual diminution of yellow fever during the

summer of 1886, the reverse coincidence being observed during the autumn of the same year.

Temperatures at which the mosquito falls into a condition of apparent death, but may still revive = 39° to 41° C. Temperatures after which it cannot revive = 41° to 49° C.

Artificial rarefaction of air in which the mosquito is for a while deprived of its power of flying or stinging, but sometimes after a while recovers = equivalent to 1,000 –6,000 feet.

Influence of Bicycle Riding on the Uric Acid Diathesis.—Dr. Robin read a paper before the Academy of Medicine of Paris on this subject, in which he stated that moderate bicycling diminished markedly the secretion of uric acid, and emphasized that this exercise does not result in lack of elimination of the uric acid, but really diminishes its production.

He finds, on the other hand, that in sclerosis of the kidneys, in which a small amount of albumin is the most constant symptom, indulgence in this form of exercise is apt to markedly increase the amount of albumin, and is therefore contra-indicated.

Thyroid Feeding in Basedow's Disease.—Treating Basedow's disease by the administration of thyroids is in opposition to much that has recently been written concerning the pathogenesis of this disease, but this is what Dr. Voisin (Medical Society of the Hospitals, Paris) has recently reported. A young woman affected with exophthalmic goître was given the thyroid gland of the sheep to the amount of two drachms daily. At the end of two weeks the tachycardia had reduced one third, the goître had considerably diminished, as had the exophthalmus. When the case was reported the only symptoms of the disease were slight swelling of the neck and slight exophthalmus. Drs. Dreyfus, Brisac, and Beclere expressed their opinion that thyroid feeding tends to aggravate the disease and increase its symptoms rather than cure it.

Hereditary Syphilis in the New-born Associated with Acute Nephritis.—Dr. Hock showed at a meeting of the Medical Club (Vienna) an infant, the second child of a syphilitic mother, who eight weeks after its birth showed a syphilitic erythema which disappeared under the influence of proto-iodide of mercury. Later the extremities and penis began to swell, and an examination of the urine showed albumin, hyaline casts, and white and red corpuscles. Other symptoms of syphilis disappeared under the use of iodide of potash.

Hysterectomy for Uretero-uterine Fistula.—Dr. Mackenrodt presented at a meeting of the Medical Society (Berlin), a woman on whom he had successfully performed a hysterectomy for the cure of a uretero-uterine fistula. An attempt was made to cure the fistula, a result of a forceps delivery, by converting it into a uretero vaginal fistula, but failing in this the operator proceeded to extirpate the entire uterus. The ureter was first separated from the uterus and then the latter removed, care having been taken to close the peritoneal cavity, and also to arrange an opening for the ureters into the vagina. Three weeks afterward an oblique opening was made in the bladder, and the utero-vaginal fistula was attached to its walls. The vaginal wound closed, and the patient made a good recovery.

Tannigen, a New Intestinal Astringent.—Tannigen, according to Professors Meyer and F. Müller, in the *Deutsche Med. Wochenschrift*, is a derivative of tannin, and is a golden-gray odorless and tasteless powder. In dilute acids and in water it is not noticed, and is readily soluble in alcohol. As it produced no ill effect when given to animals, Professor Meyer requested Professor Müller to try it clinically, and the latter gentleman has for the last eighteen months been testing it with a view to its employment as a remedial agent. The dose given was from 0.2 to 0.5 grm. three times a day, and being tasteless it was readily taken. It was given, however, in as large a quantity as would lie on the end of a knife without producing any ill effect. It was first of all given in chronic diarrhœa of different kinds, in dysentery, and in the diarrhœa of phthisis. In far the larger number of cases it reduced the number of stools and improved their consistency. This result was not, however, a constant one, especially in the diarrhœa of phthisis, and when the remedy was stopped even in the other cases the diarrhœa returned. Some patients took the drug for weeks and experienced no diminution of its efficacy. In acute diarrhœas it acted, but not constantly, and in the diarrhœa of infants it produced no effect. The proper field, therefore, for tannigen is the chronic diarrhœas, and it possesses the great advantages over tannin that it is tasteless and does not disturb the gastric functions; it does not tan the stomach, but only the intestines. Professor Müller thinks there is a decided want of such a remedy, especially in the diarrhœa of phthisis and in chronic intestinal catarrh, a remedy which can be used for long periods with good effect, which does not take away the appetite, and which can be conveniently taken and is not disagreeable.

The Parasitic Theory of Eczema.—Dr. Malcolm Morris asks and answers these four questions regarding eczema:

Are internal remedies required in eczema?

The gist of his reply is embodied in these words: "My own view, stated broadly, is that as a general rule the less internal medication there is in eczema the better. If a constitutional dyscrasia underlie the skin affection it must of course be treated on the ordinary principles of medicine."

And so if neuroses, gastro-intestinal complications, or special or general debilities occur, they require due attention. But without definite indications internal medication should be withheld.

The influence of diet in eczema.

The writer here says: "I may frankly state that my own view is that diet has no influence at all except indirectly." Qualifications are entered, of course, in the case of gout and diabetes complicating eczema, and a lowered diet is advised "if the lesions are of an acutely inflammatory type."

What are the principles on which the local treatment of eczema should be carried out?

"Speaking generally, I treat every case as if it were of parasitic origin. Even if micro organisms are not the exciting agents in the causation of the process in all cases, parasitic irritation always comes into play sooner or later as a secondary factor, and requires to be appropriately dealt with. The objects which I aim at in the local treatment of eczema are, first, to destroy micro-organisms; secondly, to protect the inflamed surface from the air and from further microbic invasion; thirdly, to sooth irritation."

How is the tendency to recurrence of eczema in those predisposed to the disease to be overcome?

"Change of climate is often productive of good in this direction, especially if accompanied by complete rest of mind as well as body."

Then, touching the efficacy of baths and medicated waters, about which so much has been said, and which is a matter of strong popular opinion, the following summary appears:

1. No spring known to me has any specific action on eczema.

2. Sulphur waters have no special effect other than that due to their anti-parasitic action.

The Rev. Cotton Mather, of Salem witchcraft epidemic fame, was much interested in medical topics. He introduced the practice of inoculation into New England at the risk of his life, and published a popular work on medicine which, as Dr. Oliver Wendell Holmes points out ("Medical Essays"), proves him to have been what to-day would be called a bacteriologist. One of his capsulas (chapters) is devoted to the animalcular

origin of diseases; at the end of which he says, speaking of remedies for this supposed source of our distempers: "Mercury we know thee: But we are afraid thou wilt kill us too, if we employ thee to kill them that kill us. And yet for the cleansing of the small blood-vessels and making way for the free circulation of the blood and lymph—there is nothing like mercurial deobstruents."

The Water-supply of Jerusalem.—The Turkish Ministry of Public Works has determined upon the reconstruction of the ancient water conduits of Jerusalem, dating from the age of King Solomon. By this means it would be possible to convey twenty-five hundred cubic metres of water daily to the Holy City. Of this it is proposed to give one thousand metres away free of charge to the poor of Jerusalem, the distribution to take place at the Mosque of Omar, the Holy Sepulchre, and other places frequented by pilgrims. The new conduits are to be joined to the ancient aqueducts of Arob, and are to be carried through a tunnel 3,570 metres in length. The total outlay in connection with these works is estimated at 2,000,000 francs.

A Historical Case of Diphtheria.—The influence which epidemic disease has had upon the course of history is a curious subject for speculation, but most of the instances which have been adduced by various writers who have occasionally touched upon the subject, have been instances of wide-spread epidemics, such as the plague at Athens and the "Black Death" in England; but the effect which certain infectious diseases, more or less constantly present in temperate climates, may have had upon historical events is less clearly perceived. A curious instance is afforded by the death of Napoleon Charles, Prince Royal of Holland, the son of Louis, brother of Napoleon Bonaparte, and of Hortense, his stepdaughter. This child died, when not quite five years old, of a disease, which, there can be little doubt, was diphtheria. The boy was a favorite of his Imperial uncle, and was generally taken to St. Cloud when Napoleon stayed there in the summer. Though Napoleon never seems to have expressed himself clearly upon the subject, it was thought by many that he proposed to make this child, who was his nearest male relative in the second generation, his heir. Among those who shared this opinion was Meneval, who, as private secretary to Napoleon, had special opportunities of forming an opinion as to the Emperor's intentions. If this child had lived Napoleon, Meneval thinks, would not have divorced Josephine, would not, therefore, have exposed himself to be insulted by the Emperor of Russia's refusal of the hand of a grand duchess, and in all probability would not have gone to Moscow, and might therefore very possibly have founded a lasting dynasty. It is curious to remember that this boy's brother—his uterine brother at least—did actually sit on the throne of France. Napoleon, who was very much moved by the death of his nephew, offered a prize of 12,000 francs to the author of the best work on the means of preventing and curing croup. The boy died on May 5, 1807, and Meneval remarks that the superstitious looked upon it as a curious coincidence that Napoleon himself died on the same day of the same month fourteen years later.—*British Medical Journal.*

The First Recorded Death in Hypnosis.—The death of Ella Salamon, in Tuzer, Upper Hungary, at her home, on September 17, 1894, while in an hypnotic state, has attracted much attention abroad, owing to the fact that it is the first recorded instance of death of this kind.—*Medical Association.*

The Church Sanitary Association is the name of a society recently founded in England. Its membership is made up of the clergy and laity of the Established Church who believe that personal cleanliness and the observance of hygienic laws are Christian duties. It proposes to organize a propaganda by the establishment of lecture courses and the wide circulation of tracts on the preservation of health. It has been suggested that the work of reform should begin with the church buildings, which are so often poorly ventilated, draughty, and dark, and where people are often compelled to sit, with perhaps wet feet and damp garments, through a long service in a chilly cavern, whose stone floor is covered with pools from dripping umbrellas.

A Bust of the Late Dr. Leidy is to be placed in the library of the University of Pennsylvania.

A Cancer Ward in a Vienna Hospital.—Baron Albert de Rothschild has just given $250,000 to build and equip a pavilion in the Empress Elizabeth Hospital at Vienna for women suffering from cancer. The money constitutes a "Bettina" fund, called after the baron's late wife, who died from this disease.

Professor Koch on Cholera.—At the recent meeting of the German Public Health Society at Magdeburg, Dr. Koch said that it is now possible to prevent the spread of cholera in any country, and he was certain that Germany would never be visited again with an epidemic if only the measures now adopted were carried out early and energetically. It was a matter of indifference to him what precautionary measures were taken in other countries, for Germany was now able to protect herself and keep the cholera out of her own borders.

Lepers in Iceland.—A physician was sent by the Danish Government last summer to make a special inspection tour of southern Iceland to ascertain the number of lepers. The number found was fifty-three, or twice as many as expected. A hospital is to be built to prevent further spread of the disease.

Opium-Eaters and the Plague.—The opium dealers of Hong-Kong have collected data and issued a special pamphlet, in which they triumphantly point to the fact that opium eaters or smokers were, almost without exception, exempt from attack during the recent epidemic of the plague.

The Song of the General Practitioner.

Sung at the Annual Dinner of the Bolton and District Medical Society, October 4, 1894.

He must not walk his rounds for fear his patients think him poor,
And dearly do they love to see a carriage at their door;
And if his horse is fat—"He must have little work to do,"
And if it's lean the reason is: "He starves the poor old screw."

Should he call upon his patients every day when they are ill,
His motive plainly is "to make a great big doctor's bill;"
If he visits them less frequently—thus less'ning their expense—
The chances are he'll be accused of wilful negligence.

He must work all day and half the night, and never say he's tired;
For the public look upon him simply as a servant hired;
And should he take a holiday he'll find when he comes back
Some patients have resented it by giving him "the sack."

Concerning money he must seem indifferent to be,
And folks will think he practises from pure philanthropy,
When we hear about him boasting of the guineas that he earns
We wonder if they all appear in his income-tax returns.

About his own afflictions he must never say a word;
The notion of a doctor being ill is so absurd!
And when, perhaps from overwork, he's laid upon the shelf
His sympathizing patients say: "Physician, heal thyself!"

J. Johnston, M.D., in *Lancet.*

Cigarette-makers' Cramps has attacked the operatives in the French state tobacco factories. It is very common in Spain, but has not hitherto been noticed to any extent in France. The cramp affects the muscles of the thumb and first finger of each hand.

Drunkenness in St. Petersburg is reported to be greatly on the increase, so much so that the authorities have become alarmed, and have instituted the most energetic measures to suppress it. Any one found drunk in the street is imprisoned for from one to three days, and the person from whom the last drink was bought, if he can be found, is fined from five to twenty-five rubles.

HISTORY OF AN EPIDEMIC OF ACUTE NERVOUS DISEASE OF UNUSUAL TYPE.[1]

BY C. S. CAVERLY, M.D.,

RUTLAND, VT.

PRESIDENT STATE BOARD OF HEALTH.

DURING the month of June, 1894, there appeared in a portion of the valley of the Otter Creek, in the State of Vermont, an epidemic of nervous disease, in which the distinctive and most common symptom was paralysis. The great majority of the sufferers were children under six years of age. The city of Rutland and town of Wallingford were first affected, later the towns immediately contiguous to these, and to this tier of towns, thirteen in number, the outbreak was almost exclusively confined.

A remarkable series of cases occurring in the city of Rutland first attracted the attention of the physicians, and later, popular interest. Many of these cases were taken sick without apparent cause. In others it was ascribed to getting over-heated, or chilled suddenly when heated, indigestion, and occasionally to trauma. After a few weeks deaths were heard of, and during the latter part of July everyone was discussing the "new disease."

From my own observation, and conversation with other physicians, it was plain to me that an epidemic of unusual, if not of unique, type was prevailing, and I decided that my connection with the State Board of Health imposed a duty on me in connection therewith. The investigation thus undertaken in an official capacity soon showed me that the information I was acquiring, while unusual and valuable from a public-health standpoint, was doubly so from that of the practitioner. I am sure, therefore, that the physicians who have so kindly given me, as a member of the State Board of Health, the bulk of the data on which this paper is founded, will pardon the use to which I propose to put this material.

This epidemic has been confined, with very few exceptions, to the narrowest part of the Otter Creek Valley. The territory is bounded on the east by the Green Mountain range, and on the west by the Taconic range of mountains. North and south it has no natural boundaries. Its area is about fifteen miles wide, including the sides of the bounding mountains, and thirty miles long. Through this valley, from south to north, flows the sluggish stream of Otter Creek, dammed at several points. The extreme heat and drouth of the early summer had rendered the stream unusually low. The only reliable figures obtainable as to temperature, humidity, and rainfall for Vermont, are furnished me by the United States Weather Bureau Observer at Northfield, Vt. Since the opening of the station at that place, in 1887, the average temperature, humidity, and rainfall per month, for the months April, May, June, July, and August, the months in which these conditions could have any influence on an epidemic occurring during the summer months, was as follows:

	Temperature.	Humidity.	Rainfall.		Temperature.	Humidity.	Rainfall.
1887	57.7° F.	76 7	3.75	1891	56.2° F.	75.8	2.98
1888	55.3° F.	72.5	3.45	1892	56.9° F.	74.8	3.76
1889	57.6° F.	74.1	3.05	1893	56.5° F.	75.6	3.51
1890	55.3° F.	87.8	3.79	1894	56.1° F.	77.3	2.25

[1] Read before the Vermont State Medical Society at its annual meeting, October, 1894.

It will be noticed by these figures that the only marked deviation from the recorded meteorological conditions of the past eight years, which has occurred during the past summer, has been in the average monthly rainfall. This has been thirty per cent. less during the past spring and summer months than the average for the past eight years during these months. While it was a matter of frequent remark that our early summer was this year unusually hot, the official figures do not bear out this statement.

The population of the towns affected in this valley aggregates twenty six thousand, of which eighteen thousand dwell in the quarrying and manufacturing centres of Rutland, West Rutland, and Proctor. The usual sprinkling of foreign elements prevails in these centres, while in the outlying farming towns the population is chiefly of the regular New England type.

The first cases in this epidemic of which I find notes, occurred in the city of Rutland and town of Wallingford, simultaneously, about June 17th. The characteristics of the disease can be illustrated by a few cases, among the one hundred and twenty-six cases of which I now have notes.

CASE I.—Boy, three years of age, American. Previous health good; active child; healthier than his brother two years older. No apparent cause. Moderate fever; coated tongue; loss of appetite; sluggish bowels. As these symptoms improved it was observed that he could not walk or even stand alone. The weakness was most noticeable in the extensors of the thigh. After ten days he began to improve, and in three weeks was quite well.

This case is an illustration of the mildest type of these cases.

CASE II.—Boy, three and a half years of age, Irish; sturdy child; apparent cause playing too hard. Fever, 102° to 103° F. Incontinence of urine for ten days; hyperæsthesia. Fever abated on third day. Then was noticed paralysis of both legs; loss of patella reflex; no anæsthesia; slight response in lower extremities to faradism. Left leg improved rapidly, right slowly. After six weeks was able to stand and take a few steps by taking hold of chairs. After three months paralysis confined to right glutei and lower spinal muscles, with considerable wasting. The weakness of spinal muscles has resulted in a spinal curvature.

CASE XCIII.—Boy, two years of age, American. Had an attack of indigestion, from which he recovered, when he was taken on a long carriage drive. Immediately developed high fever, with an erythematous rash and considerable muscular rigidity. After a few days there was paralysis of both legs and loss of patella reflexes. After a month has not improved.

CASE XCIV.—Boy, six years of age; healthy child; apparent cause chilling the body; fever, 104° F.; vomiting. Acute symptoms lasted six days. On the sixth day paralysis of right arm, followed on the seventh day with paralysis of left leg. After three months extensors of left thigh and right deltoid wasted and weak.

These three cases illustrate a very common phase of the disease. Some of the cases fully recovered, and many still suffer from probably permanent impairment of some muscles.

CASE IV.—Boy, six years of age; no apparent cause; taken sick with convulsions while playing in the street; these lasted nine hours; moderate fever; rapid pulse; vomiting; rigidity of neck and back muscles; hyperæsthesia of skin; very restless. Death on sixth day.

Case XXXII.—Female, twenty-one years of age; married; one child, aged sixteen months. Had been caring for child, which was sick; somewhat fatigued. Complained of head and backache. Pulse, 80; temperature, normal. Third day, temperature, 103.5° F.; pulse, 100. Eyeballs rolled up; head and neck drawn back. Bowels regular; urine normal; no albumin; no sugar. Red blotches on skin that came and went; urticaria; temperature, 100.5° to 102° F. for succeeding three or four days. Pulse about 100; unable to swallow or speak; answered questions by moving head; in no pain; sixth day, pulse, 60; temperature, 98.6° F. On the eleventh day had some pain in the stomach (indigestion?), neck became rigid. Pulse, 100, and temperature 98.6° F. during next two days. Then pulse sank to 45 and became irregular. On the thirteenth day some pain in right side of head and right eye. Heart gradually gave out and she died.

Case XCVI.—Boy, three and a half years of age; Italian. Headache; drowsiness; fever; on second day strabismus. Pulse, 45, irregular. On the sixth day he apparently recovered. Played too hard, and two days after developed same train of symptoms and died.

Case CXXV.—Female, aged twenty-nine; American. Married; one child, aged eight months. Does not nurse child. Neurasthenic; no apparent cause. No fever; much nausea; great head and backache; marked opisthotonos; double vision; deafness for several days and roaring in head. Retention of urine; catheterized eight days. Soreness of legs and arms; no eruption; pupils fully dilated; second day, paralysis of right arm; fourth day, right leg; fifth day, left leg; and sixth day, left arm; also paralysis of abdominal muscles and obstinate constipation; anæsthesia of limbs; reflexes gone. After three weeks has recovered slowly use of limbs except leg muscles, which she is still unable to use.

Case LXXXVIII. — Female, aged six; American. Frail child; had a spinal curvature for four or five years. No history except this. Fever; nausea; head drawn to one side; facial paralysis. On third day paralysis in all extremities; hyperæsthesia; soreness of joints; obstinate constipation; inability to use abdominal muscles. After two months paralysis continues, except slight movements of toes and fingers; considerable wasting. Bodily functions fair; mind and special senses normal. Facial paralysis passed.

These five cases illustrate the severer cases of the epidemic, many of which were fatal. There were a certain number of cases exhibiting odd and interesting symptoms out of the usual line.

Case XI. — Aged seven; American. Whooping-cough followed by broncho-pneumonia. During progress of the latter disease had loss of speech for two weeks; delirium; fever; left arm paralyzed. Recovered after two weeks.

Case LXXXVII.—Boy, aged four; American. Convulsions; double vision for one week; very drowsy. Paralysis of external rectus of one eye, which remains.

Case XCIX —Boy, aged thirteen; French. Had a fall injuring back, followed by fever, nausea, muscular rigidity of neck. From this, case ran along like an average case of typhoid fever, lacking marked typhoid symptoms except the fever curve. Fever lasted four weeks. Following this was paralysis of right arm and right leg. Paralysis improving.

Of the 126 cases of which I have notes, all except six were in the valley above described. Of these 6, 2 occurred in the town of Ludlow, on the east side of the Green Mountains, and 3 in Middletown, and 1 in Fair Haven, in Rutland County. The epidemic died out first in the towns first affected, and lingered latest in those affected last.[1] Of the thirteen towns in the Otter Creek Valley which have suffered from this epidemic, those that show the greatest number of cases—Rutland, 55; Proctor, 26; and Pittsford, 8—are immediately on this stream. The towns of Wallingford and Clarendon, also on the stream, suffered very little.[1]

It should be stated that there have been, among domestic animals in this valley, many cases of paralytic disease during the period of this outbreak. Deaths among horses have been found post mortem, according to at least one veterinarian, to be due to meningitis, and there have been also deaths among fowls and dogs described as paralytic.

It has been remarked by many physicians that the usual diseases of children, during the past summer, have been attended with exaggerated nervous symptoms. It is a source of great regret that in none of the fatal cases could an autopsy be procured, though extraordinary efforts were several times made to secure one.

In collecting statistics of this outbreak I have sought only those cases attended with marked nervous phenomena, like muscular rigidity, special sense disturbance, or paralysis, and no disease by name, seeking not to prejudge the character of the disease or anticipate a diagnosis. Without detailing further individual cases I have prepared a tabulated history of the epidemic as a whole, collecting the commonest features of the cases in my reported list of cases by themselves. I presume my list includes ninety per cent. of all the cases that have occurred.

Table 1.—Age and Sex.

Under 6 years	Male,	33 cases.
" "	Female,	16 "
" "	Not stated,	36 "
From 6 to 14 years	Male,	10 cases.
" "	Female,	2 "
" "	Not stated,	9 "
Over 14 years	Male,	8 cases.
" "	Female,	5 "
Stated between a few months and 9 years		7 "

Of the 119 cases in which the age is given, 85 are under 6 years, 21 between 6 and 14 years, and 13 were over 14 years. Of the latter was one case 70 years of age. The genuineness of this case might at first be questioned, but the train of initial symptoms was the same as in the milder cases of childhood, with paralysis of both lower extremities, clearing up after ten days.

Of the 74 cases in which the sex was stated, 51 were males and 23 females.

Table 2.—Nationality.

American	35
Irish-American	17
French	6
Jewish	1
Italian	1
Swede	1
Not stated	65

It has been noted that in the larger centres the races affected were oftenest foreign, while among the farming population Americans predominated. It has not been entirely confined to any one class, but has been most prevalent among working people and those whose sanitary surroundings were not of the best.

Table 3.—Previous Health.

Good	41
Poor	10
Not stated	75

Table 4.—Immediate Cause.

Fatigue	2
Whooping-cough	1
Over-heating	22
Chilling body	4
Indigestion	2
Typhoid fever	2
Trauma	2
Pneumonia	2
No apparent cause or not stated	89

[1] New cases, three in number, are reported from Proctor and Pittsford since the preparation of this paper. These towns were chiefly affected during August, and the last cases prior to these occurred about September 1st.

[1] The map on p. 676 will show the geographical distribution of the cases.

There has been but a single instance, so far as I can determine, in which there has been more than one case in a family, and since it has usually occurred in families of several children, I think it can be safely set down as non-contagious.

TABLE 5.—INITIAL SYMPTOMS.

A.

T. stated as above 103° F.	27
T. " " between 99° and 103° F.	22
Said to have had no fever	3
Not stated	74

B.—DURATION OF INITIAL FEVER.

Stated to be 1 day or less	4
" " " 1–2 days	2
" " " 2–3 "	6
" " " 3–4 "	7
" " " 4–7 "	26
" " " 7–14 "	4
No fever, or not stated	77

C.—NAUSEA.

Stated to have had nausea or vomiting	25
" " " " no " " "	1

D.—CONVULSIONS.

Stated to have had convulsions	12

All under 14 years.

E.—BOWELS.

Stated to have been constipated	3
" " " had diarrhœa	3

F.—BLADDER.

Stated to have had retention of urine	7
" " " " incontinence "	1

G.

Stated to have had muscular rigidity of neck or back or opisthotonos:

Fatal cases	5
Non-fatal	15

H.

Stated to have had hyperæsthesia of skin or soreness of muscles of the extremities:

Fatal cases	3
Non-fatal	24

I.—SPECIAL SENSES.

Stated to have had strabismus	2
" " partial blindness	1
" " double vision	2
" " deafness	1

K.—SKIN ERUPTIONS.

Stated to have had a simple erythema	29
" " urticaria	2

TABLE 6.—INITIAL PARALYSIS.

No paralysis	6	Fully recovered, 5; died, 1	
Not determined	7	"	7
Both legs	66	" " 43 "	4
Arm and leg (same side)	9	" " 2 "	1
One arm	5	" " 3	
One leg	6	" " 1	
Both legs and one arm	4		
Tongue and throat	2		1
Both arms	3

"Variously in arms and legs"	8	" " 1 "	1
External rectus one eye	1		
One side of face	1		
One arm and opposite leg	1		
All extremities and abdominal muscles	2		

TABLE 7.—PARALYSIS REMAINING AT TIME OF REPORT.

Glutei and lower spinal muscles of one side	1
Both legs	17
One leg	8
Both legs and one arm	3
Both arms	2
Arm and leg same side	6
Extensors one thigh	2
One arm	3
"Variously in arms and legs"	6
External rectus one eye	1
All extremities	2
One side of face	1
Extensors left thigh and right deltoid	1

It will be seen by these tables that 6 of these cases had no paralysis, as stated, but all of these had distinct rigidity of the spinal muscles, strabismus, or other symptoms referable to the nervous system, and are therefore included in this report. Of the 7 cases reported as "not known" to have had paralysis, or in which nothing is said of any paralysis, all died with distinct symptoms of acute nervous disease, and may be fairly supposed to have died in the initial stage.

Of those that died it will be noticed that, besides the 7 that succumbed early in the acute stage, 4 had paralysis of both lower extremities, 3 of all extremities, and 1 each had no paralysis, hemiplegia, tongue, and throat, and variously paralyzed.

Of those who had recovered fully at the date of the reports, which varied from two weeks to two months after the attacks, 5 had no paralysis, 43 had paralysis of both lower extremities, 2 of one arm and leg of same side, 3 of one arm, 1 of one leg.

While of the cases of which I have reports, 53 have still some paralysis at the time of the report, and it is probable that many of these are permanently disabled.

I am unable to make any statements based on statistics as to the number of cases in which there has been a wasting of the affected muscles, for the time is yet too short in most cases for marked wasting to have occurred. I hope later to be able to report on these wrecks of the epidemic. The composite picture presented by the facts I have elicited does not readily admit of a name. It is at once noticed that individual cases can be readily recognized as presenting a typical picture of poliomyelitis anterior, but that the variations from the text-book type of this disease are many and marked. Opisthotonos, eye symptoms, and hyperæsthesia are out of place in the phenomena of this disease, so that the epidemic, as a whole, presents notable departures from the regular features of the disease.

Again, cerebro-spinal, especially spinal, meningitis, is quickly seen in certain phases of this outbreak, but the season of the year, the general absence of the special sense disturbance, particularly ear disease, the low mortality, the absence of purpuric eruption (stated by some as the most important diagnostic point in this disease as an epidemic), are strong arguments against this diagnosis.

Without further detailing the arguments that present themselves to all of us for and against the claims of individual diseases to recognition in this connection, I am glad to be able to quote the opinions of high authority in regard to this point.

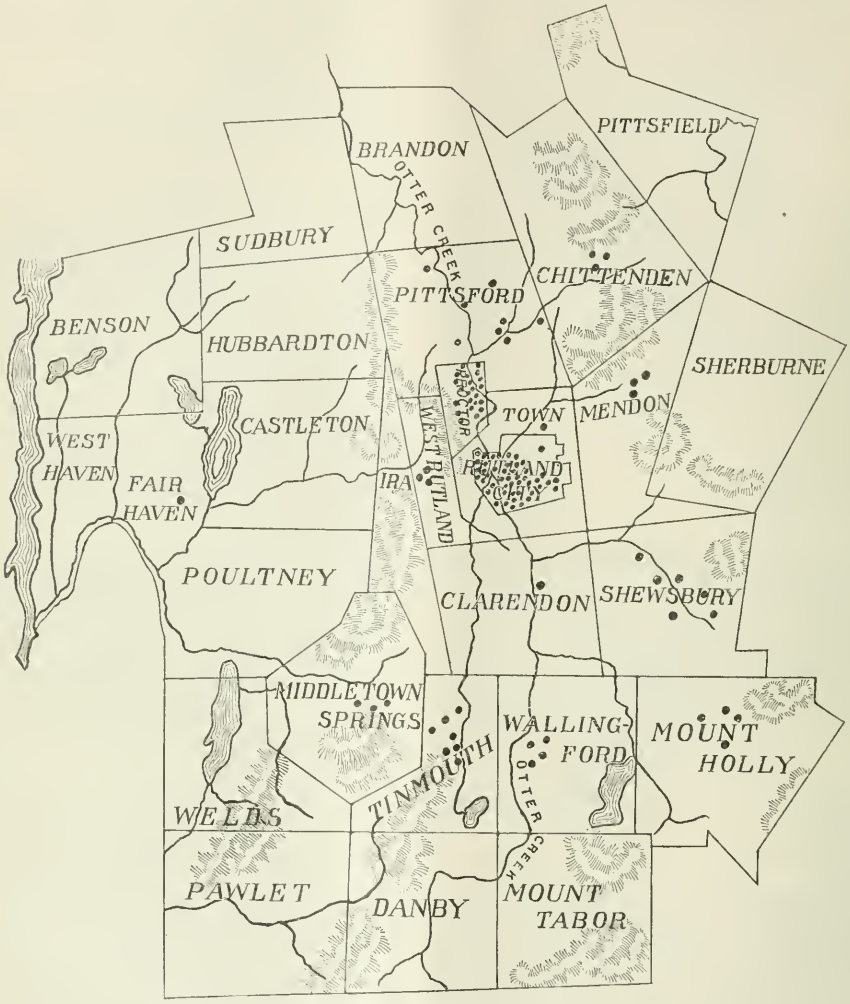
Dr. A. Jacobi, whose knowledge of this outbreak is gained solely from my written description, has very kindly permitted me to quote him on this point. He says: "All your cases belong to the same class, cerebro-spinal meningitis. They prove that nature does not walk in ruts as most of our text-books do, and that transitions and variations are common. Two years ago I made two autopsies in which the main lesions were in the lumbar portion of the spine. I have no doubt they had a chance to become paraplegic if they had lived. The frequency of paralysis in your cases is something very uncommon; so is your low mortality; both prove that your cases were more spinal than cerebral."

This opinion, coming from so high an authority in medicine, is of course entitled to the greatest respect.

Dr. M. Allen Starr saw, in September, ten of these cases, at that time, of course, in the chronic stage of the disease. His conclusions in regard to the epidemic, which I am permitted to give, are: "The cases seen, if seen without a history, would have all impressed me as cases of acute anterior poliomyelitis, without a doubt. The history does not appear to me to contradict this diagnosis, and while in some respects unusual, viz., in eye paralysis, in stiff neck and pain, there is not as much difficulty in assigning them to anterior poliomyelitis as there is in assigning them to cerebro-spinal meningitis. Epidemics of anterior poliomyelitis are not unknown."

He cites one reported by Cordier in *Lyon Médical*, January and February, 1888; one in Switzerland in 1889 (account not found); one near Boston, reported by Putnam two years ago, and one in Stockholm, reported by Medim, *Neurolog. Centralblatt*, 1891, p. 397. Dr. Starr further says, "As to eyes, there are some cases on record of ocular palsy with infantile paralysis. Sachs had such a case. As to pain, in the majority of adults and young people able to state symptoms, pain was complained of. I saw such a case yesterday."

The Stockholm epidemic, reported by Medim, an account of which Dr. Starr furnishes me, occurred in 1887. The disease first appeared in the month of May, and by August 9th had assumed an epidemic character. From the latter date to September 23d, Medim saw 29 cases, and knew of 44 during the summer, from May to November. The cases reported by him, as a whole, resemble more nearly the typical cases of poliomyelitis than those in the Vermont epidemic. Three of his cases were fatal in the acute stage. "There were noticed paralysis of the abducens in 5 cases, disturbance of speech in a few; in 1 case paralysis of the tongue, in several of the accessorius, and in others symptoms referable to the vagus Disturbance of the voice and paralysis of the muscles of mastication, and vaso-motor paralysis were seen in 2 fatal cases. In 1 ophthalmoplegia externa. At the time of this Stockholm epidemic of poliomyelitis, during August and September, polineuritis appeared and was thought to be due to the same source. This neuritis was followed by considerable tenderness; in some cases twitching and tremor; also there was ataxia of movement during convalescence. These neuritis cases, however, showed no wasting. Medim considered infantile paralysis a specific infectious disease, in whose acute stage the entire organism is affected. Autopsies by Rissler support this theory. He found in the spinal cord an acute parenchymatous inflammation in the anterior horns, with degeneration of the ganglion cells and secondary degeneration of nerve-fibres in the association tracks, in the anterior columns, and in the anterior nerve-roots; also in the nuclei of the hypoglossus, vagus, facial, and abducens nerves. In most of the cases the anterior horns were particularly affected; in other cases also the peripheral nerves and



Rutland County. Cases indicated by black dots.

brain cortex. It was possible that all the nerve nuclei in the medulla and pons should be affected."

I have quoted freely from Medim's report because his is the only epidemic of poliomyelitis of which I can secure accurate facts. Dr. Charles L. Dana has also permitted me to quote his opinion of this epidemic. His knowledge of the outbreak was likewise gained from my written statements to him, and from an examination of the cord and brain of a fowl sent him, which was suffering from paralysis of legs and wings. His statement is as follows: "Dr. Dunham, of the Carnegie Laboratory, very kindly made a bacteriological examination of the cord and sciatic nerve of the fowl; but with negative results. Microscopic examination shows an acute poliomyelitis of the lumbar part of the cord, and no meningitis. Dr. Dunham's inoculating needle did not strike the affected part.

"Apart from the results of this case, which, of course, may have no relation to the epidemic, I feel the greatest possible confidence that the disease is in most cases a true anterior poliomyelitis."

Of course the epidemic and apparently infectious character of the disease points to a microbic origin. That epidemic poliomyelitis has such an origin is not a new hypothesis. Dr. Dana in an early letter to me says: "Roger, Thornot and Masselin, Bourges, and Vincent, produced poliomyelitis in rabbits and guinea-pigs by inoculation of the coli bacilli, streptococcus of erysipelas modified by culture."

On this point it is to be hoped that Dr. Dana's further examination of the cord and brain of the fowl will throw some light.

In a recent letter Dr. Starr further says that "there is now a tendency to revise the pathology of poliomyelitis," the regular descriptions of which are founded on Charcot's statements. Dr. Starr gives me the gist of an article published by Goldschreider in the *Zeitschrift für klin. Med*, 1892, in which he says that his (Goldschreider's) conclusions, founded on a review of all the cases with autopsy, was that the disease began with a "very intense congestion of the central arteries of the spinal cord which come up on each side of the central canal, and spread out in the central gray matter and into the anterior horns. These arteries have branches passing backward into the gray matter of the posterior horns, but the posterior horns are chiefly supplied with blood from the peripheral arteries, and hence are less affected when the inflammatory condition is limited to the distribution of these central arteries. After the engorgement of all the arterial twigs, diapedesis occurs and the surrounding nervous tissue is permeated by small cells and by serum. It is this choking of the gray matter by the inflammatory products which leads to the suspension of functional activity, and when, as in many cases from impoverished nutrition, the cells of the anterior horns are actually disintegrated by the inflammatory products, permanent destruction of the nerve-tissue ensues.

Goldschreider believes, therefore, that the primary condition is a congestion in the domain of a definite set of arteries, quite comparable to the condition occurring in the lung in a pneumonia, and in the intestine in a typhoid fever.

Siemerling has also written a very careful article on the "Pathology of Infantile Paralysis," in the *Archiv für Psychiatrie* for January, 1894. His conclusion is as follows: "After a careful review of all the literature, we reach, therefore, the following conclusion, that in the pathogenesis of infantile spinal paralysis the inflammatory lesion of the interstitial tissue in connection with a distention of the blood-vessels, especially in the region of the anterior spinal arteries, plays the chief *rôle*. A primary inflammation of the ganglion cells, in the sense given by Charcot, is not to be admitted."

Dr. Starr further says: "One more point. If you consult the descriptions given of congestion of the cord, you will find many of the general symptoms of pain, stiffness of the muscles, pain on movement, and general tenderness, which were present in the early stage of your epidemic. If now we grant that this newer pathology is correct, these symptoms are easily explained on the theory that the congestion and the inflammatory processes were in your epidemic not limited to the domain of the anterior spinal arteries, but extended to the posterior parts as well."

The quotations thus liberally taken from so competent authorities leave very little to be said in regard to the pathology or diagnosis of our disease. Admitting Dr. Starr's reasoning in regard to the congestion of the posterior as well as the anterior portions of the cord to be correct, supported by his citations from Goldschreider, Siemerling, and Rissler, the phenomena of this epidemic can be reconciled with a diagnosis of poliomyelitis. The pain, hyperæsthesia, special sense disturbance, and muscular rigidity, the most important departures in our epidemic from the established symptoms of poliomyelitis, are rendered explainable under this newer pathology. A diagnosis of epidemic cerebro spinal meningitis would certainly be more strained. The disease, cerebro-spinal meningitis, in epidemic form being more common, its symptoms and behavior are correspondingly better understood than poliomyelitis.

Gowers states that it has usually prevailed chiefly in winter and spring, ceasing about July. This seems to be very uniformly agreed to. Its features are discomfort, later pain in the head, backache, vomiting, stiffness of neck and back muscles. Pulse not uniformly rapid; temperature usually very high, 104° to 106° F. Eruptions, especially herpetic and purpuric, are common. Cranial nerve symptoms, and deafness and blindness as sequelæ, are the rule in a certain number of cases. Cases, and even epidemics, of an abortive form of this disease are not unknown. Gowers states that the mortality varies from twenty to eighty per cent. Hemiplegia, and in spinal cases paraplegia, are occasional sequelæ, but they are always attended by rigidity and contractures of the muscles. These are the long-recognized features of epidemic cerebro-spinal meningitis. There must be admitted to be some marks of similarity between this description and our epidemic. The almost universal paralysis in our cases, and its irregular and varied character, are entirely foreign to the generally described features of cerebro-spinal meningitis. Likewise, too, the season of the year, the general absence of eye and ear impairment, and of herpetic and purpuric eruptions, the low mortality, and the absence of contractures.

In an epidemic like this, in which there is a blending of the symptoms of two or more diseases, the decision must rest between the symptoms which are most uniformly present and which are most pathognomonic of each disease. And while, as Dr. Jacobi, speaking—we are always glad to admit—from a vast experience and long study, intimates that there are important exceptions in actual life to the stereotyped description of the books, the exceptions in this outbreak to the long established symptoms of cerebro-spinal meningitis seem to be so marked as to really overshadow those that would be left to establish that diagnosis. Under the newer pathology given of poliomyelitis, symptoms referable to the meninges and cerebral ganglia can be reasonably explained.

In conclusion, let me acknowledge the uniform courtesy with which the practitioners of Rutland County have responded to my requests for statistics of this outbreak. The list includes nearly all the practising physicians of this county. Comparatively few of the cases have fallen under my direct observation, and without their aid it would obviously have been impossible to make any record of this unparalleled epidemic approaching completeness.

Army Medical Museum.—There are now 32,269 specimens in the Army Medical Museum in Washington. The number of specimens received during the year ending June 30, 1894, was 1,363.

PREMATURE DELIVERY OF A DEAD CHILD, INDUCED BY ACUTE APPENDICITIS, WITH REMARKS ON APPENDICITIS IN WOMEN.

By PAUL F. MUNDÉ, M.D.,

NEW YORK.

Although there is no real anatomical or pathological reason why acute inflammation of the appendix vermiformis should not occur as frequently in the female sex as it does in the male, it is only within recent years that the reports of appendicitis in women have become so numerous as to attract attention. One reason for this apparent immunity of the female sex from this disease probably was that in the ante operating days such inflammations in the right iliac region were looked upon as pelvic "cellulitis," or peritonitis, the incorrectness of this diagnosis never being exposed, either because the patient died of general peritonitis and no autopsy was made, or because the abscess fortunately opened into the bowel, the pus was evacuated per anum, and the patient recovered without a suspicion of the true nature of the case.

I remember perfectly seeing such a case of supposed inflammatory exudation between the layers of the right broad ligament, some twenty years ago, in which I ordered the usual blister and hot-poultice treatment. The idea of an appendicitis, or perityphlitis as it was then called, did not occur to me, although I had shortly before assisted at several operations for perityphlitic abscess in men. Some two weeks after seeing this woman I was called to her house, and found a fluctuating swelling in the median line between umbilicus and pubes, which I aspirated. The true nature of the case was then revealed, for the fluid removed had a decidedly feculent odor. I incised the abscess freely, and in course of time the sinus healed.

Since it has become the rule to open the abdomen and remove all pus sacs, whether of ovary or tube, as soon as the presence of suppuration is discovered, and in cases where the pus points toward the abdominal skin to open the abscess there freely, as in a subcutaneous abscess occurring anywhere else, we have met with more and more cases of unsuspected abscesses of appendiceal origin in the female, the existence of which had been masked by the great frequency of inflammatory and suppurative disease of the uterine appendages. I have seen in consultation and in the hospital at least half a dozen cases of exudate in the right ilio-ovarian region which were supposed to be due to pelvic peritonitis or cellulitis, where the high location of the exudate and the absolute freedom of the right appendages showed the exudate to be caused by appendicitis, and the opening of the abscess confirmed this diagnosis. In one case an ovarian tumor of the size of a grape fruit occupied the right hypogastric region; the pain and high temperature were supposed to be due to an inflammation of the cyst, probably from a twisted pedicle. Vaginal examination revealed nothing but a rigid vaginal vault. On opening the abdomen the ovarian cyst was found not inflamed, and after its removal an abscess was discovered between the layers of the broad ligament which had worked its way down from the right peri-appendiceal region. The appendix was found to be gangrenous.

It would be well, therefore, to bear in mind in every case of inflammatory exudate or suppuration in the right half of the female pelvis, particularly if the exudate extends up as high as, or higher than, the crest of the ilium, that the primary cause of the exudate may be an appendicitis, whether the uterine appendages of that side be inflamed or not. If the appendages are healthy, and the exudate is due to inflammation of the appendix vermiformis, the finger per vaginam will find the right vaginal vault empty, the uterus normally movable, and the exudate not reachable from below. We must not forget another possibility, however, namely, if the exudate extends much above the crest of the ilium, it and the suppuration may be of perinephritic origin, and thus retro-peritoneal.

I have recently seen, in consultation with Dr. D. Froehlich, a lady just recovering from an attack of severe pain in the right iliac region, the seventh in three years, when under anæsthesia the swollen, curled appendix could readily be felt through the abdominal wall.

I will mention, *en passant*, that occasionally an entirely unexpected fortunate termination of the case may be brought about by the bursting of the perityphlitic abscess into the bowel, whereupon the swelling in the right iliac fossa disappears and rapid recovery takes place. I have seen two such cases, in one of which the diagnosis was made and operation fixed for the following day; in the other, the swelling was in the median line, resembling the distended bladder, and exploratory aspiration was to be performed on the next morning. In both cases during the night a chamber-vessel full of stinking pus was evacuated from the bowels, the swelling disappeared, and the patient rapidly recovered.

The above instances show how the diagnosis of an appendicitis in the female may be masked, and even rendered impossible before the operation, owing to the common inflammatory diseases of the uterine appendages, even more frequently than is the case in the male. My object, however, in this short paper is rather to lead up to the occurrence of acute appendicitis at a particular time in a woman's life, which has, to my knowledge, heretofore not been mentioned, than to discuss the general subject of appendicitis in the female. I refer to the influence which inflammation of the vermiform appendix occurring during pregnancy may have on that condition and the welfare of the child.

So far as I am aware there is no case on record of appendicitis during pregnancy. There is, of course, no reason why such an inflammation should not occur at that time. But, if any such case has been reported, I have not seen it.

The rarity of the occurrence and the practical importance of thinking of its possibility, and consequently detecting its presence at an early stage, have led me to report the following case which recently came under my observation:

On the night of September 21st I was called by Dr. E. Hochheimer to see, with him, Mrs. F——, then at the end of the eighth month of her first pregnancy. I saw her at about one o'clock on the morning of September 22d, when she was in active labor, the mouth temperature being 104° F.; the pulse, 140; the face much flushed and expression anxious. The history given me by the doctor was, that on the 15th he was called to see the lady for "pain and tenderness in the lower part of the abdomen, equally severe in the median line and on both sides. This was accompanied by a rise of temperature to 101° F., and eventually to 102° F. on the fourth day. Rest in bed, light diet, and hot-water bag, together with occasional ⅛-grain doses of morphine p.r.n., were ordered. The pain gradually subsided and the temperature fell till the evening of September 20th, when it was 99° F., and she was expected to sit up on the following day. On the 21st, about 9 A.M., she was seized with atrocious pains in the pelvic region, accompanied by pronounced chill, and temperature 101.5° F., at the same time labor pains began and continued until you saw her." The foregoing account is from a letter to me written after the patient's recovery. With a large obstetrical experience and considerable acquaintance with appendicitis from personal observation, it still, very naturally, did not occur to Dr. Hochheimer to attribute the pain and fever in this case to so unexpected a cause as appendicitis, and when I saw the patient the pains were so universal over the whole lower part of the abdomen, both during and between the uterine contractions, that it was impossible to localize any one particularly painful point. About 2.30 A.M., on September 22d, a dead child was born without any artificial assistance. Desquamation of the epidermis on one leg showed that the child had been dead at least twenty-four hours. There was no difficulty in delivering the placenta, nor any post-partum hemor-

rhage, but the patient went into a semi-delirious condition, and appeared very much prostrated, so that further examination was postponed. I was at that time in great doubt as to the cause of the fever and premature delivery of a dead child, particularly as the history gave the very decided possibility of infection from scarlatina and diphtheria, to both of which diseases the patient had been exposed during the two previous weeks. The abdomen, even after delivery, was universally so tender that no reliance could be placed on the location of the pain as an aid to diagnosis. On seeing the patient again, about twelve hours later, however, decided dulness could readily be made out, together with a very acute pain on pressure in the right iliac region, the outlines of the uterus being clearly distinguishable. Per vaginam, the right vault was found free. No particular pain elsewhere in the pelvis or abdomen. Temperature now 102° F; pulse, 120.

The probability of general scarlatinal or diphtheritic infection was now excluded, and the choice lay between typhoid fever, pelvic peritonitis, and appendicitis, of which I chose the latter as the most probable. I had never heard of or seen a case of this kind during pregnancy, but could see no reason why it might not occur. And I ascribed the severe pain on the morning of the day preceding delivery to the perforation of the appendix and the discharge of pus into the peri-cæcal cellular tissue, since its discharge into the general peritoneal cavity would have been followed by general peritonitis and speedy death. At any rate the peritoneal cavity could safely be considered closed from the cavity of the abscess by adhesions. As the patient's condition was much improved, I preferred to wait until the immediate shock of the confinement had passed away, especially as rather intractable bilious vomiting came on, which depressed the patient both morally and physically. Dr. Hochheimer and I therefore decided to defer the inevitable operation for appendiceal abscess a few days, so long as the patient's condition allowed it; my own chief reasons for this postponement being the absence of any symptoms requiring immediate operation, the undoubted sealing off of the abscess cavity from the general peritoneal cavity, and the possible danger of puerperal infection from the abscess after it was opened. With the understanding that I should see the patient again, three days later, unless something unexpected occurred, I left her on September 24th, and on the 27th I found that, after nearly normal temperature on the 24th and 25th, the thermometer had again shown a rise to 102° F. on the 26th, and was 101.8° F. when I saw her. The dulness in the right iliac region was as marked as ever, although the pain was less severe. I now advised immediate operation, which was deferred until the next day in order that Dr. Willy Meyer, at the request of the family, could be present to examine the case and assist at the operation. Accordingly on the 28th, Dr. Willy Meyer concurring in the diagnosis and indication for operation in his presence, and with the assistance of Drs. Hochheimer and B. H. Wells, I opened the abscess, which was found completely closed by a thick wall of agglutinated intestines. Drainage tubes were inserted, and the after-treatment left to the care of Dr. Hochheimer. Convalescence was practically uneventful.

I need scarcely say that the death of the child was due to the high temperature, and the premature labor to the effort of the uterus to expel its dead contents. It is providential that the high temperature preceding, during, and following labor did not produce, at least, an acute endometritis, which would certainly have been the case had the cause of the fever been a general septic infection. As a preventive, an ice-bag was kept on the abdomen for several days after delivery.

I am indebted to Dr. Hochheimer not only for the opportunity of seeing the case, but also for the permission to publish it as an example to other physicians who may happen to see pregnant women with acute pain in the right iliac region accompanied by fever. I think that in a future similar case I would open the abscess at once, as soon as a reasonable probability of its existence could be settled, without reference to the pregnancy or the impending or completed delivery. I would rather take the chances of puerperal infection from the abscess than of its unexpected rupture at any moment into the peritoneal cavity.

20 West Forty-fifth Street, November 8, 1894.

A CONTRIBUTION TO THE STUDY OF THE LOCATION AND PHYSIOLOGY OF THE VISUAL CEREBRAL CENTRE.

As Shown by a Case of Monocular Amaurosis which Terminated in Complete and Permanent Recovery.[1]

By ALFRED HINDE, M.D.,

Chicago, Ill.

Senior Surgeon to the Eye and Ear Department of the Central Free Dispensary; Instructor in Diseases of the Eye and Ear, and Ophthalmologist to the Neurological Clinic of Rush Medical College, Chicago.

The sparseness of its literature, because of infrequency of occurrence, the apparent seriousness of the clinical picture, and a desire to aid in elucidating an interesting brain condition, prompt me to briefly record the following case.

S. D. T.——, female, American, single, age nineteen, school-teacher, a florid blonde, in height, five feet six and one half inches, and weighing 145 pounds, was referred to me from an adjoining State, because of total blindness of the right eye.

She detailed a good non-neurotic family history, and had had no severe personal sickness. At the age of seventeen she first menstruated scantily, and thereafter repeated the function at intervals of five weeks for the first year. During the succeeding twelve months the intermenstrual period of time had shortened, and, when the case presented itself, was only of three weeks' duration. The discharge continued to be of slight amount, lasted for three days, and its commencement was associated with pelvic distress, as well as before, during, and after the period; there was considerable nerve-storm, that presented itself in an irritable temper, with anorexia and insomnia, besides vulvar heat, and frequent micturition.

Mentally bright, industrious, and of studious bent, she said she had lately lost only slightly in weight, but greatly in bodily strength and endurance, so that the least physical exercise, or mental application, resulted in extreme exhaustion, and produced a perfect whirlwind of unrest.

When eighteen years old, and "preparing an essay," for a school examination, she was under considerable mental strain, and was seized with a condition of uncontrollable nervousness which lasted one week and necessitated her return home. During this entire time consciousness was retained, but she lost all control of herself —would laugh and cry alternately—and though realizing her ludicrous behavior, she seemed utterly unable to prevent her strange actions. With rest of brain mental quiet ensued, but during the past year minor recurrences have happened, whenever her surroundings were not to her liking, or when she again attempted further studious efforts; and the attacks were most prone to occur at the menstrual periods.

During the last week of December, 1893, she became a subject of the grippe, and soon after its onset she noticed that the vision of the right eye was failing, and it became progressively worse during the following six weeks, so that at the end of this time not only no objective vision was retained, but also perception of light was annulled; day and night were alike to this eye. She observed that her recognition of colors, and that of objects, was gradually reduced; and that for light was the latest to be perceptibly affected.

This condition of right-eye blindness had lasted for

[1] Read before the Chicago Medical Society, October 15, 1894.

about six weeks when I first saw her on March 31, 1893. At this time there was no apparent disease of motility, or structure of either eye; ophthalmoscopically both were alike and normal. The pupils had a diameter of 4 mm., were circular, and the iritic reflexes—direct and consentaneous—were actively and equally present in the two eyes. Of the left eye there was no complaint. It had more than average vision and read half of the $\frac{20}{xv}$ types of Snellen at twenty feet distance. Its color-sense was perfect. The visual field, however, was inconstant. At the commencement of the testing it was perfect throughout and of full size, but before the close of the examination it contracted slightly in its periphery, above, below, and nasally; or in those portions of the retina that are least richly supplied with nerve-elements. This decrease in size of the visual field was solely due to exhaustive effort, however, for after eye rest the field was again found to be full sized, but again contracted, as before, on continued testing. This apparent asthenopia of the peripheral nerve-tissues is of cortical origin, because, in cases where both visual fields are present, a corresponding simultaneous contraction in the untested field occurs, thus showing an exhaustion of function of central location.[1]

Covering carefully the left eye, a concentrated beam of the strongest gas light, cast within the pupillary area of the right eye, was said to be totally unseen, and surprise flashes were without conscious reflex results. The diplopia confusion tests for simulated blindness of one eye, together with Stilling's test of colored letters on a black ground viewed through colored glasses, were negative. Thus was proved the presence of the claimed right amaurosis.

The special senses of taste, smell, and hearing, and that of ordinary cutaneous sensation, were normal and alike in both halves of the body.

Digital pressure over the right supraorbital notch elicited acute pain, and deep pressure over the ovarian regions, more especially the left, produced a sickening weakness which spread throughout the body, perspiration followed and she appeared to be considerably disturbed and was very restless. She stated that the symptoms present were similar to, but less severe than those experienced at the first nervous seizure of spontaneous outset, and almost exactly like the minor attacks that occurred later. Here was present an ovarian hyperæsthesia, besides an increased sensitiveness of the superficial branches of the ophthalmic division of the right fifth nerve.

Galvanic testing developed photopsia in the left eye, with one-third the current strength required to produce the same result in the right eye. A 5-milliampère current was needed to arouse flashes of light in the right eye when first applied, but before the termination of the testing a weaker current was sufficient to start them. When compared with the left, this indicated a markedly decreased galvanic reaction of the right visual tissues, together with the probability of restoration to the normal after repeated galvanization—because of the improvement in light perception before the close of the sitting.

The right auditory nerve did not develop the Brenner reaction even with 6-milliampère currents; whereas, continued hissing tinnitus was produced in the left ear on KaCl, and slight transient hissing on AuO, the testing pole in each instance resting in the external auditory canal.

Here we had a patient in whom, up to puberty, there had been no complaint, but when that time arrived, with its disturbing nerve-storms, the cerebro-spinal system had to share with the sympathetic the existing nerve-stream—the diversion of a portion of which resulted in a hyperæsthesia of the pelvic viscera. Along came the grippe infection, reducing still further the already weakened nerve-tone, and in some indeterminate way its ptomaïnes, acting locally upon especially suitable tissues, produced the right-eye amaurosis. Thus we had present the anomalous condition of a strictly localized cerebral anæsthesia, together with an ovarian hyperæsthesia, briefly, a disarrangement of forces rather than a destructive process. The equal pupils and the absence of ophthalmoscopic signs proved eye escape. The presence of the iritic reflexes, as first pointed out by Von Graefe[1] in 1868, excluded disease as far back as the corpora quadrigemina. The motion of the irritant luminous ray was still appreciated by the right retina and so transferred, through rhodopsin-reduction and other chemical processes, to the molecules of its bacillary layer, and hence backward to be switched off at the reflex centre and returned by the third nerve-trunk, thereby excluding disease in this arc. The optic thalamus and the posterior limb of the internal capsule had escaped, for there were no evident symptoms present implicating these areas. Therefore, we had remaining only the termination of the visual path in the left occipito-angular cortex, and whatever normal stimula were conducted to this part were without conscious perception or effect. Here, we presumed, was the site of the pathological process, and the cortical nerve-cell as the part especially affected, and, because of the increasing appreciation of galvanic irritation, we considered the condition present as one of simple inhibition of function—a rare example of suppression of visual will, or visual consciousness of the left cortical centre, and that besides the psychical condition there was also some uncertain molecular change in the affected cells. Because of this interpretation, a favorable prognosis was given, and it was thought that insufficient time had elapsed for permanent changes in nutrition to result. Yet this opinion must be regarded as very venturesome because in functional inactivity, as in excessive use, there are physical changes, and if the abolition is sufficiently prolonged these may be irremovable and function remain permanently[2] abrogated. Our hopeful opinion was, moreover, founded upon the ready institution of returning function as shown during the galvanic testing.

No time-limit for available eye-use was, however, hazarded because of the well-known persistence of many cases of central neurasthenic, or hysterical, asthenopia, *i.e.*, those cases where there is present perfectly acute vision momentarily, but in whom the sight melts rapidly away upon attempted continued use, this being most probably due to insufficient nerve charging of the tissues employed, or else to an impairment of visual will.

Remembering the psychical element in our case we directed her to practise and exert her will upon all occasions where self-control was endangered; to restrain her flightiness; to avoid over-excitement and over-fatigue, both mental and bodily, and to live the details of a quiet daily life with clock-work regularity. The usual medicines for the hysterical state were given. Above all things her impressionable mind was not permitted to grasp the idea that she was the subject of any possibly irremovable physical imperfection over which she might pore. She had no womb to be tinkered for imaginary disease from my saying so, and her thoughts were steered away from this end of her anatomy.

We thus avoided the institution of that aura of melancholy that too often surrounds such cases and engulphs them, alas! impenetrably, so that all our efforts to remove their fancied and real ills are without avail.

In ordinary health the storehouse of the nerve-centre is surcharged with nerve-power, and but a small portion of it is in actual use at any one time, the remainder being retained to draw from, so that continuous work without conscious fatigue can be accomplished; but here the storage battery was only sufficient to keep charged temporarily the nerve-tissues of this brain—feeble efforts resulted in rapid exhaustion, and in the elements of the left visual centre it appeared to be entirely lacking.

To aid the restitution of a normal condition the con-

[1] Schiele: Archiv f. Augenheilk., Bd. xvi., quoted by Gowers, Diseases of the Nervous System, vol. ii., p. 147, 1893.

[2] For examples see Gowers, loc. cit., p. 165.

stant current was applied with the anode to the closed right eyelids, and the cathode to the left occiput, thus trying to bring within the range of the ascending current the entire visual path. The current strength used was only sufficient to arouse and barely maintain the sensation of photopsia in the right eye. The séances were daily and lasted about ten minutes. The applied current was started at zero, steadily increased to the exciting strength, and after continuing it at this point for the requisite time, it was gradually reduced to zero again without a break. The necessary current was always strongest at the beginning of each sitting, and before its close had to be reduced to avoid excessive photopsia with dizziness. The first treatments needed a current-strength of 5 milliampères, but as function became restored weaker and still weaker currents were sufficient. General galvanization and faradization were also resorted to.

Improvement was rapid, and after the fifth treatment, and with the left eye carefully covered, a concentrated beam of gas light suddenly flashed into the right eye, startled the patient, and she said she "felt a flickering sensation" in it, and a feeling of weakness diffused itself throughout the body. On further examination, at this time, it was ascertained that only the central portion of the retina was momentarily aroused by the strong light, the remaining parts being wholly anæsthetic. The constant current had produced irritation sufficient in the optic tissues to start the subjective light-flash, but in the feeble recognition of this strong light we had the first evidence of actual light perception—the light-sense was awakening. From this on a daily improvement in light sensitiveness of the right eye was perceptible both quantitatively in the centre of the retina as well as in increase of area of sensitive tissue. The first faint flicker of light-perception grew steadily stronger, and a weak flicker spread nasally over an increasing surface. Progressing uninterruptedly daily, the nasal limit of the retina "felt the flicker," and, latest of all, the temporal periphery became sensitive to it. By this time the central retina had advanced in sensitiveness, so that a very much weaker light was recognized as such. Of natural light, that of the morning was first seen on awakening, but after being observed for a short time it faded entirely from view. Each morning it appeared stronger and stronger, lasted longer, and finally continued all day. Large objects then began to appear, very indistinctly at first and only temporarily. In this we had the first commencement of the returning form sense—and eleven days after the beginning of the light sense. This objective vision improved rapidly, and progressively smaller and smaller objects appeared to view, and the larger ones, first seen, became more clean-cut in outline. Objective vision was also only temporary at first, but became more and more permanent with voluntary exercise and time. In forty-eight hours after the initiation of objective vision, Snellen's 200 feet type could be read at six inches; and twenty-two days still later, the vision of this right eye was $\frac{20}{-}$, and it could read the smallest type of Snellen with the near point at six and one-fourth inches. Nervous asthenopia was still a prominent symptom, however, for vision for minute objects was only transient. As the light-field had contracted on effort from periphery to centre, and, at first, had totally disappeared, so the patient said she noticed the form-field get steadily smaller and smaller, until only the type-letter looked at remained visible; and during the first days even this melted from view, all that remained was merely perception of light.

About the return of the color sense we have no exact data further than that it was gradually restored, but more rapidly than either that of light, or form, and last of all, but it finally became as acute as in the left eye.

From this observation it would seem certain that the light-sense and form sense are separate and distinct from each other. The rapid return of the color-sense interfered with our observation of it, and I regret greatly that I failed to map out the color-fields of each eye for purposes of comparison. From the fact, however, of the frequently observed cases of simple color hemianopsia, without any affection of the half fields for objects and for light, leads us to believe in a separate centre for colors also. That there are separate centres for light, form, and colors has been recently asserted by Wilbrand,[1] quoted by Gowers, who adds that for light and form "it is not yet certain that this is so," but, on account of the cases of simple color hemianopsia, he appears to agree with Wilbrand, who suggests that the color centre "is in some part of the occipital cortex in front of the apical region," and Swanzy[2] places it in "the posterior part of the superior and inferior occipito-temporal convolutions."

The observation of cases of crossed amblyopia has been frequently made. In these there is simply a reduction of the normal acuity of vision of the eye opposite to the lesion—there is still remaining a portion of the visual function for light, form, and color. Our accompanying case, however, is unique, from the fact that there was a complete suspension of the function of the right eye, and, lasting several weeks, a true amaurosis. I am not conversant with a strictly parallel case. Those that most nearly approach it are the transient monocular amauroses of purely hysterical origin.

That the area of disease was cortical there can be no doubt. That the half vision centre of the occipital lobe was not involved is equally patent, yet it usually is affected in the cortical visual cases. The few autopsies in cases of crossed amblyopia point to the angular region as the seat of disease, and Gowers adds that the field of the same side as the lesion is also represented, but to a much slighter degree than the one of the opposite side, because there is usually a "slight restriction of the field of the eye of the same side." This localization of the diseased site perfectly fits this case, and we are led to presume that the intensity of the acting bacteriological process in our case was greater, in order to completely annul function, than occurs in the ordinary cases of crossed amblyopia. If we are correct in the selection of the seat of the disease we choose at the same time the site of the light, form, and color centres, viz., the "occipito-angular" region. The phenomena of disappearance and return of these senses would seem to imply either separate centres, as Wilbrand and Gowers maintain, or that these functions are dependent upon different degrees of physiological life of a single centre.

We are here treading on purely polemical ground, however, because though numerically observers are agreed that the visual cortical centre in man occupies the occipital lobe, yet it is by no means decided that it is solely limited to this district, but that more probably it extends anteriorly into the angular region, as Ferrier first pointed out. Therefore, with doubts as to the exact limitation of the whole visual cortical centre we can readily understand the greater difficulty of the exact localization of its several parts for light, form, and color. On this account further exact observations along this line are greatly needed, and I reiterate Gowers's request that bedside examination of medical cases should be carefully carried out and the results recorded. This field is particularly one for the family physician.

Before full restoration of visual acuity of the right eye, with equal endurance for work of the two eyes, there was a period of fifty-six days of treatment. By daily exercise the time-limit for comfortable use of the right eye became steadily more and more prolonged until each eye became alike in its working power. Distinct and easy near vision lasted in either eye only twenty-three minutes, and the near point was farther off than the age of the patient would indicate—showing an impairment of accommodation. With + 1.25 D lenses the normal near point (4 inches) was restored and with these glasses

[1] Gowers, loc. cit., pp. 147 and 155, 156.

[2] Swanzy, Ed. 1892, p. 409. He also adds, p. 410: "It is also probable that the centres for the three visual perceptions of light, form, and color are distinct from each other, and that they are arranged, as it were, in layers, one over the other."

binocular vision was comfortable for a greatly prolonged time. The left eye that had read half of the $\frac{20}{xx}$ types on the first testing, now read correctly every letter of this line. This would indicate an improvement in the formsense of this eye and predicates a slight previous affection of its centre also, or may be it was due, as Gowers claims, to the influence of the diseased centre belonging to the other eye. The hysterical state appeared to be completely overcome, and with greatly improved general health she left for her home. Since then further improvement has occurred. She has resumed her occupation of teaching, and now, seventeen months since her discharge, without any signs of eye-relapse or impairment of general health, we have every reason to hope for the further permanency of the recovery.

In conclusion, I may say that the evolution of this case, as told by the patient, and its involution as noted by myself, form one of the most interesting and perfect clinical pictures that it has been my good fortune to observe.

16 Laflin Street.

THE RATIONAL TREATMENT OF DIPHTHERIA.[1]

By B. VAN D. HEDGES, M.D.,

plainfield, n. j.

The author's warrant in presenting this subject for your consideration lies in the realization that we are living in an age when men and methods are judged alike by the cold logic of practical results.

In an uninterrupted series of cases, upon which this paper is based, we have the pleasure of reporting thirty-five per cent. recoveries in cases of croup under five years of age demanding intubation, and a mortality of only six per cent. in diphtheria not requiring operative interference. These results, we believe, are directly due to methods of treatment which it shall be our pleasure to discuss this evening.

How interesting it would be, had we the time, to turn our gaze backward and note the different remedial measures in vogue from century to century, all of them empirical, because founded upon a faulty conception of its true pathology and etiology. But the mists have cleared away, the darkness has had its dawn, and in the clear, strong light of modern research we are able to positively assert that diphtheria is due to the presence of a definite specific micro-organism that can be isolated and detected in the very earliest hours of the disease, and that it is primarily and essentially a local trouble, with secondary constitutional symptoms, due to the absorptism of septic products from the local seat of lesion. Upon the proper appreciation of these two fundamental truths rests the modern rational treatment of diphtheria.

It was the author's privilege, during the past year, while resident physician at the New York Foundling Hospital, to have had under close personal observation some sixty-seven cases of genuine diphtheria, proven to be such in each instance by bacteriological examinations, conducted by Dr. Wm. H. Park, of the New York Board of Health. The assistance thus rendered us by Dr. Park in enabling us to effect prompt isolation and early treatment was most valuable. From this series as well as from the accumulated experience of others in this same institution during former years, the writer begs leave to draw the conclusions embodied in this present paper. He is indebted to the staff of attending physicians for their kind courtesy in allowing him full use of the histories.

If, then, diphtheria is a local trouble, with constitutional symptoms dependent upon the amount and virulence of the toxic ptomaïnes developed and absorbed into the system from this primary source, we must first consider the

Local Treatment.—Welsh and Abbott have shown, after long and careful investigation, that the bacilli are most abundant in the very outermost layers of the membrane, and comparatively absent in the deeper portions; hence the indication is to attain thorough local disinfection, and not necessarily the entire removal of the membrane—a radical measure which is further contra-indicated by the fact that we leave behind us a raw, bleeding surface, a most tempting field for the reinvasion of the hosts of germs that hover about.

As to the best means for obtaining local disinfection it would seem as if the neutral solution of peroxide of hydrogen was the most valuable. Williams, of Boston, claims the best results with a strong concentrated thirty to fifty volume solution. Squibb's ten volume solution, with the addition of a small amount of bicarbonate of soda to neutralize the hydrofluoric acid which is so often present, proved equally efficient, and has the advantage of being much less irritating. Bichloride of mercury has many drawbacks. To do its work well, it must be strong, yet in this strength, if swallowed, it may give rise to serious symptoms. The writer will never forget the sudden and violent death of a little one under his care, due to the accidental swallowing of three large syringefuls of a 1 to 3,000 solution. Carbolic acid and the stronger antiseptics are all open to the same objection, but in peroxide, with its powerful affinity for inorganic matter, we have a remedy which thoroughly disinfects the outer layers of the membrane, and has no bad effect upon the stomach even when swallowed in large quantities.

If the child is tractable and will allow the tongue to be depressed, either an atomizer or a hard rubber syringe can be easily used. But when the little one fights and struggles against such interference, it is best to simply irrigate through the nostrils, rather than incur the risk of provoking cardiac failure; and yet we must remember that the very reason the child is sick, the very reason we fear cardiac failure, is because of these highly toxic products of the Loeffler bacilli. The extent to which we can safely proceed in our efforts at local disinfection must always be determined by the attending physician upon the merits of each individual case.

After the throat has been irrigated and cleansed with peroxide, we would advise the application of papoid, either in the form of a powder—and for this purpose Osborn's insufflator is best—or a strong solution painted upon the parts. It is a powerful digester of membrane, acts in any medium, and is very tenacious to any surface with which it comes in contact. Acting also upon the outer layers of the membrane, it forms a rational and valuable link in our chain of treatment. It is much superior to any of the older combinations of pepsin, trypsin, and sulphur.

The local action of the tincture of the chloride of iron—both astringent and antiseptic—belongs to the realm of ancient therapeutics, and yet the writer believes it to be most beneficial and efficacious, particularly in those cases where there is a condition of profound anæmia. A most delightful vehicle for its administration is the syrup of pineapple—made fresh from the fruit and not from the worthless extracts sold in the shops. Besides making a palatable menstruum, it has a valuable proteolytic action upon the membrane itself, and is a powerful aid to stomachic digestion, as ably demonstrated by Professor Chittenden, of Yale, in a recent number of the *Journal of Physiology*.

Just a word in regard to the matter of prophylaxis while making these local applications. To guard against any bit of membrane being blown into the eye, it is well for the doctor or nurse to wear a pair of large goggles. A lovely woman, in perfect health, who lost her sight, and almost her life, through an accident contracted in this way, has made an impression upon the writer that will never be forgotten. Indeed, it is safer to wear a mask over the entire face. One of New York's well-known physicians lost his only daughter, a few years ago, through a piece of membrane coughed into his beard and retained there despite subsequent washing.

[1] Read before the Plainfield Medical Society, October 1, 1894.

In a word, then, we would advise as local treatment: 1. Thorough disinfection with peroxide solution, with spray or syringe, either through mouth or via the nostrils. 2. The local application of the tincture of the chloride of iron, administered in syrup of pineapple. 3. Insufflation or painting of papoid.

Constitutional Treatment.—Next and equally important is the constitutional treatment. We are dealing with a disease that at any moment may strike its fatal blow. The battle is not a long one, as in typhoid and the protracted fevers, but short, sharp, and decisive, hence the necessity for prompt action at the very start.

Alcohol, in the writer's opinion, pushed to the point of tolerance, is our strongest bulwark of defence. It dilates the superficial vessels, relieving internal congestion, its carbon forms a direct food to the body tissue, its action as a cardiac stimulant and tonic in conditions of profound toxæmia is unsurpassed. Next to alcohol, and almost equally valuable, is strychnine, preferably given hypodermatically through a small needle, the prick of which the child scarcely notices. Taken by mouth it is too apt to derange the stomach. As a pure heart tonic strychnine is equal, if not superior, to alcohol, and it is surprising to what an extent it can be pushed before we get the exaggeration of the deep reflexes, a point beyond which it is unwise to proceed. A child three to four years of age will often take one-thirtieth of a grain every four hours with marked benefit.

The local action of the tincture of the chloride of iron has already been mentioned. In cases of profound anæmia, a condition easily demonstrated by Gower's hæmaglobinometer, the constitutional effect is also valuable. Sometimes the stomach is intolerant of any form of iron. In such cases it should be promptly stopped, for in nourishment properly administered we have after all our most valuable aid—one which is too often overlooked in our zeal to obtain local antisepsis and cardiac stimulation. The soreness and pain that often accompanies each act of deglutition, the irritability and fretfulness of the patient, the utter loss of appetite, are all factors that conduce toward a starvation diet if the watchers are not constantly on the alert. Concentrated fluid nourishment — milk-punches, eggnogs, the expressed juice of meat, Rudisch's sarcopeptones, Mosquera's beef-jelly, panopeptone, and the different forms of nutritious broths should be our main reliance. To avoid the introduction into the stomach of an unnecessary amount of septic matter it is wise to administer the nourishment immediately after the local disinfection with peroxide.

The fever, as a rule, runs a low course and requires no treatment. A temperature above 103° F. can be controlled by cool sponging; under no circumstances by the exhibition of the coal tar antipyretics. Ipecac, quinine, turpeth mineral, veratrum viride, and the long list of drugs formerly held in high repute, it is best to altogether discard. Preserve the integrity of the stomach at all hazards, so that digestion and assimilation may be as perfect as possible. See that the child gets the proper amount of nourishment at stated intervals; guard the action of the heart by the judicious use of alcohol and strychnine, and we have the gist of our constitutional treatment.

Among the complications demanding our attention croup ranks *facile princeps*. In nineteen cases that fell under the writer's observation during the past year, bacteriological examinations have shown in each instance the presence of the Loeffler bacilli. They have been found present in over eighty per cent. of all cases examined by the New York Board of Health, so that we feel warranted in establishing an identity between the two diseases.

At the very first suggestion of any stenosis we would begin with calomel fumigations, burning fifteen or twenty grains of the powder every two hours. Whether it acts solely as a local antiseptic or constitutionally by diminishing the plasticity of the blood, and so decreasing the amount of fibrinous exudation, is a matter of minor import. We know that it does good if begun early in the disease and vigorously pushed. An umbrella, covered with a sheet and raised over the little one, makes a handy and convenient tent. A wash-bowl, two cross pieces of iron, a tin platter, and an alcohol lamp complete the outfit. To avoid the danger of salivating the nurse, a complication of no mean moment, the room should be thoroughly aired after each fumigation. It is surprising how often very severe cases will yield to this treatment alone, without resort to graver measures. The inhalation of medicated steam relieves the condition of dryness so often present, promotes expectoration, and acts as a local antiseptic. A solution of carbolic acid, eucalyptus, and turpentine—a favorite combination of J. Lewis Smith's—is valuable for this purpose. The addition of lime water is possibly of some assistance.

If every case of croup were given the benefit of this conservative method of treatment, thoroughly and conscientiously tried from the very start, there would be a marked improvement in our mortality statistics. But when the symptoms of stenosis grow steadily more and more pronounced, when the air no longer enters the lower lobes, as determined by the absence of vesicular murmur on auscultation, when there is marked intercostal and supra- and infra clavicular retraction with each inspiration, then we only hazard our patient's chances by delaying operative interference. We must choose between tracheotomy and intubation.

In cases complicated by intense œdema of the epiglottis and marked tonsillar enlargement, the older operation is much to be preferred. In simple uncomplicated cases of laryngeal stenosis it has to-day been almost entirely superseded by the more modern method, thanks to the genius and untiring industry of Dr. Joseph O'Dwyer.

I should say its main advantages were these: 1. It is a bloodless operation and entails a minimum amount of shock, the whole procedure taking less than a minute in the hands of a deft operator. 2. The consent of the parents can always be obtained when the very first indication presents itself. There is no delay until the patient's strength and vitality are both at such a low ebb that no interference avails. 3. The air, as it enters the lungs, is warmed by passing first through the natural channels. 4. There is no wound for reinfection; no scar to mar the beauty of later life. 5. In intubation the tube can usually be removed within a few days. In tracheotomy it is a matter of weeks before recovery is complete. 6. The tracheotomy tube requires untiring watchfulness day and night by trained attendants. Only the ordinary care is required in intubation.

On the other hand it has its disadvantages. Membrane may be dislodged and pushed down by the introduction of the tube, closing up its lower orifice. It happened to me once in one of my earlier cases. In such an emergency the expulsive power of the lungs is usually sufficient to eject both tube and membrane, as in this case, when the tube can be reinserted. To avoid any unpleasant sequelæ of such a complication, it is wise to leave the string attached to the tube, fastening the free end to the cheek with a small bit of adhesive plaster, and instructing nurse or parent to pull it out if the child suddenly chokes or becomes blue. Again, the operation is one which requires a great deal of manual skill and dexterity. If done in a bungling manner, extensive harm can be committed, and tracheotomy, under such circumstances is always to be preferred.

But the operation is no longer an experiment. Weighed in the balance, it has not been found wanting, and its most bitter opponents of former years are to-day its warmest advocates.

Diphtheritic conjunctivitis, either by direct contamination or extension through the lachrymal duct from the nares, is fortunately a rare complication. It demands most energetic and prompt treatment. Here, as in the throat, we found the neutral solution of peroxide most valuable. Applications were made to the membrane every half hour, followed by the cleansing solution of boracic

acid. Out of four cases three recovered. In the fourth, where there was also a complicating malignant scarlet fever, both corneas became involved, followed by extensive sloughing, before death supervened.

Diphtheritic paralysis occurred in only one instance, and yet it taught us a most valuable lesson, showing the danger of sudden cardiac failure. There was first the paralysis of soft palate, regurgitation of fluids through the nose, and partial disability in the lower limbs. All symptoms became markedly improved at the end of two weeks. Some few days later, the child, a "run around" of four years, grew excited while at play with some other convalescents in the same room. An attack of tachycardia suddenly developed, and death followed in ten minutes from the onset. A case under my care, here in Plainfield, while sitting upright on a vessel and straining over a constipated movement, died in very much the same way. Prolonged rest in the prone position, the positive interdiction of any active exercise long after convalescence seems established, and the faithful use of heart tonics, would seem to be the lesson taught us by these fatal cases.

Albuminuria was present in seventy-five per cent. of the cases, leaving an acute nephritis that proved fatal in only one instance, and that two months later. In all the others the kidney symptoms entirely disappeared. A rigorous fluid diet, giving the kidneys a minimum amount of work to perform, and small doses of sweet spirits of nitre where secretion was scanty, were the only measures used.

The treatment of broncho pneumonia, one of the most frequent of the fatal complications of croup, hardly falls within the province of this paper. Vigorous counter-irritation over the entire chest, with warm mustard poultice at the very outset, and the use of ammonium carbonate to promote expectoration, and at the same time stimulate the heart's action, gave us best results.

The new treatment by injections of antitoxin is as yet only an experiment. Endorsed by Koch and many of the most eminent men on the Continent, it is worthy of faithful and extended trial. And yet we must remember that the cure for tuberculosis came from the same source. To-day it is of doubtful diagnostic value only to the veterinary surgeon.

It may be of interest to note for a moment more, in detail, what has been accomplished in the treatment of our 67 cases. In the 17 cases of croup demanding intubation there were 6 recoveries, or thirty-five per cent. In two instances the children were brought to the hospital in a dying condition, and the operation was simply done for euthanasia, death following within a couple of hours after admission. Two others recovered entirely from their laryngeal stenosis, but died ten days later from a malignant complicating scarlet fever. This leaves us 13 cases where the treatment was given a thorough trial, with 6 recoveries, nearly fifty per cent. Among the other 49, not demanding operative interference, there were only four deaths, and one of these was due to the accidental swallowing of a poisonous dose of bichloride, leaving us a mortality of only 3, or six per cent. Including all the fatal croup cases there is a total mortality of only about twenty per cent., a most favorable ratio in comparison with that of other institutions. At the Emperor and Empress Frederick's Children's Hospital at Berlin, during the last three years, the mortality in 1,081 cases was 38.9 per cent. M. Roux, of the Children's Hospital in Paris, reports, during the last four years, 3,971 cases, with 2,029 deaths, a mortality of over fifty-one per cent. In this same institution, during the past few months, 448 cases have been treated with the antitoxin injections, with 109 deaths, or twenty-four and one-half per cent.

In conclusion, then, gentlemen, we would beg leave to offer the following suggestions as the epitome of the thoughts advanced in this paper.

Local Treatment.—1. Thorough disinfection with peroxide solution, rendered neutral with bicarbonate of soda. 2. Administration of freshly prepared pineapple juice, either alone or with the tincture of the chloride of iron, if a condition of anæmia be present. 3. Application of papoid, either by insufflation of powder or painting with strong solution.

Constitutional Treatment.—1. Alcohol given in heroic doses. 2. Hypodermatic injections of strychnine pushed until there is exaggeration of the deep reflexes. 3. Concentrated nutritious diet.

Realizing that our knowledge must be drawn from the wells of experience, and that we have with us to night those who have drunk long and deeply from this fountain source, the writer hopes that there may be a full and free expression of opinion, to the end that we may be better able in the future to cope with this dread disease.

THE NERVOUS SYMPTOMS OF PATIENTS SUFFERING FROM CHRONIC URETHRITIS.

By R. K MACALESTER, M.D.,

NEW YORK.

ASSISTANT VISITING PHYSICIAN TO THE COLUMBUS HOSPITAL; PHYSICIAN TO THE FRENCH HOSPITAL, AND NEW YORK DISPENSARIES.

The nervous disorders that are often connected with chronic urethritis may be classed under the acquired functional nervous diseases, although they may sometimes attain such a degree of severity as to resemble the psychoses, and often lead us to consider them as something more serious than mere functional disturbances. They present certain characteristics and peculiarities, which, in connection with the underlying disorder, form, on the whole, quite a typical group of symptoms.

It is a well-established fact that irritation and disease of the genito-urinary organs are frequently the cause of manifold nervous disturbances, familiar to all practitioners, who, however, often fail to recognize the connection. Beard,[1] in his classical work on neurasthenia, writes: "Disorders of the genital apparatus are continually exciting disease in remote organs. In men a little prostatitis, or urethral or preputial irritation, not only phimosis, but even elongation, with secretion of smegma, are constantly the sole and demonstrable origin of hypochondriasis, dyspepsia, and other nervous symptoms."

Furthermore, I have but to allude to the nervous disorders coexisting with or following sexual excesses, masturbation, interrupted coitus, operations, or manipulations on the urethra, etc.

Therefore it is not surprising that a person, knowing that he has a gleet, should succumb to some nervous malady, the more so when, by allowing his mind to constantly dwell upon this fact, it should become a source of worry and all kinds of imaginary troubles. Indeed, the nervous disturbances may progress to such an extent and prominence as to become the predominant feature of the case, and the urethral disease is overlooked or regarded as one of the imaginary troubles. This latter is to be all the more regretted, inasmuch as when the true nature of the disease is recognized, the sufferer may either be completely cured by an appropriate treatment, or at least greatly improved.

Having had occasion to observe quite a large number of cases both here and in Europe, I think that the nervous complications are more frequent in this country; at least they are more conspicuous, and oftener attain a higher degree of severity. In fact it is, in my experience in this country, rather exceptional to find a person who, being aware of having a gleet for some length of time, does not betray some marked nervous symptoms, while in Europe this is very common, but by no means the rule.

I have at my disposal the records of numerous cases bearing upon the subject under consideration, but will content myself with detailing the histories of three, that

[1] A Practical Treatise on Nervous Exhaustion. New York, 1880.

will suffice to illustrate the more important features of the clinical picture.

Case I.[1]—M. D——, twenty-five years of age, sculptor, of Roumanian parentage, single. His mother always suffered from general nervousness. He was always strong and healthy previous to the gonorrhœal troubles. Is temperate in the use of tobacco and alcoholics, drinks a small amount of red wine daily; is, on the whole, a man of regular habits and in moderately easy circumstances. Denies ever having practised masturbation. No history of syphilis. Has had eight attacks of acute gonorrhœa in all, or, as he states, several of these may have been acute recurrences of the chronic trouble. The first he acquired at the age of sixteen, and the last about one year ago, the acute stage of which lasted for two months; then it subsided, and left him with the gleet. Had been treated by several doctors, who passed sounds, made local applications to the urethra, etc., without obtaining any evident amelioration.

This state of affairs has been a source of great worry, anxiety, and discouragement to him, and he has been getting more and more nervous. He feels weak, despondent, at times drowsy, has to frequently quit his work, feeling exhausted, and lie down to rest in daytime; at night has difficulty in falling to sleep, and when asleep is restless, starts and awakens often; on arising in the morning feels as if he "had been on a spree the night before," which discomfort is not a little added to by his being day after day confronted by his *goutte militaire*, which is the first thing he thinks of, and looks for in the morning. Patient has become irritable, very excitable, sensitive, and depressed in spirits; lost his interest in people and things in general. It is with reluctance and difficulty that he can accomplish any work at all. Has been obliged to give up two or three "jobs" on account of his inability to concentrate his thoughts and attention on his work; is overcome with a feeling of exhaustion and uneasiness, so that he cannot force himself to continue. Is very fond of changes. His sole desire and ambition is to get cured of the terrible disease, as he terms it, that robs him of his peace of mind, health, and all enjoyment of life; and if this cannot be effected, would rather die. He has a heavy feeling and dizziness in the head, and frequent headaches; complains of poor memory; paræsthesiæ in the form of numbness of the extremities, and creeping sensations along the inner surface of the thighs. His hands and feet often feel cool, while he frequently experiences flashes of heat to the head, and cold feelings in the back. He thinks the disease "has gone to his eyes," as things often look blurred. Complains of dyspepsia, which troubles him the most when his nervous symptoms reach their climax. The symptoms referable to the genital organs are: A continuous feeling of "weakness," a prickling sensation and sometimes numbness along and around the urethra; has lost his sexual desire to a great extent; his sexual potency is, however, fair; has involuntary and premature emissions, and when he attempts a second coitus it is either very long, or impossible. Worries greatly over loss of semen, which he notices after an erection or defecation. Has a feeling in the legs opposite the scrotum as if there was a hollow place in his flesh, which sometimes feels numb, at others over sensitive.

Status præsens, July 27, 1893.—Well nourished, strong and robust looking, skin and mucous membrane pale. Organs of the special senses normal. Sways slightly on standing with closed eyes. Fine tremor in tongue and hands. Superficial and deep reflexes lively. No objective sensory disturbances, with the exception that the spines of the dorsal vertebræ are slightly hyperæsthetic. Extremities feel cool, hands clammy. The physical examination of the thoracic and abdominal organs reveals nothing abnormal. The urine contains no albumin or sugar, but many coarse fibrous, and fine mucous threads; it is clear, and specific gravity 1.016. With the test of the two glasses, both portions of the morning urine contain threads. Sounds could be passed up to 26 (Charrière), a resistance was felt in the pars bulbosa. Examination of the prostate gland, per rectum, showed this organ to be enlarged to about twice its normal size, somewhat increased in consistence, and not painful on pressure. The microscopical examination of the "seminal loss" showed it to be composed of secretion from the prostate, mixed with a small amount of pus; there were no spermatozoa present, but I was able to demonstrate gonococci.

Treatment.—Begun on July 27, 1893. Gradual dilatation of the stricture, local applications of solutions of argent. nitric. with the Ultzmann syringe, cool sitz-baths, and 0.5 natr. salicyl. t.i.d. were ordered for the genito-urinary trouble. For the nervous disorders I prescribed a general dietetic hygienic régime, a moderate amount of exercise in the fresh air, cold spongings in the morning, abstinence from Baccho et Venere, etc., and ordered 1.0 natr. bromid. to be taken in the evening.

Under this treatment patient improved rapidly. On August 15, 1893, his stricture had been dilated up to forty-two; a five per cent. nitrate of silver solution was injected; the drop in the morning had diminished in size, and become nearly transparent; the urine contained but very few fine threads, and the nervous symptoms had markedly improved. The treatment was continued, and on September 25th the patient was entirely free from any urethral discharge; the examination of the urine revealed no evidence of disease, the threads had disappeared, and he told me that he could no more find "the morning drop," and did not lose any more semen. His nervous troubles had left him to a great extent, although he was still restless, fidgety, and anxious; but on the whole he was greatly benefited, took more interest in his work and people, felt encouraged, more hopeful, and contented with his lot. Had he continued to abstain from Baccho et Venere, and kept in the path of virtue, I am confident that he would have made a complete recovery in every respect. But alas! Two months later I learned that he had contracted a fresh gonorrhœa just before he was about to marry, and that he was again nearly mad with despondency and despair.

(The treatment of the chronic urethritis with strictures, employed in all these cases, is that which is recommended by Dr. E. Finger, of Vienna, for old cases, and which I learned in his clinic. Judging from his results and my own, I cannot speak too highly of this method of treatment as being most reliable and efficient. In brief it is as follows: If possible, the patient comes daily for treatment; if not, every two or three days. The strictures are gradually dilated by means of the Oberländer dilator, until the full dilatability of the normal urethra is reached. The gradual dilatation consists in increasing the calibre of the dilator by two numbers of the scale at every consecutive séance. The dilatations alternate with applications of argent. nitr. to the entire length of the urethra by means of the Ultzmann syringe, beginning with a half per cent. solution, and gradually increasing to a five per cent., or even ten per cent., solution. If the disease gets sluggish, the argent. nitr. solution may be changed for one of cupr. sulph., which can be used in a ten or twenty per cent. solution if necessary. After this has been used for a while, the argent. nitr. solutions are resumed, and often with a surprisingly good result. If the increasing strength of the applications and the dilatations prove too irritable, it is advisable to either not increase them, or discontinue them entirely, until they are tolerated again. The golden rule, impressed upon us by Finger, was: Never employ any method that will irritate the urethra, and set up acute symptoms or complications. He prefers this plan of treatment to the local applications through the endoscope, because the introduction of this instrument is irritative to the urethra. During the treatment the patient may take some astringent or antiseptic internally, such as acid, or

[1] Cases I. and III. are taken, with Dr. Ramon Guitéras' (chief of clinic) kind permission, from my records in his clinic at the French Hospital, of which I am in charge. Case II. was my private patient.

natr. salicyl., which is also a good prophylactic against cystitis. If the treatment fails to be efficacious in the course of several weeks, it is advisable to discontinue it, give the patient a rest for about a fortnight, and then resume it. The advantages of the Oberländer dilator (or a similar instrument) are obvious if we consider that the dilatability of the urethra *de norma* is: In the external orifice, 24, in the pars cavernosa, 30 to 35, and in the pars bulbosa 40 to 45 (Charrière). The Oberländer dilator is so constructed as to dilate these different portions correspondingly to their normal relations. Therefore the use of ordinary sounds that dilate the urethra equally in all parts is quite irrational. By this means a sufficient degree of dilatation of the bulbus, for instance, cannot be effected, which, *nota bene*, is the most frequent seat of strictures, and the patient may be treated for any length of time without being radically cured.)

The above history gives a fair example of a patient who is a familiar bugbear to most of us. When we have to treat such a subject, we find him most exacting, changeable, often irritable, taking pleasure in disconcerting and tormenting his adviser, as if he were bent upon making others share his misery. It is no wonder that such a patient wanders from doctor to doctor, or from dispensary to dispensary, telling everyone that nobody understands his case. Beginning in a general medical department, as a rule, he in turn passes to the surgical and genito urinary surgical clinic, and finally, if nobody succeeds in curing him, he is, in despair, shoved on to the neurologist.

Notwithstanding that such an individual is inclined to exaggerate his ailments, and taxes our patience to the utmost, still he is an unfortunate being, for his mental sufferings are doubtless great. He is a deserving object for our pity as well as our skill.

When such a patient presents himself for treatment, I impress upon him the importance of energetically following out the prescribed plan, and the necessity of regular attendance. I emphasize the fact that the treatment will last for two or three months. I exact a promise that, once begun, he will continue for that length of time. With what success our endeavors will be crowned, under the circumstances, depends as much upon the patient's perseverance as upon our making a correct diagnosis of the underlying urethral disorders, and applying the appropriate treatment.

Case II.—H. B——, forty-two years of age, single, Custom House employee, born in the United States; father, German; mother, English. The family history is good. Patient is a man of regular habits, comfortably situated; being the only son, his mother has perhaps spoiled him; was always inclined to be nervous; does not indulge in the alcohol, or tobacco habit; no rheumatic history. Practised masturbation, beginning at the time of puberty, for several years. Had gonorrhœa and chancroids at the age of seventeen, and the former disease again about six years ago; the acute symptoms of which soon abated under appropriate treatment, but ever since he notices in the morning that the meatus is either stuck together, or that there is a drop of yellowish or white fluid in it. After defecation, or overhearing the conversation of his colleagues, which in their leisure hours is wont to turn upon the fair sex, he either has an involuntary emission, or observes a little thick, sticky, and clear discharge from the urethra. He has nocturnal emissions every two or three weeks. On questioning him he gives an exquisite history of cerebro spinal neurasthenia, even to the minutest details, the enumeration of which, in order to avoid repetition, will be omitted. In addition to the general symptoms he presents others which are referable to the affected parts, such as itching, tingling sensations in the penis and scrotum, twitchings, and pains that start in the genital organs, radiate to the lower abdominal region, where they at times become quite intense and are increased by urinating, sexual excitement, fatigue, or micturition. He has other paræsthesiæ of these parts in the form of hyperæsthesia, and continuous irritability of the urethra. He complains of numbness of the whole genito-urinary tract, and keeps repeating: "Doctor, my privates and bladder feel as if they were dead; all the life has gone out of them; they have been weakened by self-abuse, and I don't think there is any help for me." Questioned as to his sexual potency, he answers, that as he "takes no more stock in girls," he is unable to say how this is, but that he otherwise has only very weak erections, even when the nocturnal emissions occur; he denies experiencing any sexual desire; penis always feels cold.

Patient has other marked hypochondriacal ideas and fears. Besides reproaching himself incessantly for his past sins, he pours forth a host of new complaints and ailments at every séance, as for instance: "Doctor, I have to raise such a lot of thick phlegm from my stomach that I am sure it must be diseased." On his producing this one day, I found it to be simply a minute quantity of mucous secretion, probably from the pharynx. He also worries over the smegma on the glans penis. Having heard of paresis, he is sure he is developing it; he is sure something dreadful is going to happen to end his unfortunate existence, etc. He is in constant fear of catching cold; carries a cap in his pocket which he puts on immediately on taking off his hat; in summer he almost always has an overcoat at hand, and when the weather is at all cool, he fastens his coat tight around the chest, and the sleeves around the wrists with safety-pins, for fear the cold air might get in. He eats little, although his appetite is fair, fearing it might be injurious; drinks only a small quantity of liquids, fearing to have to urinate oftener and thus increase the "funny painful feelings" in the genitals and abdomen. Some of his symptoms approach melancholia: he is extremely sensitive; imagines that everybody ridicules and dislikes him; at times secludes himself at every possible occasion, sits for hours in the same chair, and mopes over his past sins and sad condition; has morbid fears of various descriptions; according to his mother, he has had hallucinations of hearing several times, but this is quite uncertain.

Last spring he went to the Catskills to spend the summer, but he could not stand it longer than three weeks, because some friends (?) there ridiculed him and his eccentricities, and insinuated that he was fit for an asylum. He is very exacting and inquisitive with his physicians; at every visit wishes to be examined from head to foot, and when told afterward that there is no cause for so much worry, he feels relieved for the moment. He has been discharged by several doctors, rather abruptly, as a hopeless "crank" and undesirable patient, after they had tried to cure him by all manners and means.

Status præsens.—Short, rather delicate looking, fairly well nourished, weighs 110 pounds; the head looks too large for the body, but shows no deformities; the skin and mucous membranes are markedly anæmic; temporal veins prominent; arteries normal; pulse regular, soft, sixty-eight beats per minute. The physical examination is negative. On standing with closed eyes, he feels dizzy, and sways perceptibly. The deep reflexes are exaggerated. Over the middle dorsal vertebræ there is a hyperæsthetic area. No further sensory or motor disturbances. Eyes normal, the sense of smell is very acute, hearing normal. The urine is clear, slightly acid, of high color, specific gravity, 1.021; no albumin or sugar; on standing a thick sediment consisting of phosphates is deposited. Both the first and second portion of the morning urine contain finer mucous, and coarser threads. In the latter the gonococcus is present in considerable numbers. The measurement of the urethra shows two wide strictures: one in the middle of the pars pendula, and one in the pars bulbosa, of 25 and 29 calibre, respectively. The prostate gland is about the size of an English walnut, and indurated. The palpation of this organ is extremely disagreeable to the patient,—as is also any manipulation upon the urethra—for it puts him in a state of excessive nervousness and excitement.

Diagnosis.—Urethritis chronica anterior et posterior, strictures; prostatitis chronica levis, prostatorrhœa, phosphaturia; anæmia, neurasthenia gravis (hypochondriasis?).

Treatment.—Mr. B—— was sent to me on August 28, 1893. After examining him thoroughly and detecting the urethral disorder, I expressed the opinion that this was probably the main seat of his troubles, and if it could be cured the other symptoms would either disappear entirely, or be greatly ameliorated. At this statement he seemed to be satisfied and relieved, and consented to undergo the treatment I proposed. The treatment, directed against the genito-urinary disorders, was the same as in the previous case. Iron, arsenic, and strychnine were ordered as a tonic for his anæmia, and his bowels regulated by laxatives. I tried to induce him to drink more liquids in the forms of mineral waters, milk, weak tea, etc., in order to dilute the urine, which was always small in amount and concentrated; but this advice, I fear, was scarcely heeded, owing to the subjective discomfort he experienced when having to urinate frequently.

As the patient had already been "saturated" with bromides, anodynes, and narcotics by his former medical advisers, without achieving any favorable results, I refrained from any medicinal treatment of his nervous symptoms, and put him on a general hygienic régime (cool salt-water baths, a cold sponge bath mornings and evenings, a moderate amount of out-door exercise, massage, a cold compress on his head if wakeful at night, etc.), and general faradization. I also tried the mental treatment, encouraging and sympathizing with him.

This plan of treatment was followed out scrupulously and methodically by both patient and physician, and the former improved most satisfactorily. In due time his gonorrhœa was cured and his strictures dilated to the full extent of the normal urethra, which, owing to his extreme sensitiveness and nervousness, was no easy task. On November 5, 1893, I had noted: No more evidence of strictures, gleet cured, both portions of morning urine clear, no threads, or other evidence of urethritis; patient notices no more discharge of any description.

His nutrition, color, and general health had also greatly improved, he gained weight and strength steadily.

In regard to his nervous symptoms, the progress was slower, although he worried less over his genito-urinary trouble, was more hopeful, took more interest in others and his business, could sleep better, and felt encouraged by the result of the treatment; still he had a number of paræsthesiæ and morbid ideas left that he could not overcome; he still mourned over his past sins, especially over masturbation, "which must be the cause of all his troubles."

On November 11th he came to my office, complaining of rheumatic pains in the lumbar region. I suggested giving him static electricity, and the next day directed him to come to Dr. Dana's clinic at the Post-Graduate for that purpose. But, "the big machine and the sparks" proved too formidable for him, especially as the latter were—at one of my colleagues' suggestion—applied rather intensely on the nape of the neck for the purpose of alleviating his neurasthenic symptoms. The patient decided to discontinue treatment for a season, and has not returned since.

This case is very similar to the preceding; the nervous symptoms are, however, of a severer type. They show a decided tendency to hypochondriasis, or even melancholia. It will be observed that the victim of these afflictions had practised masturbation for several years. A combination of the consciousness of this failing with that of the urethral affections is most pernicious, especially in a neuropathic subject, and, as I have frequently observed, is prone to give rise to a grave group of nervous and mental symptoms. The above described mental and physical wreck is the result of such a combination.

The following history is interesting, inasmuch as the subject is a negro. He is a very intelligent, bright, and reliable man; the clearness and manner in which he relates his history, especially in reference to his nervous troubles, is quite remarkable and unique.

Case III.—C. W. P——, thirty five years of age, colored; married; works in a marble shop. He gives the following history: No syphilis. Acute gonorrhœa four years ago; has never been entirely free from the urethral discharge since. For the last two years pains and abnormal sensations referred to the region of the bladder; thinks he must have stone in the bladder, because his brother had. Itching in the back part of the urethra. Is obliged to urinate every one or two hours in daytime, and at night gets up two or three times for that purpose. States that urine is sometimes cloudy and smells bad. No discharge lately, but "the lips" are invariably glued together after sleeping for several hours. He has been treated for the urethral disorder off and on for two years, the meatus was slit, and sounds passed up to No. 30, but a radical cure was not effected.

Some of the nervous symptoms of which he complains and details in his quaint way are: A heavy, stupid, and empty feeling in the head; forgetfulness; general weariness and weakness, especially in the back, so that it is harder, and more tedious for him to get through his work. He formerly saw the bright side of things, but is now down-hearted and despondent, worrying continuously over his health generally, and especially over his "bladder trouble," which nobody seems able to cure. Poor sleep; in the morning gets up feeling unrefreshed and but little fitted to begin the day's labor. "Funny, darting feelings, starting in the neck of the bladder and extending all over the privates and stomach." The sexual functions are weak; has very little desire in this direction.

Status præsens (December 15, 1893).—Well-nourished, strong, robust man; color of mucous membrane good; no evidence of syphilis; arteries and pulse normal.

Examination.—Deep and superficial reflexes lively; sways considerably on standing with closed eyes; fine tremor in hands on extension; otherwise no objective signs of motor or sensory disturbances. The physical examination is negative. The urine is neutral, cloudy, contains threads, flakes, and a small amount of pus in both portions, no albumin or sugar. The examination of the urethra reveals a wide stricture in the bulbus, of 32 calibre. Prostate slightly enlarged.

Diagnosis.—Urethritis chron. ant. et post.; cystitis chronica (?); stricture of pars bulbosa. Neurasthenia of mild type.

Treatment.—The usual method described above was employed for the chronic urethritis with an astoundingly good result. As he also had some dyspeptic symptoms I put him on rhubarb, soda, and tincture of nux vomica, and gave him some general directions in regard to diet and hygiene.

He progressed steadily and markedly; in less than three months the genito-urinary trouble was radically cured and the nervous symptoms had entirely disappeared. This period might have been shorter, had the patient been able to come for treatment oftener than twice a week. On taking leave of me he seemed very happy, and said: "Doctor, I feel like a new man, I feel stronger and I can work first-rate again. That 'stretcher' (dilator) you have is a wonderful instrument; it has cured me entirely." Probably the psychical influence of the "wonderful instrument" aided greatly in the cure of his nervous troubles!

Remarks.—I think that all the nervous manifestations enumerated in the foregoing histories can unquestionably be classified in the great symptom-complex of neurasthenia. Morbid fears and other marked hypochondriacal symptoms are very common in neurasthenia; even be they of so severe a type as described in Case II., they fall nevertheless within its limits. The same applies to the symptoms of a tendency to melancholia.

Following Dana,[1] this case comes under the classification: "The Modified Types," "Degenerative Neurasthenia," and Dana rightly says: "This type of neurasthenia is often described as 'sexual,' or as 'primary.' It is really a manifestation of neurotic degeneracy, and may be looked upon as an abortive form of paranoia."

Considering how many sufferers from chronic urethritis are afflicted with nervous disorders, it would seem reasonable to attribute to the former an important part in the etiology of the latter. Whether the urethritis, *per se*, is the causative factor, or whether it is the mental effect of this, is difficult to determine, for there are many men suffering from gleet for years who are entirely free from any nervous disturbances until they become aware of its existence. The knowledge of this immediately brings on nervous prostration. In my estimation the psychical factor is the more powerful of the two.

On the other hand, there are men afflicted with chronic urethritis and neurasthenia, notwithstanding their ignorance of the former's existence. But if we consider how wide-spread both of these diseases are, it is not surprising that we should find both of them co-existing independently in the same individual. Nobody will deny that many of our more enlightened city inhabitants are neurasthenic, and nobody who will take the trouble to inspect the urine of his male patients will fail to be convinced of the frequency of chronic urethritis. Moreover, evidence of this can be procured indirectly by other means, such as Noeggerrath's statistics.

All authors agree in attributing to genito-urinary disorders a more or less important part in the etiology of neurasthenia. Beard considers involuntary emissions, partial or complete impotence, and irritability of the prostatic urethra as mere accompanying symptoms of increased irritability. But one must be rather sceptical in regard to such conditions, for, as I have observed, they, as well as many others, generally turn out to be the manifestations, or consequences of chronic urethritis which is the primary cause.

Finally, we have the question before us: Does chronic urethritis invariably give rise to nervous manifestations? No, I think not. I have seen men (in Europe) with normal nervous systems, who showed no evidence of neurotic disorders notwithstanding the knowledge and long duration of a chronic urethritis. Therefore it is necessary to recur to a third etiological factor, viz., a neuropathic constitution or predisposition. Dana, under neurasthenia, puts it in a very plausible way. He refers to prostatic and urethral disorders as reflex causes of neurasthenia, but presupposes a neuropathic constitution. My own observations go to corroborate this view, to which I would, however, add the psychical factor, viz., the patient's knowledge of the urethral disease, which factor is, in my opinion, the most active. Thus, the important etiological factors of the cases under consideration are: the neuropathic constitution or predisposition as predisposing, the chronic urethritis, and the patient's knowledge of its existence, as exciting causes.

In the *symptomatology* of all cases of neurasthenia connected with chronic urethritis, there is a great multiplicity and diversity of the manifestations in one sense, but in the other a striking monotony. Common to them all are the more localized nervous symptoms, directly referable to the genito-urinary apparatus, which clearly point to these parts as the seat of the disease, causing the bearer no end of worry, anxiety, and discomfort, and giving the hypochondriacal tone so prominent in these cases. These symptoms have been sufficiently enumerated and described in the foregoing histories.

The symptoms of Case I. are a little above the average degree of severity, though they are of every-day occurrence. The patient was a healthy, steady-going, reliable, and thrifty artist previous to the onset of his gleet, but afterward he was almost entirely incapacitated for any mental or physical work, unreliable, changeable, and more or less an invalid.

[1] Text-book of Nervous Diseases, New York, 1893.

Case II. shows to what extent the neurotic disturbances may progress. Here we have a perfect mental and physical wreck before us, with marked hypochondriacal symptoms and a tone of melancholia. It will be remembered that this patient had a neuropathic constitution, to begin with, and had practised masturbation for several years, which factors must not be neglected in accounting for the severity of the case.

Case III., presenting no neuropathic history and being a negro—the male sex of which race, I believe, is not so much inclined to functional nervous disorders—it is not surprising that his symptoms should be of a milder type and the course a more favorable one.

From these considerations it would appear that the severity of the neuropathic manifestations depended upon the power of resistance of the bearer's nervous system, which is the case in all functional nervous diseases.

The chief features of the cases under consideration may be summarized as follows: A history of gonorrhœic infection. Symptoms of general cerebro-spinal neurasthenia. Nervous disturbances directly referable to the genito-urinary apparatus. Prominence of the hypochondriacal symptoms, and a tendency to melancholia.

The *prognosis* of the milder and average types of neurasthenia is, as in neurasthenia from other causes, favorable; even more so, for here the seat of the trouble can be reached, which, if cured, and the physical factor being, also, thereby removed, the patient will generally make a complete recovery. If the neurotic trouble is more deeply seated and of a degenerative type, and there are other factors concurring with the urethral disorder (such as a neuropathic constitution, the consciousness of masturbation, or other previous or present vices), then their prospects of complete recovery are doubtful, although the patient may greatly improve. The troubles arising directly from the urethral affection will disappear under appropriate treatment; the other neurotic disturbances may also improve markedly, and the patient be benefited in every sense; but his morbid thoughts and imagination will take a fresh direction, new fears, worries, troubles, etc., will develop, and he will probably remain a neurasthenic subject, if nothing worse, for the rest of his days.

The plan of *treatment* of the chronic urethritis has been described in the foregoing, and some stress laid upon it, because the favorable results observed in Dr. Finger's clinic, and in my own experience, prompt me to consider it a great advance in modern science.

In the milder cases of nervous disorders, nothing more than general directions in regard to hygiene, diet, and mode of living are required. In severer cases it is advisable to resort to some sedative remedies, for the treatment of the chronic urethritis, especially in the beginning, often aggravates the nervous troubles for a while. Then the bromides are very serviceable: Natr. bromid., 1.0 in the evening, or if necessary, 0.75 t.i.d. Static electricity, or general faradization, applied cautiously, are useful if the patient can "stand it." It is also advisable to prescribe tonics, alone, or in combination with antidyspeptic remedies, if in any way indicated. The following improvement of the patient's nutrition and color, in connection with the progress achieved in the treatment of the urethral disorder, will add greatly to the psychical effect of the "cure," endowing the sufferer with more courage and hope. This latter factor is of no minor importance, for his perseverance in continuing the treatment depends to a great extent upon an appreciable improvement. Furthermore, the mental training of the patient is imperative; he must follow out the prescribed directions implicitly, and be prevailed upon to entirely change his mode of life. An appreciation of the subsequent improvement will be more than sufficient to deter him from falling back into his former habits.

Last, but not least, the physician must show much kindness, consideration, patience, and interest for the sufferer. This class of patients like nothing better than to be carefully and repeatedly examined, assured that there is no

grave disorder, and that they are progressing satisfactorily. They always feel grateful for such attentions at the hands of the doctor, and even if the effect be but psychical and momentary, it is, nevertheless, deserving of being practised.

23 West Fifty-third Street.

NOTES ON APPENDICITIS.[1]

By EGBERT H. GRANDIN, M.D.,

new york.

President of the Medical Society of the County of New York; Gynecologist to the French Hospital, etc.

When invited to read a paper before the Queens County Medical Society, I accepted the honor with all the more pleasure because it enabled me to introduce for discussion a topic which, to judge from the number of instances I have seen in consultation in this neighborhood, will elicit most valuable information from your Fellows. Notwithstanding the relatively large experience which it has fallen to my lot to have with appendicitis in the rôle of consultant, I am about as much in the dark in regard to the symptomatology and treatment as I was when the surgery of to-day replaced the medicine of yesterday in the management of this affection. It is to the general practitioner, of which this body is largely composed, that I look for the elucidation of a number of obscure points, and I feel that my visit here will result in the personal acquisition of greater information that I can give you. The remarks I have to make are suggestive, although founded on much experience.

I have come to the conclusion that there is no absolute group of symptoms which points to appendicitis, and that there is an absolute group of symptoms which calls for surgical interference. I do not believe that every case of appendicitis calls for the knife, even though palliative treatment never effects cure in an anatomical sense. I am firmly convinced that a trilogy of symptoms, which I proceed to dwell upon, stamps a type of the disease —called infectious appendicitis—as demanding surgery as immediate as possible.

A constant symptom present in appendicitis is pain. This pain at the outset may be located at any point of the abdomen; it is often sub umbilical; it is frequently diffuse abdominal. It is described as being acute and agonizing, and sooner or later the maximum seat of intensity lies over the ileo-cæcal valve. This pain, however, is not alone of diagnostic value, since it is an associate of other intra-abdominal lesions besides appendicitis. Its localization awakens our suspicion that the cause is near the cæcum; its presence, however, never certifies absolutely to appendicitis. A mere impaction at the cæcum may give as much pain. The decrease in pain, or its disappearance, on the other hand, may, as I will show later, be a bad omen.

High thermometric range, associated with great abdominal pain, both factors being continuous, is rather characteristic of instances which recover symptomatically without operation than the reverse. Frequently these instances terminate in local abscess, on the incision of which the symptoms subside. It is the instances where, notwithstanding the temperature subsides, the pulse yet remains rapid, which always should cause anxiety, and which nearly uniformly demand surgical interference. The fall in temperature, the subsidence of the pain, the relatively high pulse-rate, point to beginning septic infection, and if the focus be not removed general peritonitis sets in of a type uniformly fatal. Decrease or absence of pain, and flat instead of tympanitic abdomen, mean generally perforation of the septic appendix. The aim of surgery in this region is to forestall perforation and the resulting peritonitis. The gist of my argument, then, is that I am more alarmed by the subacute nature of the symptoms thirty-six hours or so after the initial attack than I am by the maintenance of acute symptoms. In the latter event apparent cure will often follow on purely medical measures; in the former instance incision, as soon as may be, frequently offers the sole hope of saving life.

It is above all important, in cases where the diagnosis of appendicitis is suggested by the symptoms, to avoid masking these latter through the administration of opium. If the stomach be tolerant, it is desirable to secure free catharsis in the early stage, since a loaded cæcum not alone may simulate appendicitis but intensify its symptomatology. High rectal enemata of ox-gall, turpentine, glycerin, and saturated solution of Epsom salts will frequently be of service while awaiting the action of laxatives given by the mouth. Hypodermatic injections of a saturated solution of sulphate of magnesium, given deep in the nates (3 j. doses half hourly) have also repeatedly in my hands had a purgative action. For the relief of the pain the ice bag answers better than the poultice, being a local anæsthetic, and at the same time lowering the temperature without affecting the heart, as all the coal-tar series of antipyretics may. If, notwithstanding these remedial measures, at the end of thirty-six hours the symptoms show no signs of abating, or else the abatement is in the unfavorable direction I have noted above (fall in temperature, relatively rapid pulse, flattening belly), then, as the result of my experience, I feel that the time has come for surgery. If we wait for the formation of a distinct tumor, general sepsis may set in before operation can be performed; if we wait until there is evidence of beginning perforation, operation will prove nugatory.

In my operative experience, which includes thirty-two cases, I have met every form of complication—the gangrenous appendix, the appendix full of pus on the point of rupture, the appendix which had perforated into the general peritoneal cavity causing purulent peritonitis, the appendix simply congested and denuded of its peritoneal coating (the so-called catarrhal appendix), the perityphlitic abscess. In this neighborhood I have seen 18 cases of appendicitis; of this number I operated upon 10, with a loss of 3. In 1 case operation was refused, and the patient died within forty hours. The remaining 7 cases recovered without operation. The 3 fatal cases following operation were all instances of general peritonitis, a type which yields an almost absolute death-rate.

Through the courtesy of your colleague, Dr. R. F. McFarlane, I am able to show you to-day three patients on whom I have recently operated for appendicitis. The little girl's initial attack dated back about forty hours. The rapid pulse, the relatively low temperature, the diminishing pain pointed to perforation or to beginning septic infection. Operation was advised and accepted. On section I found a gangrenous, perforated appendix and active peritonitis. Her recovery is due to the unremitting watchfulness of Dr. McFarlane. As a rule, instances of this nature die, no matter what the treatment. In a case of the like nature, seen recently in New York City, with Drs. Smith and Warner, operation was performed in the presence of a temperature of 99° F., pulse of 120, flat belly, and no pain. The same condition of affairs was found; the child lived ten days, finally succumbing to septic infection, characterized chiefly by absolute intestinal paresis.

In the little boy the symptoms were more acute than in the girl. The facies, however, had that anxious, drawn, ashy look suggestive of septicæmia. I opened in the usual locality; behind the cæcum I found the firmly adherent appendix yielding fluctuation. There was no peritonitis, and to avoid infection of the cavity I opened behind, found a posterior rupture with pus, and counter-drained after asepticizing the cavity posteriorly.

This man was operated upon in the quiescent stage. He had had repeated attacks and had grown weary of the interference with his business. I found omentum as thick as the thumb, which I tied off; underneath this an adherent cæcum which I separated; below this the ad-

[1] Read by invitation at the Semi-annual Meeting of the Medical Society of the County of Queens, October 30, 1894.

herent, convoluted appendix, which I removed. I drained him for thirty-six hours, and then sewed him up carefully. Contrary to the advice of Dr. McFarlane, he left his bed in twelve days and refused to wear a truss. His contumacy resulted in this hernia.

Here are a half dozen appendices, which I present as samples of the kind I have removed. You notice that they are large and distorted, perforated at one or more places, denuded of epithelium. All of these, and such has been the necessity I have ever been under, have required a liberal incision in order to free and remove them with safety to the patient and without unnecessarily infecting the peritoneal cavity. In the majority of my operations I have utilized the Trendelenburg posture, which has enabled me to see what I was doing and to protect to better advantage the peritoneal cavity. This position you may improvise at any time by tying an ordinary hard bottom chair on a table, so as to form an inclined plane. I have further, in all pus cases, irrigated freely with hot one per cent. salt solution and with full-strength peroxide of hydrogen, neither of which act as irritants, as bichloride does. Further still, whenever feasible, I have counterdrained, and in large peri-appendicital abscesses I have avoided digging up the appendix, a procedure which can only result in breaking down nature's protecting wall of adhesions and in thus infecting the general peritoneal cavity.

Such are the discursory thoughts I would offer for discussion. The principle which mainly guides me in selecting surgery in these cases is the feeling that it is preferable to perform an aseptic exploratory section and be proved wrong in diagnosis, than to wait on nature until an operation is forced upon me after perforation and in the presence of peritonitis.

36 East Fifty-eighth Street.

THE INDIAN WOMAN IN LABOR.

By GUY C. M. GODFREY, M.D.

First Lieutenant in the Medical Department, United States Army; Post-Surgeon at Fort Washakie, Wyo.

As the Indians are very reticent about their child-births facts in the matter are hard to obtain, and my thanks are due to Dr. F. H. Welty, the physician to the Shoshone Agency in Wyoming, for his invaluable aid in preparing this article.

The Indians at this agency are Arapahoes and Shoshones, and it is about them that I write. The Shoshone women are rather short and heavy set, with broad pelves. Their temperament is lymphatic. The Arapahoe women, on the contrary, are tall and slender, with fine figures and broad pelves. They are of a bilious temperament. In both tribes the women are stronger than the men, on account of the enormous amount of work they do. As the habits of any people have a direct bearing on their health, a few words in regard to the customs of the Indians will not be inappropriate.

The women are very industrious and perform nearly all of the manual labor done in the village, including chopping wood, carrying water, cooking, etc. They also do the sewing and bead work. Their recreation is gambling. They, as well as the men, are filthy. As regards virtue, conflicting reports are heard, some claiming that the prairie Indians (Arapahoes, Cheyennes, and Sioux) are virtuous, others claim that no Indians are virtuous. Several years ago the Shoshones had a custom of cutting off the tip of the nose of any woman caught in adultery. After the woman's nose was clipped, she was considered a harlot of the tribe. When a woman walks by herself she is not considered virtuous, and is fair game for any buck. Therefore two women generally keep together. A custom prevails among the Arapahoes of eight or ten young men lying in wait for a solitary female, and when one appears in view they seize and ravish her. The girls begin menstruating when twelve or thirteen years of age, and continue until they are forty or forty-five. They are very regular. The half-breeds and Shoshones sometimes suffer from suppression of the menses, but the Arapahoe women are never known to have any menstrual disorders. During menstruation a woman retires alone to a small wickyup or tepee, and remains there until the flow has ceased. Whether this custom is compulsory or voluntary is not known. The child-bearing age is between thirteen and forty-five. The average number of births per woman is about ten or twelve. As a rule they marry quite young, because the constant drudgery of their lives breaks them down, and a squaw is often a wrinkled hag at the age of forty. The bucks, on the contrary, often keep their age well. A young man takes a wife and when, after a certain number of years, she loses the bloom of youth, he takes another and so on. As a rule the squaws are quite healthy, with the exception of scrofulous subjects, scrofula being the most common disease among them. Cancer is never found among these Indians. During pregnancy there is no morning sickness, although at other times the Indians often have dyspepsia from their gormandizing and monotonous diet. The pregnant woman is not constipated any more than at other times. As a rule they have no sickness whatever while they are with child. During labor the woman lies on her back supported in a semi-recumbent position by a head-rest made of sticks covered with skin or cloth. This rest is wedge shaped, about three feet long and two feet high at the base. It is placed on the bed usually occupied by the patient. The men are all required to leave, and the patient is only attended by two or three old women who live in neighboring tepees. They have no regular midwives and rarely apply to a white physician for any assistance during labor. The old women remove all of the clothing below the waist and stay by the patient's side during delivery. In case the latter is slow or difficult they occasionally knead the abdomen with their hands. If the labor is unusually difficult two of the women hold a stick between them at a height of about a foot from the ground and across this the patient is required to lie with the abdomen downward. This, of course, stimulates the contractions of the womb and causes increased abdominal pressure from the patient's weight. The above constitute all the resources of the old women, and if they fail, the "tona-hay-hay," or medicine-man, is called in. He is a very important personage in the tribe, and has the full confidence of all. His art consists in making a big "pow wow," calling on the Great Spirit and rattling his "medicine-box." He, of course, does no good, but as Indian labors nearly always terminate successfully by natural methods, he gets the credit. The delivery, as a rule, is short and easy. It seldom lasts more than three or four hours. The patients seem to suffer much less than white or negro women. The vertex usually presents. Abnormal presentations, like pelvic malformations, are very rare. Only one case has been reported at this agency during the last six years. Indians are very unwilling to talk about such matters, but I conclude, from the meagre scientific information obtained, that it was a transverse presentation. This case lasted four days. The old women kneaded the abdomen with their hands and hung the patient across the stick. These two methods having failed, the medicine-man was called in. He danced, shouted, and rattled his medicine-box for two days, and as neither spontaneous version nor evolution occurred, the patient died from exhaustion on the fourth day. No autopsy could be obtained, and the mother was buried with the child undelivered. No white physician was called, because the Indians do not know the extent of science and art in obstetrics. The Indians know nothing of artificial delivery, consequently it is never attempted. Neither placenta prævia nor tumors ever occur to complicate delivery. I have never heard of a prolapse of the cord occurring in labor, although I believe it does rarely. Retention of the placenta is not unusual, and for this the white physician is generally called. When the doctor arrives he finds that the med-

icine man has failed, the old women make no attempts to extract the placenta beyond tying the umbilical cord to the patient's leg. They do this, they say, to prevent the cord from slipping up. The doctor then explains that if Credé's method fails he will introduce his hand and remove the after-birth. This he does after taking the proper antiseptic precautions. Whereupon the women pat him on the breast and exclaim "ohoh ohoh!" which means "bless you." When he emerges from the tent the bucks shake hands with him and, solemnly pointing upward, say: "Heap big medicine man!"

Multiple pregnancy is unknown among full-blooded Indians. Only two cases have been reported at this agency during the past six years, and in each case the father was a negro and the mother an Arapahoe. In each case the children consisted of a boy and a girl. Triplets never occurred. The duration of the puerperal period is usually only a few hours. At the end of that time the patient is up and doing her usual work. In scrofulous subjects the period sometimes lasts longer, even extending to a week's duration. In one case which recently came under Dr. Welty's observation, the patient, being a scrofulous woman, was unable to suckle her child.

Puerperal eclampsia is unknown. Puerperal septicæmia is very rare, only one case having occurred here within the last five years. This case was also attended by Dr. Welty, who says that it was caused by a decomposing retained placenta. The patient, a syphilitic, had by that time contracted puerperal septicæmia from which she died ten days after delivery. Mammary abscesses are quite frequent, and are caused by exposure and the filthy habits of the patients. The maternal mortality is very small, only two deaths having occurred here in the past six years—one from exhaustion and the other from septicæmia, as reported in the two cases mentioned above.

The fœtal mortality is very small, only two children having died during the past six years. Abortions are rare among full blooded Indians, but are rather common among half breeds. An abortion is generally the result of a fall, kick, or blow. The Indians have no special knowledge of its etiology or treatment. The foregoing facts were obtained with great difficulty, as very few of the Indian women speak English. They are backward about talking through an interpreter, because they are very, very much averse to giving any man any knowledge of their sexual troubles. Therefore I offer this article, not as an ultra-scientific study in obstetrics, but as an interesting collection of facts concerning the "noble red man's spouse."

VAGINAL HYSTERECTOMY BY ENUCLEATION WITHOUT LIGATURE OR CLAMP.

By J. RIDDLE GOFFE, Ph.B., M.D.,

NEW YORK.

PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC; ASSISTANT GYNECOLOGIST IN THE SKIN AND CANCER HOSPITAL.

The possibility of enucleating the uterus per vaginam without the use of a ligature or clamp, is a recorded fact in surgical literature, dating from 1822. So that, in contemplating this apparently new procedure, we are faced at once with the stubborn fact that there is nothing new under the sun.

It was accomplished for the first time, as far as we know, by a surgeon named Sauter, of Constanz, Germany, in the year 1820. The feat becomes the more extraordinary when we consider that he did it without the use of an anæsthetic or a speculum. The operation was done for cancer, the woman was bound fast to the edge of the bed, and the tissues were severed by scissors, the points of which were guided by the fingers. The account is extremely interesting, and is quoted in extenso in a work entitled "A Handbook of Surgery," by Chelius, of Heidelberg, and translated into English by South, of London, under the title of "A System of Surgery." The translation was published by Lea & Blanchard, Philadelphia, 1847. Although Sauter's patient recovered without serious hemorrhage or other accident, no one seems to have followed in his footsteps till recently, when the operation was revived by Pratt, of Chicago.

What the benefits or advantages of this procedure may prove to be, I am at present not prepared to state. But every new fact or principle established in surgery, as in every other branch of science, may contain in itself possibilities of far wider significance than the present moment can imply. At present, however, we know that the tightening of ligatures on nerve-fibres produces a certain amount of shock, and the placing of these ligatures requires a certain amount of time. These are important factors to the patient in every operation of this kind. By this method they can both be eliminated.

The secret of avoiding hemorrhage in this procedure is to adhere so closely to the uterine wall in the dissection, that the anastomosis between the uterine and ovarian arteries is avoided, and only the small branches are severed as they penetrate the uterus.

The opportunity of trying this method presented itself to me recently, and I put it to the test. The patient was an Irish woman, forty-six years of age, who had been suffering for the past seven years with complete procidentia uteri and all its train of torture. My hope was not only to relieve the tissues from the drag of the heavy uterus, but to secure the end of the vagina to the broad ligaments at a point sufficiently high to make them hold up the vaginal wall and bladder.

The field of operation having been made aseptic, I made a circular incision around the cervix through the vaginal wall with a scalpel, and pushed the tissue away from the cervix all around with the handle of the knife. It occurred to me that Thomas's spoon saw would be a good instrument for this dull dissection from this point on, and I found it to work admirably, enabling me to adhere very closely to the uterus, and to separate the tissue with ease and despatch. Upon reaching the peritoneum in Douglas's pouch I snipped it with the scissors, and tore it right and left with my finger.

To prevent the peritoneum separating from the vagina too much at this point, also as a preliminary step in closing the upper end of the vagina, I now passed a strong catgut suture through the wall of the vagina entering the needle on the peritoneal side and passing it straight through into the vagina, and then back again, thus leaving the loop on the vaginal side. The two ends were then caught in a clamp forceps and left hanging out of the vagina. Continuing the dull dissection with the spoon saw, I separated the bladder from the uterus, even tearing through the peritoneum above it and enlarging the opening to either side with my finger.

Although I had been in momentary expectation of seeing a spurting artery and was ready at any moment to apply a ligature, no arterial hemorrhage occurred. I therefore pushed on with the spoon saw, and soon had the satisfaction of seeing the two horns of the uterus sustained by nothing except the round ligaments. Before severing these I passed through the upper part of each broad ligament, high up on either side and transfixing the round ligament, a single strand of braided silk, letting the two ends of each hang out of the vagina without having tied any knot. The round ligaments were then cut away at either horn and the uterus delivered, thus demonstrating that the uterus can be enucleated without sufficient hemorrhage to demand either ligature or clamp.

To complete the occlusion of the upper end of the vagina, one strand of the catgut suture already placed was rethreaded and passed through the anterior vaginal wall, entering it on the peritoneal surface and passing it back as formerly in the posterior wall. These two ends of the catgut were now tied together, thus bringing peritoneal

surface in contact with peritoneal surface, and turning all raw tissue into the vagina.

The broad ligaments are now drawn well down into the vagina by the silk sutures previously passed, and securely tied together across the upper part of the vagina. A light packing of iodoform gauze completed the operation. The entire time consumed was a few seconds less than thirty minutes, much less time than it has ever taken before.

The operation was done at the New York Skin and Cancer Hospital, October 12, 1894, and I believe it is the first time the operation has ever been done in New York.

The patient had a slight hemorrhage three hours after the operation, but it was found to proceed from the vaginal wall and was controlled by a firm tampon of gauze. Aside from that, recovery has been uninterrupted.

22 East Thirty-fifth Street.

Progress of Medical Science.

Skin Diseases and Visceral Affections.—According to the *Medical Bulletin* for June (see also *Deutsche Medical Zeitung*), Kaposi spoke at the Vienna Medical Club of a misapprehension that prevails concerning Hebra and his school, to the effect that they look upon cutaneous diseases as simply external abnormal conditions having no relation to alteration of internal organs. This is not true of Hebra and his followers. While opposed to an uncritical assumption that such relationship exists, such conceptions obscuring comprehension and exerting a pernicious influence on prognosis and therapy, Hebra continually recognized such connection and turned the fact to practical account in treatment. Acne may be taken to illustrate the case in point. It is asserted that this disorder depends upon digestive disturbances. Yet when a disease can be explained in its totality, in its clinical and anatomical course, by demonstrable associations, a search for ulterior causes is unnecessary. Acne generally occurs at the age of puberty, when an active physiological process is going on in the follicles of the skin, though it may originate later in life. There is usually a depressed condition of nutrition, atony of the tissues involving the glands. The ducts of the glands are not properly contracted, giving rise to comedones and acne. The keratinization of the skin is also abnormal, and often alterations occur in the functions of the sudoriparous glands. There is not infrequently hyperidrosis. In this class also belongs acne cacheticorum, which itself depends upon lowered nutrition, though it may also be due to psychical influence. In acne varioliformis, more common in men than women, Kaposi spoke of excellent results from Carlsbad water, while local treatment is usually of small benefit. Pure hyperidrosis of the palms and soles arises during youth; in other instances it may come on abruptly and continue for years, disabling the patient for work. Here, again, general depression of nutrition is a cause. There is weakened action of the heart, reduced vascular tonicity, and the hands are generally cyanotic. As nutrition improves, there is apt to be a change for the better in the hyperidrosis. A similar result takes place in that affection recently known as erythromelalgia and characterized by the appearance of a persistent patch of congestion, often on the sole of the foot, attended with swelling and pain. Acne rosacea is linked with nutritive disturbances, sometimes with digestive errors, sometimes with uterine disturbances. Urticaria has been supposed to be due to changes in the alimentary tract; yet the mere sight of the specially harmful food will bring it on in some persons. Acute circumscribed œdema is nothing more than a giant urticaria due to vascular spasm.

In eczema, especially recurrent eczema, there is a relation between the skin disease and internal organs. Furunculosis, often referred by mistake to glycosuria, occurs in persons who suffer from eczema. Boils are not common in diabetes; but dermatitis diabetica is not unusual. How great the caution to be exercised in the etiology of skin diseases is illustrated by elephantiasis arabum tropica, certainly produced by the filaria sanguinis. Yet in a typical case observed by Kaposi, no trace of filariæ could be found. To depressed conditions, lupus erythematosus may also be ascribed. But it is wrong to consider pruritus senilis as due to digestive troubles; there is usually atrophy of the skin, with irritation of the nerves. Another form, developing in middle life, is accompanied by albuminuria and glycosuria. Pruritus universalis is a frequent accompaniment of pregnancy, of disease of the genital tract, and may also depend exclusively upon psychical causes. Impetigo herpetiformis also arises in pregnancy. Kaposi has seen seventeen fatal cases under such circumstances. Erythema, especially erythema nodosum, and purpura are the result of infection. Yet many cases exist that are dependent upon uterine or ovarian abnormities, and disappear when these are remedied.

The Treatment of Ophthalmia Neonatorum.—Kalt recommends irrigation of the eye with a 1 to 5,000 solution of potassium permanganate introduced through a small funnel, one end of which is placed between the eyelids, and the other connected with the bottle containing the fluid, which should be placed about a foot above the patient's head. The irrigations should be made twice a day, and two quarts of the fluid should be used at each time. If the disease is attended with serious or extensive trophic changes in the cornea, the irrigations must be used more frequently, say four times a day, and gradually lessened as the inflammation disappears. [At a recent meeting of the Ophthalmological Section of the New York Academy of Medicine, this plan of treatment was favorably commented on by Dr. H. Knapp, who had seen its application by Kalt.]

Toxic Effects of Thyroid Feeding.—Bêclère presented to the Medical Society of the Hospitals, Paris, a patient illustrating the cure of myxœdema by thyroid therapy. During the course of her treatment she accidentally took a large quantity of thyroid gland, ninety-two grammes in eleven days. At the end of this time she had developed such symptoms as tachycardia, pyrexia, insomnia, tremor of the extremities, exophthalmia, polyuria, albuminuria, and glycosuria, in fact a complete picture of Basedow's disease. The writer, therefore, concludes that the latter disease is due to a hypersecretion of the thyroid gland which may be caused in more ways than one. He thinks that Basedow's disease should no longer be classed as one of the neuroses, but as auto-toxic from an etiological point of view.

Gastropexy.—Duret presented to the Paris Academy of Medicine a woman on whom gastropexy had been performed after all other measures had failed to relieve a severe enteroptosis with dilatation and descent of the stomach into the infra-umbilical region. He is of the opinion that in cases of prolapse of the stomach of long standing gastropexy is an efficient method of treatment, both with reference to fixation of the stomach and cessation of the majority of the morbid symptoms.

Acute Pancreatitis.—Dr. Paul contributed to the Clinical Society of London the history of a case of acute pancreatitis in which the prominent symptoms were the sudden onset of pain, which was colicky in its nature and of short duration, constipation, and some vomiting. On examination, slight distention of abdomen, pulse and temperature somewhat increased. After the action of a simple enema the patient suddenly collapsed, the temperature rose to 104° F., and death followed speedily. The urine passed just before death contained a large amount of albumin, and granular and hyaline casts. Post-mortem examination showed an acute hemorrhagic and parenchymatous pancreatitis. The remaining organs were healthy except a cloudy swelling of the kidneys.

New York, December 1, 1894.

CHLORIDE OF CALCIUM IN THE TREATMENT OF ACUTE PNEUMONIA.

IN 1893, Dr. A. Crombie called attention to the supposed value of chloride of calcium in the treatment of pneumonia (*Indian Medical Gazette*, January 18). Dr. D. M. Moir, of the Indian Medical Service, confirms this opinion of its value in an article in *The Practitioner* of November, 1894. Dr. Crombie believed that he showed that in lobar pneumonia (1) chloride of calcium reduces the temperature and keeps it within safe or normal limits, in spite of the continuance of physical signs; (2) that there is a tendency for the morbid process to be arrested at whatever stage the drug is given in efficient doses, and that the course of the disease is thus shortened or rendered milder; (3) that there is a singular freedom from all anxiety, distress, and danger, a freedom not usually associated with continuous high temperatures; (4) and that there is a corresponding reduction in mortality.

Dr. Moir reports two cases in which the symptoms were alleviated by the administration of this drug. He gave it in doses of from sixty to ninety grains daily (ten or fifteen grains every four hours).

Many drugs have a reputed value in pneumonia, but none are yet accepted as in any sense standard remedies in the disease.

The evidence in favor of chloride of calcium is sufficient to demand for it some attention, and we can only trust that further experience will show that the drug is undoubtedly useful.

ACUTE ARTICULAR RHEUMATISM AS A GERM DISEASE.

BIRSCH-HIRSCHFELD, in 1888, reported five cases of acute articular rheumatism in which he discovered streptococci and staphylococci in the articulations and cardiac valves.

Bouchard and Charin, in 1891, reported that they had found the staphylococcus albus many times in the synovial secretions in subacute and chronic articular rheumatism.

Triboulet, during the same year, found the articular fluid sterile in a case of rheumatism with chorea, but on death the pericardial fluid and the blood of the heart and vena cava was found to contain the staphylococcus albus.

Sahli, in 1892, in a case of acute rheumatism with pleurisy and pericarditis, found that the synovial fluid of the knee contained microbes resembling the staphylococcus albus.

Dr. J. Sacaze (*Archives Générales de Médicine*, November, 1894) reports the results of his investigations in the same line. Dr. Sacaze made, however, bacteriological examinations of what he calls the "points of entry" of the rheumatic infection. In one case, a man had a wound on the foot followed by acute articular rheumatism with relapse. In the fluids of the knee-joint he found pure cultures of the staphylococcus albus. In three other cases the patients had an acute tonsillitis followed by rheumatism, there also the secretions of the tonsils were examined with the result of finding staphylococci.

He concludes that very often in acute rheumatism there is a local lesion which precedes the rheumatic outbreak. It is through this passage that the pathogenic microbes enter the system and the staphylococci seem to be often the infecting agents.

The history of gonorrhœal and other septic rheumatisms supports the view that acute inflammatory rheumatism must be classed among the microbic diseases.

THE CURSE OF KISSING.

PROPERLY applied, both as to time and place, the participators being mutually agreeable and fairly healthy, there is little to be said against the kiss, practised in moderation. When, however, one party to the transaction is an infant, not yet up in self-defence, or a maiden whose resistance is of no avail against the physically stronger aggressor, or an inanimate body prepared for burial, we claim the right to champion their cause against the reckless kisser. We have little to say concerning that form of disease known as kissing-fever, of which instances are now and then reported, especially from smaller towns. The over-affectionate man, who lurks in lonely places and pounces with his osculations upon unprotected women, without distinction as to size, age, or color, belongs in the same mentally unbalanced class as the despoiler of school girl tresses, the destroyer of white lawn dresses, the ink-thrower, the hugger—and when still more depraved—the ripper.

We leave him to the officers of the law and the alienists, provided an outraged brother, father, or husband has not already attended to his case "out of court." The child-kisser by habit really does more harm than the lady-kisser by disease, for while the latter shocks an occasional belated female on a lonely road, the former is constantly teaching the children with whom he comes in contact that it is not wrong to kiss comparative strangers, and a most dangerous, if not disgusting, habit is fostered.

Scientists have never yet discovered why it is that syphilitics, tuberculous subjects, persons with very bad teeth, and tobacco chewers, are the greatest kissers of infant and youthful humanity, and invariably implant their token of affection directly upon the lips. Such, however, is the fact, as any careful observer may discover for himself.

If there were any possibility of this reaching those who alone could answer, we would ask why the maiden aunt, who never was very fond of the children at best, insists upon coming into the room and kissing them as soon as they are down with the scarlet fever, diphtheria, measles,

or the mumps? Why must she, who "never kissed a living man" and doesn't believe in kissing anyway, press her lips to those of some cold corpse? This death-kiss may well be called a sanitary sin, and unless we, as physicians, continually discountenance it, as well as put our face against sick-bed kissing, we must hold ourselves more than equally responsible, for we know the dangers better than they.

Sanitarians have tried many times to introduce songs among the people tending to offset and counteract that very pernicious one which begins: "There is no harm in kissing," but they have never become popular.

Must we, then, leave the youngsters in happy ignorance of mouth hygiene? Can we keep their innocent minds free from thoughts of the bacilli swarming beyond the ruby lips? Should we ever neglect an opportunity to strike at the mouth which bears a mucous patch or where lurks the poison of phthisis or to defend the defenceless babe from the onslaughts of the male and female kisser.

SPECIALISM AND MEDICAL PRACTICE IN TEXAS.

Dr. R. P. Talley gives the following list of modern specialists (*Texas Medical Journal*) and makes some interesting comments upon them. There are, he says:

"1. The eye, ear, nose and throat *specialist*. 2. The gynecologist *specialist*. 3. The railway surgeon *specialist*. 4. Whiskey, opium, etc., *specialist*. 5. Dentist, or oral surgeon *specialist*. 6. Orificial surgeon *specialist*. 7. The Arkansas Hot Spring *specialist*. 8. The self-constituted midwives, and on down the line to the street medicine man, the Christian science doctors, the pile doctors, the Keeleys, etc., about whom and which I shall have nothing to say on this occasion."

The doctor speaks kindly of what he calls real specialists who are masters of their work and confine themselves to it. But he has a grievance against the railway specialist because (and Dr. Talley seems fond of enumeration):

"1. These surgeons are backed by a powerful financial corporation.

"2. They get a handsome salary for a fraction of their professional time.

"3. They are not required to give their whole time and energies to their specialty.

"4. Out of all they get a big 'ad.' by which they step from the practice from the employees to their families and friends, as well as to the practice for the employer, not allowed under the rules of the Hospital Association.

"This is all very nice and desirable for the railroad doctors, but I think it is a devil of a hardship on the 'other fellows.'"

Dr. Talley does not like the Hot Springs specialist. His virtues, he says, "are advertised on every telegraph-pole, hog-pen, etc., throughout the entire country. Unless we can make people understand that water can be made as hot in Texas as it can in Arkansas, our patients will continue to slip out and pay ten times as much for their troubles as if they would try in any sort of good faith their family physicians."

Incidentally we are given a painful picture of the over-crowding of the medical profession of Texas. In the town of Temper, where the doctor, who is President of the Austin District Medical Society, resides, there are twenty-two doctors to something less than 6,000 inhabitants, and in the country around there are twenty-four more within ten miles. "Some authority," he adds, "has estimated that in the army, in time of war, one physician can serve five hundred soldiers, and that in civil life one thousand and five hundred patrons are required to support one general practitioner. According to this estimate, in my town we have eighteen out of twenty-two doctors to spare, and if we cannot get rid of this excess, somebody will be hurt." "We presume this has as much reference to the patients as to the doctors." "This excess in number leads to all manner of 'sharp work' to get practice. Such a crowded population of doctors reminds me of a crowded population of poor people, where we find hot-beds of all sorts of pernicious diseases, moral as well as physical. Why, in too many localities our doctors are crowded, as well as illy bred as doctors, until the slime of local rivalry rises mountain high. If some local brother steps a little aside from what some other local brother thinks is ethical, he forthwith gets all sorts of infamy heaped upon his professional head. Who ever heard of two or three doctors getting together, singing a song and praying for some professional sinner, who had perhaps even sinned without knowing it? There is only one occasion when doctors may get together and sing and pray for one another, to wit: When one dies they can sometimes meet around his grave, and say amen, and then pass resolutions of condolence with a prayerful and perfect unanimity."

We wonder why the doctors of Texas have been working so hard to establish a medical college if their country is so well supplied. The causes of the over-supply in that State, as President Talley should know, are two-fold: one is the cheapness of medical education; the other the ignorance of the people and their willingness to accept anyone for a doctor if he can make a presentable appearance at the bedside, and shrug his broadly expressive shoulders at the other fellow.

NOT ALL DIE YOUNG.

One hears so much depressing talk about the life of a physician not conducing to longevity that it is cheering to note exceptions to the rule.

The following, cut from an exchange, is doubly interesting because we believe we can beat it.

"Oldest Physician in the Country.—Since the recent death of Dr. James Kitchen, of Philadelphia, Dr. Hiram Corson, of Montgomery County, Pa., is declared by Philadelphia papers to be the oldest physician in the United States who has been in continuous practice. He will be ninety years old next October, and has been in active practice ever since 1827. He is still in excellent health, with astonishing preservation of his physical and mental powers. Dr. Corson is now writing his personal recollections of the anti-slavery movement, in which he took an active part, having assisted many a fugitive slave to escape by the 'underground railroad.'"

Our entry for the long distance championship is Dr. Hull Allen, of Milford, Conn., born May 16, 1798, and

consequently in his ninety-seventh year. He was licensed to practise medicine at Newark, N. J., in 1821, and began in the same year at Sparta, N. J., subsequently removing to Milford, Conn., where he continued in active practice till 1870. Since then he says "he doesn't go out much nights," but until recently he has continued to give advice to those who call upon him at his house.

Dr. Allen has always enjoyed excellent health, and is to-day remarkably bright and active for one so near the hundred-mile post. May he be an example for many years yet to those who grieve because ministers and lawyers reach a riper age than we.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE report of the Surgeon-General of the Army for the year ending June 30, 1894, contains much that is of general interest, as the report of any head of a department so progressive in his ideas as General Sternberg, necessarily must. The question of the reduction in numbers of the medical staff is discussed at some length, but as we shall refer to this elsewhere it is not necessary to enter upon the subject here. An examining board had been convened to fill the ten existing vacancies, but when Congress reduced the force there were no longer any vacancies, the board was dismissed and the candidates were notified not to appear.

The Army Medical School has been in operation about a year, and the wisdom of its establishment has been already satisfactorily demonstrated. The principal object of its foundation was to impart a knowledge of preventive medicine, which is not often possessed by the recently graduated medical man, and also to provide for special instruction in military medicine and surgery. The school is established in the building recently erected in Washington for the Army Library and Museum, where also there is abundant material for bacteriological and chemical study. The course of instruction embraced the following subjects: Duties of medical officers in war and peace, military surgery, hygiene, and medicine, general and sanitary chemistry, pathology, and bacteriology, hospital corps drill, first aid to the injured, and equitation. The latter was not so superfluous as might be supposed, since two members of the class were entirely unused to riding. Nine medical officers were in attendance at the school during the year.

The work of the hospital corps is referred to with approval, the wisdom of establishing this branch of the service having been amply demonstrated. The number of members of the corps in service is 790, 49 less than the authorized quota. The number has been purposely kept down in order to keep the expense of the corps within the limit of the appropriation for its support.

Reference is made to the Medical Department of the National Guard in connection with the fourth annual meeting of the Association of Military Surgeons held in Washington in May. The Army Medical Department looked favorably upon the organization of the Association as a medium by which it might keep *en rapport* with the medical corps of the National Guard, in view of a possible contingency in which the State and National forces might be called upon to act in concert. The Surgeon-General of the Army was very properly chosen president of the Association for the present year.

The health of the army was nearly as good as during any previous year, the admission rate per thousand being 1,289.04, a great improvement on the average annual rate for the past two years (1,424.2) and only slightly greater than the lowest rate (1,247) ever furnished by our troops. The death-rate was 6.91 per thousand living, but little greater than the lowest rate ever recorded in our army (6.33) and considerably less than the average for the past ten years, namely, 8.51. The death-rate from disease alone, excluding accidents and injuries, was 4.01 per thousand.

Other questions treated of in the report are the quarters, some of which appear to be in a disgracefully dilapidated condition, poorly ventilated, badly drained and insufficiently supplied with water. The food supplied to the men was in general of a good quality, as was also the clothing.

The reports of medical officers regarding the habits of the men were generally favorable. At some posts where houses of bad repute are established in the vicinity, the sick report often becomes burdened with the results of dissipation, particularly after pay day. The recruits at Columbus Barracks are in particular exposed to harmful influences of this kind, owing to the location of the barracks within the limits of a city.

Inadequate provision for bathing is reported from several posts.

The benefit accruing from systematic work in gymnasiums is appreciated by all army medical officers.

THE BRUTALITY OF FOOT-BALL.

THE events of the past week have most thoroughly discredited the game of foot-ball as at present played. The contest at Springfield between the Yale and Harvard teams was one of the most unwholesome performances that ever masqueraded under the name of amateur sport. Players slugged into unconsciousness, eyes nearly gouged out, brains concussed, disabling sprains and bruises constantly interrupted the progress of the game, which even an ex-ball-player and friend of the sport declares to have been characterized by "sickening brutality." Besides this we hear of a student made insane through injuries received in playing, and two fatal accidents are reported. The number of young men who are permanently injured and who go through life more or less crippled in consequence of foot-ball playing can never be known. We should be sorry to see foot-ball abolished altogether from our colleges. There is no game that equals it in many ways when played as a manly sport and not for gate receipts. But the new rules are plainly ineffective, and unless some change can be made, the game really deserves to be placed under the supervision of Boards of Health working in co-operation with an efficient police.

Yale Medical Journal is the name of the most recent acquisition to medical journalism. It is edited and published by the medical students of Yale University under the auspices of an advisory board composed of some of the prominent alumni of the university. The first number makes a favorable impression. We wish it well.

News of the Week.

Antitoxin for Diphtheria.—Dr. Walter Wyman, Surgeon General of the Marine Hospital Service, in his annual report, says that investigations have been conducted concerning the etiology and pathology of the eruptive fevers, and the preventive inoculation against acute infectious diseases. A bacteriologist of the service is now in Europe familiarizing himself with the latest advances in preventive inoculation. This officer has transmitted to the bureau a supply of toxin from the Pasteur laboratory, with which animal immunization has already been begun (a horse having been purchased for this purpose) to obtain the antitoxin serum for the cure and prevention of diphtheria. On the return of this officer it is expected that the methods of preparing the toxin and obtaining the antitoxin serum from the immunized animal will be demonstrated from time to time to State health officers, in order that the benefits of this new remedy for diphtheria may be as widely distributed as possible.

The Samuel D. Gross Prize.—The quinquennial prize of $1,000 under the will of the late Samuel D. Gross, M.D., will be awarded January 1, 1895. The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens." The essays, which must be written by a single author in the English language, should be sent to Dr. J. Ewing Mears, 1429 Walnut Street, Philadelphia, before January 1, 1895. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer.

Death of Dr. Octavius Sturges.—We have to record the untimely death of Dr. Octavius Sturges of London. While still in the prime of life, Dr. Sturges was knocked down by a cab in Cavendish Square a few days since, and sustained a fracture of the left thigh. He appeared, however, to be recovering from the effects of the accident, and there was apparently no special cause for anxiety, but he died suddenly on November 3d leaving a large circle of friends to mourn his unexpected demise. It is a curious coincidence that, within the short space of one year, the President and the Senior Censor of the Royal College of Physicians should both have died in harness.

The Leading Medical Journals in the United States, as might have been expected, had much to say which was sympathetic and kind upon the subject of the death of Dr. Oliver Wendell Holmes. The memorial notices which seemed to us to be most worthy of the man appeared in the MEDICAL RECORD and the *Boston Medical and Surgical Journal.—Medical Press.*

The Woman's Medical Club of Chicago gave their first banquet Wednesday evening, November 14th. Gertrude G. Wellington, M.D., was Chairman of the Committee of Arrangements.

Iowa Association of Railroad Surgeons.—In pursuance to the call published September 25th, there was a good attendance of Railway Surgeons of the State of Iowa, at Sioux City, on October 10th, when the Iowa State Association was duly organized.

Middle Tennessee Medical Association.—The first regular meeting of the Middle Tennessee Medical Association was held November 20 and 21, 1894, in the Senate Chamber of the Capitol at Nashville. The Association was called to order by the President, Dr. J. B. Cowan, Tullahoma, at twelve o'clock. A large number of physicians were present.

The Northern Ohio District Medical Society.—The annual meeting of the Northern Ohio District Medical Society will be held at Fremont, O., December 6, 1894.

Mitchell District Medical Society.—The forty-sixth semi-annual meeting of the Mitchell District Medical Society will be held at Mitchell, Ind., December 27 and 28, 1894. This society is one of the oldest and most favorably known in the country, and this meeting promises to eclipse all previous ones.

Chicago Gynecological Society.—At the sixteenth annual meeting of the Chicago Gynecological Society, held October 19, 1894, the following officers were elected to serve the ensuing year: *President*, Dr. Franklin H. Martin; *First Vice-President*, Dr. A. J. Foster; *Second Vice-President*, Dr. J. C. Hoag; *Secretary*, Dr. H. P. Newman; *Editor*, Dr. T. J. Watkins.

Wabash Railway Surgeons.—The annual meeting of the Wabash Railway Surgeons was held at St. Louis, Mo., Thursday, November 1, 1894, in the parlors of the Southern Hotel.

New York State Association of Military Surgeons.—At the annual meeting of the New York State Association of Military Surgeons, which was held in the building of the Academy of Medicine on November 15th, the following officers were elected: *President*, Dr. R. S. Harnden, of Waverly; *First Vice-President*, Dr. C. S. Parkhill, of Hornellsville; *Second Vice-President*, Dr. J. A. Van Duyn, of Syracuse; *Secretary*, Dr. C. E. Herrick, of Troy; and *Treasurer*, Dr. J. F. Valentine, of Brooklyn.

Eastern Kansas Medical Society.—The Eastern Kansas Medical Society met at Kansas City, Kan., October 9, 1894, and elected a number of new members.

The New Hampshire Hospital Association.—The annual meeting of the New Hampshire Hospital Association was held at Concord, N. H., November 15th, with delegates present from Portsmouth, Manchester, Dover, Keene, Claremont, and Concord. Dr. C. F. Towne read an interesting paper on "The Relation of the Citizens to the Hospitals." This was followed by a general discussion of hospital needs. The next session will be held in Portsmouth in May.

The Eastern Iowa District Medical Society met at Keokuk, Ia., November 15, 1894. Dr. J. A. Scroggs, of Keokuk, Ia., president, in the chair.

A Chicago Physician.—Dr. Arthur Von Luna committed suicide on November 23d. He came to this country from Germany last summer.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, November 19, 1894.

SAMUEL B. W. MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

Habitual Constipation; Its Treatment.—DR. HENRY ILLOWAY read the paper. Constipation was becoming more and more common, and was tolerated by persons who claimed to be in good health in other respects. It was a relative term, but was applicable, the author thought, to all cases where there was not one free passage in two days. Regularity might exist and the person have but one passage a week, and he knew of a woman who had her bowel scooped out once a month by a midwife.

Acute and chronic forms existed, but the author considered on this occasion only the latter. These were divided into: *a*, constipation depending directly upon a well-defined morbid process, such as cicatricial narrowing, cancer, etc., or secondary to disease in other organs; *b*, constipation depending upon inaction of the bowel. The paper was confined to this group. The author considered briefly the longitudinal and circular motion of the gut, the several sources of nerve-supply, and the influence of pathological conditions in some other organs, as the heart and spinal cord, in producing constipation. He did not think catarrh a cause of chronic constipation, and if cases of colic were excluded it was questionable whether there was such a condition as entero spasm.

Causation.—One frequent cause of constipation was neglect to answer promptly the call of nature, whereby tolerance was developed on the part of the mucous membrane and terminal nerve-filaments. Want of closets for use by the moving public was largely to blame in this matter. A second important cause was use of foods not containing sufficient residual matter. Our diet was composed too much of starches, sugar, fats, and meat. A third cause was the habit people were acquiring of trying to fill their heads (by reading) while emptying their bowels. A fourth was relaxation of the abdominal muscles brought on by absence of physiological exercise and deficient oxidation. The author did not lay much stress on the habit of purgative taking, although when carried to excess this might act like too much and too coarse residual matter, causing over-excitation.

Protracted constipation led to dilatation of the gut, the colon having been found of a circumference even of fifteen inches. In old people scybalæ were liable to form. The existence of fistulæ led the patient to avoid passages and thus tended to aggravate the constipation.

Fecal Intoxication.—The author thought this was liable to take place only where soft fæces flowed over long-retained masses. The question was also raised as to the manner in which the breath of the chronically constipated took on a bad odor, whether from the stomach or lungs.

Prognosis and Treatment.—Recognition of the cause was of first importance in outlining the treatment and pronouncing a prognosis. Each case had to be treated upon its individuality. In some a permanent cure could be expected; in others, only temporary relief. Where constipation depended upon disease of the heart, lungs, liver, or anatomical abnormalities, special measures would be called for. To overcome an atonic condition of the muscular structure of the intestine and to stimulate the nerves use calabar bean; nux vomica, arsenic, belladonna, hyoscyamus, and stramonium were sometimes indicated, but otherwise would prove positively injurious. Use belladonna for venous stasis. The author had not had success from very small doses of podophyllum, for which claims had been made in France. Other measures were mechanical, dietary, massage, and electricity. Walking, riding, and rowing were valuable, especially walking. Oxygen stimulated peristalsis. Riding was best for shaking up the bowels, for congestion of the liver, and for getting rid of and preventing the formation of gas. Hydrotherapy was useful, including injection of water at about 75° F. In some of the more obstinate cases use hot water and cold water alternately. Massage was indicated in all cases of atonicity and for the dispersion of residues. It was practised upon the naked belly, with unoiled hands.

Faradic electricity was more effectual than galvanic over the abdomen, while the latter was more effectual within the rectum. The author did not approve of dilatation of the sphincter in the treatment of constipation unless this were associated with fistula. Incontinence of fæces which might follow was a most horrible condition. One party had claimed good results from suggestion in the hypnotic state.

Constipation in Childhood.—DR. J. LEWIS SMITH thought that many of the severe standing cases of constipation in adults dated back to infancy. It was a wonder the patients lived so long, but they often finally succumbed to the condition unless the cause, perhaps a constriction of the bowel, were removed. Where an anatomical cause was not present, the diet was most likely to be at fault. One cause of delayed movement of the bowels in infancy was greater length of the sigmoid flexure than existed later. Carrying infants exclusively in the horizontal position favored constipation. Painful defecation would lead the child to suppress the act. Medicines were not an uncommon cause, including purgatives which were far from being so simple and harmless as their name would indicate. He did not approve of mothers giving the baby "castoria," "syrup of figs," etc. In institutions the best means of unloading the bowels was by an injection of one to two teaspoonfuls of equal parts of glycerine, castor-oil, and sweet-oil, added to a tablespoonful or two of water, allowing it to remain in the bowel as long as it would. The glycerine rendered the masses softer. Curative remedies were dietetic rather than medicinal. He had not found cane-sugar as efficient as had been claimed. Massage was of some use. Maltose was efficacious. Some of it might be given with each feeding in order to get a more regular movement of the bowels.

Permanent Cure Only in Recent Cases.—DR. S. W. DANA thought that by such means as the author had mentioned—electricity, massage, diet, etc., recent cases of constipation could be permanently cured, but not so the really habitual ones. Trousseau had commended belladonna, but it was not curative in this country; neither were the cannon-ball, the compressed sponge, or boracic acid. Habitual constipation was associated with a sedentary life. There were cases, more than we knew of, which were hereditary. In them, to seek to remove the cause would require going back to the parents and grandparents. As children these persons might suffer little, but as soon us they grew up and became seamstresses or pursued sedentary vocations they became obstinately constipated.

Camp Out.—Massage would relieve constipation. But Dr. Dana knew a better method. There were a large number of business men who went every October to the Adirondacks, lived in a log hut open on one side, spent their time hunting and leading an active life. These men had told him that during this time their bowels, which had been constipated the whole year, became easy and natural. On returning to the city they soon became constipated again and had to take laxatives until their next outing.

Dr. Dana did not know why there should be such an outcry against the use of purgatives. Elderly people especially had passed the time for a permanent cure of constipation. They were in misery unless their bowels moved. In many cases a regular passage could be secured by a dinner-pill, the patients felt better for it,

and were not more given to ills than persons who did not take them.

Dr. J. G. Coyle said that when he entered upon the practice of medicine he was not prepared to find constipation in women exist to the extent that it did. The cynical and sententious definition of woman by a college professor seemed not altogether inappropriate: a constipated thing with a pain in the side. The first doctor, whoever he was, must have been employed to relieve constipation. Massage was nothing more nor less than exercise of muscles, and with few exceptions as good results could be obtained by active exercise, but the passive form appealed to women. For men it should only be recommended to those who had more time than brain. In atony of the bowel no drug was so effective as fluid extract of cascara sagrada. In some cases strychnia and belladonna were very useful.

Dr. F. M. Nye had once relieved himself of an attack of obstinate constipation by green corn. He had heard of a man who "couldn't get a hole through his patient, sent out for a quart of yeast, squirted that up his bowel. Blazes! it didn't come away, and that's what made him croak." Dr. Nye had found a small dose of calomel, given regularly for a time, relieve constipation in infants.

Dr. Achilles Rose exhibited a cannon-ball, weighing over three pounds, a form which had given satisfaction to himself and others in constipation.

Dr. Illoway, in some closing remarks, said Trousseau had recommended belladonna only in cases of constipation supposed to be due to spasm of the bowel, and in such cases it was of value. He did not think length of the sigmoid flexure in infants had much influence, while milk from a constipated mother and use of soothing syrups and brandies had.

"**Medico-Chirurgical Notes on the Works of Hippocrates and Galen**" was the title of a paper read by Dr. R. Harcourt Anderson. Mention was also made of anæsthetics in the early and middle ages.

Clinical Department.

A CASE OF TETANUS NEONATORUM—RECOVERY.

By EDWARD C. RUNGE, M.D.,

ST. LOUIS, MO.

INSTRUCTOR OF PHYSIOLOGY AND ASSISTANT CLINICIAN AT THE CLINIC FOR NERVOUS DISEASES OF THE ST. LOUIS MEDICAL COLLEGE DEPARTMENT OF WASHINGTON UNIVERSITY, ST. LOUIS, MO.

On August 7th, Mrs. H——, called me to see her newborn babe, which appeared to have been afflicted in a peculiar way for some days. I found the premises located in a healthful portion of the city, and bearing the stamp of a good sanitary condition: foul air, cesspools, or any other anti-hygienic elements did not make themselves apparent upon close inspection. Everything in the house indicated the order and care of a well-regulated household. The father seemed to be in perfect health. The mother had enjoyed good health during the entire period of gestation, except for a certain "nervousness" which was more pronounced during the early part of her pregnancy. This is her fourth child, and the first one to give any trouble. The fœtal movements were almost absent during the last month; some feeble ones were felt just a week before birth, which took place on July 23d, about one month before full term according to the mother's calculations. The labor lasted nine hours, the pains not having been at any time severe. It was a head presentation. The umbilical cord is said to have made four turns around the child's neck, and was severed some little time after birth. The placenta was not adherent, and came away about ten minutes after the child. The latter, a boy, weighing eight pounds, was profoundly cyanosed, "almost black," but uttered a short cry very soon after his birth. An enema was administered at once, for some occult reason. Whether the babe had received a bath at that time, or how the cord was managed, could not be ascertained, as the attending midwife had beaten a hasty retreat before my arrival, and the entire anamnesis had to be elicited from the mother. The latter did not notice anything unusual about the babe for two days. The cyanotic hue of the skin had given way to an intense redness; no "jaundice" was ever noticed. The little fellow nursed well and eagerly, and cried at times, but never lustily. The eyeballs seemed somewhat too prominent, and an occasional cast of one eye was observed. The intestinal and renal functions seemed normal. On the third day the mother was surprised at the "unusual strength" displayed by the babe; it would grasp her gown, and only with difficulty loosen its hold. The umbilical cord had become detached on some day before the mother's leaving the bed, which happened on the tenth day after confinement. A daily bath had been given since the detachment of the cord. On the tenth day after birth there seemed to appear the first difficulty in swallowing, the babe refusing to take the breast. Complete locking of the jaws supervened. This condition was aggravated by any attempt at introducing the nipple or a spoon. On the eleventh day the spasms of the masticatory muscles continued with temporary relaxations, during which some milk was forcibly given by the spoon. The milk was, at times, vomited (or probably ejected before it had reached the stomach). This condition was soon followed by tight shutting of the eyelids, stiffening of the extremities, and by drawing back of the head. The midwife, nothing daunted, was still directing her efforts toward combating this "unusual attack of colic" with castor-oil, rhubarb, and castoria. The parents finally concluded to call in medical aid, and on August 7th I found myself at the bedside of the little sufferer, on the fifteenth day of his extra-uterine existence, and on the seventh day after the onset of the malady.

In the dim light pervading the darkened room the babe's face showed a high degree of emaciation, the eyelids were closed, the countenance pinched, but otherwise normal. A curtain was raised for better inspection. No sooner had the bright light struck the infant's face than the forehead was thrown into transverse wrinkles, the eyelids, of which the superior ones appeared œdematous, shut more tightly, the mouth was puckered up as if in an attempt at whistling. The lower jaw was immovably fixed, so as to render the introduction of my finger utterly impossible. This paroxysm was accompanied by a half-suppressed, whimpering cry. I succeeded with considerable difficulty in extricating the little patient from a mass of coverings, cotton-batting, and lard-stained rags, and found him to be an apparently fully developed infant. The emaciation was general and extreme. The skin was of a dirty icteric hue, and covered with a papular miliaria, while the sclera and the mucous membranes did not show any icteric discoloration. There was a slight hernial protrusion at the umbilicus; the latter was perfectly healed, and did not show any sign of inflammation, past or present. I also made out a right scrotal hernia. The fontanellar pulsations were absent. The head was drawn backward by the rigid cervical muscles; a slight degree of opisthotonus was noticeable; the forearms were slightly flexed and crossed over each other; the fingers were tightly clasped over the thumbs in extreme flexion; the thighs were flexed upon the abdomen, and the legs upon the thighs; the toes were widely separated, and their extensors in an almost rhythmical clonus. The abdominal muscles hardened upon the lightest percussion. The paroxysm was followed after some time by a period of partial relaxation, the rigidity of the muscles never disappearing entirely. The slightest irritation—as by a touch, a sound, a change of light, a breath of air—did at once cause an acute exacerbation of all the tetanic symptoms. The alvine discharge, removed at the time of my first examination, was of a semi-solid consistency, dark

brown, and extremely offensive. The whole picture was so characteristic of tetanus neonatorum as to preclude any possibility of a diagnostic error.

I immersed the babe in a bath at 99° F., and kept it under water for six minutes. This seemed to bring on considerable relaxation, which lasted just long enough to enable the infant to take about one ounce of dilute milk from the bottle. A small portion of the milk was rejected, and the removal of the bottle ushered in another paroxysm. I ordered chloral in 0.24 doses every four hours by rectum, 0.03 of antipyrin and 0.12 of potassic bromide in solution cautiously dropped on the tongue every two hours; an immersion bath at blood-heat every four to five hours, each to last ten to fifteen minutes; nutrient enemata, consisting of milk, egg albumin, and sodic chloride; egg water by the bottle or spoon whenever the child's condition would permit the procedure. I, of course, insisted upon the exclusion of all adventitious sounds from the darkened sick-room, and upon keeping the patient well wrapped in simple coverings, discarding the complex apparatus of the conventional babe dress.

August 8th.—The pauses between the paroxysms have grown somewhat longer; this made more frequent feeding possible. The egg-water was never vomited. Diuresis was more active; the alvine discharges were more watery and less offensive. The skin felt hot. The thermometer was not used for fear of disturbance. Peptonized milk was ordered, and treatment continued, except for decreasing the dose of the chloral to 0.12, and adding whiskey in repeated five-drop doses.

August 9th.—The egg-water and peptonized milk were taken in greater quantity, and retained. The mother succeeded in straightening the lower limbs during the bath without producing an exacerbation of the tetanus. The nutrient enemata were discontinued on account of rectal irritability. Medication: Chloral 0.12 twice, antipyrin and potassic bromide every three hours. Baths the same as before.

August 10th.—The babe nursed more easily and willingly. It tired readily, but as soon as the bottle was moved the sucking was taken up, without producing a masticatory spasm every time. The face wore an improved look. Treatment continued.

August 11th.—The skin appeared more natural, having lost its icteric hue. The eyelids opened slightly, and involuntary winking was noticed for the first time. The trismus appears very much less frequently; the feeding was more successful, one ounce of peptonized milk being ingested each time. An enema brought a rather copious dark-colored discharge. The fingers could be separated with some effort. The cervical and dorsal spasms were still quite pronounced. Treatment continued.

August 12th.—The babe nursed well, taking about one ounce of milk every two hours. It seemed to crave the bottle, for the cry had lost its whimpering character, and was evidently appeased by the bottle. The eyes were opened, and remained open for some time. The fingers were more readily unclasped. The introduction of the thermometer into the rectum caused quite a severe tonic spasm of the muscles of the lower limbs. At 6 P.M., rectal temperature 104° F. Treatment continued, except chloral given but once.

August 13th.—The patient nursed well. The intestinal discharge showing undigested casein, the milk was given in greater dilution. The cries were quite natural. Relaxation was more persistent, and particularly marked after the baths. The babe was ordered back to the breast. Rectal temperature, at 10 A.M., 102.2° F.; at 5.30 P.M., 102° F. No chloral; antipyrin and the bromide every four hours; baths.

August 14th.—The breasts began to yield more milk; still the bottle was given at intervals. Rectal temperature, at 10 A.M., 100.9° F.; at 5.30 P.M., 100.4° F. Treatment continued.

August 15th.—General relaxation very marked. Alvine discharges of natural color. The eyes were opened readily and quite frequently. Rectal temperature, at 10 A.M., 100.9° F.; at 6 P.M., 101.4° F. All medication suspended. Baths continued.

August 16th.—The patient appeared weak, otherwise much improved. Relaxation continued, except that the fingers were still flexed, but the fingers overlapped the thumbs, and the clasp was not tight. The tetanic condition has disappeared completely. Rectal temperature, at 10 A.M., 99.2° F.; at 6.20 P.M., 101.1° F. The number of baths reduced to one in twenty-four hours.

August 17th.—Doing well. Rectal temperature, at 10.30 A.M., 101.2° F.

August 18th.—The babe is entirely breast-fed; weight, seven and three-quarter pounds. Rectal temperature, at 4.30 P.M., 101.1° F.

August 24th.—Weight, seven and three quarter pounds.

September 1st.—Weight, eight pounds.

September 14th.—The boy seemed bright. All functions were normal. He had the full use of his limbs, no muscular impairment whatever being noticeable. Rectal temperature, at 1.30 P.M., 100.1° F. Weight, ten pounds. The patient appeared in every respect a perfectly normal child.

I may sum up the important features of this case as follows:

The tetanus set in on the tenth day after birth; all of its manifestations disappeared completely on the fifteenth day after the onset.

The development and course of the disease in this case place the latter in the category of so-styled chronic tetanus, with its less gloomy prognosis.

As to the therapeutic measures, it would be impossible to decide how far they have contributed toward bringing about the favorable result. To serve this purpose they would have to run the gauntlet of much more extensive clinical experience. In managing this—my first—case of tetanus neonatorum, I had to overcome a strong prejudice against any, save physiological and hygienic, measures in dealing with the new-born. I felt that the occasion did not warrant the taking of extemporizing half-measures, or any dosing in strict accordance with hard-and fast pharmacopœial rules; 0.03 of antipyrin and 0.12 of potassic bromide every two hours, and chloral in 0.24 doses every four hours, seem a good deal of medicine for a patient just entering upon the tenth day of his earthly existence; but the violent nature of the malady rendered the adoption of truly heroic measures simply imperative. The frequent and prolonged bathing was a prominent feature in the management of the case, and I will say that it caused more lasting relaxation than any of the other remedial agents, produced repose more nearly akin to natural sleep, and, at the beginning of the treatment, stayed the trismus for a sufficient time to enable the patient to take some nourishment by the mouth. Rectal alimentation, which I should never neglect to institute, is not quite as satisfactory in the new-born as in infants at a later period of life.

Any attempt at solving the question as to the etiology of the tetanus in the case under consideration would lead directly into the field of conjecture and speculation. The umbilicus having failed to show any evident pathological changes, the case would most likely be classified as one of non-traumatic or "idiopathic" tetanus. It was not within my power to ascertain whether the baths given before the onset of the disease were improperly tempered. Foul air did not play any rôle in establishing the disease. The atmospheric changes were devoid of any startling features; from the reports obtained at the local weather bureau, I learned that for the three days preceding the attack, and on the day of the attack, the mean temperature registered 74°, 80°, 83°, 82° F.; the range between the maximum and minimum, 16, 21, 16, 21; the departure from the normal, — 4, + 2, + 5, + 4. These data point to an equable state of the atmospheric temperature; the same holds true for the first ten days of the child's life. The meconium had been passed in a normal way, and the alvine discharges had assumed

their usual character. In these and some more directions causes of tetanus of the new-born have been sought after. Upon perusing the literature on this subject I came to the conclusion that the etiology of non-traumatic tetanus is still a sealed book to us. Just to illustrate on what extremely weak grounds the explanation of the causation of this disease sometimes rests, I make mention of the case reported by Hein, as quoted by Dr. J. Lewis Smith: A citizen of Berlin lost, successively, two children with tetanus soon after birth. When the second child fell ill he observed that its cradle was exposed to a current of air. At the third accouchement the position of the cradle was changed and the infant escaped! Our salvation may possibly lie in the further pursuit of such experimental work as has been done by Beumer and Riper; its final result may prove that every genuine case of tetanus neonatorum is of microbic origin. Bearing such solution of the problem in mind, we should be ever careful of giving our new-born the benefit of the most approved surgical methods while we are inflicting upon them their first, unavoidable, trauma. Clean hands, a thoroughly cleansed cord, aseptic ligatures, sterilized scissors, a dry protective dressing, consisting of some non-irritating antiseptic powder (*e.g.*, equal parts of iodol and boracic acid) and gauze, are all essential features in the equipment of the modern obstetrician possessed of truly surgical instincts.

A CASE OF FATAL HICCOUGH OF UNKNOWN ORIGIN.

By D. B. McCARTIE, M.D.,

NEWARK, N. J.

WITHIN the last few months a new and continuous form of hiccough has appeared, unaccompanied by organic disease or surgical malady. The minute history of all these cases I cannot substantiate, but I know all were continuous and irremediable, and in several instances caused death. Some cases were treated in the hospitals, others at home, with meagre results, and most were looked upon as excessive forms of ordinary hiccough, when probably the disease was a new manifestation of nerve disturbance occasioned by some functional neurosis.

CASE I.—History: J. C——, bartender, aged twenty-eight; habits and family history good; no special nervous traits in family; an active, strong man; weight, 150 pounds; middle height. For years previous to present disease, on being shaved by his barber, he noticed that when the razor touched a circumscribed spot on the side of his chin, at the edge of the inferior maxillary bone beneath the mental foramen, a trifling scratch instantly brought on an attack of hiccough. This happened repeatedly, but the reflex action never continued longer than for a few seconds. He always could check it by the usual domestic remedies, as sipping water, holding the breath, etc. The last and fatal attack began after he had been shaved, and lasted five or six weeks, after which he died of exhaustion. The hiccough was almost continuous, except during sleep and for some periods to which this brief sketch particularly refers. After a day or two the case aroused much popular interest, since the patient was well known; and as a newspaper wonder stood out strongly in long, exciting paragraphs. As a consequence, cure after cure was recommended and tried, with faith in each new method, only to end in sad failure. Among thousands of popular devices nitrite of amyl was oftenest recommended, even outside the medical world.

It would be waste of valuable space to add any of the extraordinary remedies suggested; suffice it to say they all failed. The medical treatment for days was as hopeless, and in this department few remedies were left untried. The sedatives naturally were tried, but after slight relief the hiccough was renewed. One medical gentleman suggested the stomach-tube, which was eventually the only means by which a short reprieve could be obtained. The use of food in any form, after being swallowed about half an hour, caused the patient such distress by augmenting the hiccough, that he anxiously introduced the tube or artificially produced vomiting, for when the stomach was empty the hiccough weakened. I saw the case many times, and tried pressure on the phrenics in the neck. This lessened the hiccough very much and allayed the spasms of the chest, but on removal of the pressure the phenomena returned as vigorously as ever. I then strapped the lower ribs, which apparently lessened the spasms, yet the patient complained that they had not subsided internally. Cocaine pills were next administered, and much relief followed; but this was not sufficient to cause a sudden disappearance of the trouble, which the patient and everyone thought was to be obtained by some mode of action or drug. After this the patient continued to hiccough and grow weaker. Rectal alimentation did little to maintain his strength. About one week later an operation was performed on the irritable spot in the cheek, but failed to cure, having no scientific exactitude underlying its performance. On a second visit to the unfortunate fellow I observed that he was losing all his strength, and was very exhausted and wasted. As a last resource I tried massage, and to my surprise, after working gently at the toes and lower extremities for a brief time, he complained of an indefinite feeling about the epigastric region; presently he retched up some greenish watery fluid, and the hiccough stopped immediately. The patient brightened up and took some nourishment, which remained in his stomach without producing the hiccough. The interval lasted twenty-four hours, when it began again. The man now despaired and sank spiritless in his bed. Being called again, I tried the same remedy with instantaneous success. The hiccough stopped two days, then returned. In the meantime hundreds of letters arrived daily, and continued annoyance was kept up about the dying man. He also tried every remedy guaranteed as a sure cure. I saw him again three days later, and massaged him all over; again instant relief followed, and he remained free from the attacks an entire week, at the end of which time they recurred. I saw the case no more, as now he submitted to all kinds of treatment, plus an operation. One week later he died of exhaustion; no autopsy.

These cases appear to be of nervous origin, and, like any other hysterical malady, are prolonged by attention. They appear to be causeless, except through functional nerve perversion. In the above case no organic cause existed, or in any of the group lately reported. The disease is not due to organic stomach trouble, or pressure on the phrenic nerve; nor does there appear any reason as yet to ascribe it to any brain tumor or lesion which would not be lacking in various other symptoms. It remains at present to class this phenomenon as a neurosis of functional character. Most works on medicine ignore it, except as a concomitant to alcoholic excess, or antecedent to death, or accidental to obvious causes, such as pressure on the nerve trunk. The treatment, where exhaustion is the cause of death, would be suggested by like cases of functional nerve depression, like that of bedridden or hysterical patients. Little need be said on this score, except that the disease be recognized as a disease. Isolation, rest, removal from home, forced feeding, encouragement, electricity, and, above all, in these cases, massage, since the results above ascribed to it were undoubtedly manifest and instantaneously successful.

108 BELLEVILLE AVENUE.

Library of the Surgeon-General's Office.—In the Army Medical Library there are now, according to the recently issued report of the Surgeon-General, 114,567 bound volumes, and 183,778 monographs and theses on medical subjects.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE BRADSHAW LECTURE—INFANTILE SCURVY AND RICKETS—PATHOLOGICAL SOCIETY—PERFORATION OF THE PALATE IN SCARLET FEVER—DEATH OF DR. STURGES—SMALL-POX—DIPHTHERIA—CHELSEA HOSPITAL AGAIN.

LONDON, November 10, 1894.

THE Bradshaw Lecture was delivered on Thursday before the Royal College of Physicians. This year the Lecturer was Dr. Thomas Barlow, who took for his subject "Infantile Scurvy and its Relation to Rickets." Dr. Barlow has worked assiduously at this subject and made it quite his own, and was, therefore, listened to with great interest. It is now eleven years since he stated the results of his observations on thirty-one cases. At that time the disease had not been generally differentiated, and such cases were spoken of as "acute rickets," even in the German school, where the idea that they were scurvy was repudiated chiefly because sponginess of the gums had not been noticed, but this symptom has been since shown to sometimes occur. Dr. Cheadle first reported this, and to him we owe to a great extent the present state of our knowledge of the clinical features of these cases. The soundness of his conclusions was maintained by Dr. Barlow, who has himself contributed chiefly to our knowledge of the pathology of the disease. In this Bradshaw Lecture he reviewed the main clinical and anatomical aspects of the disease, recalled the conclusions of his first paper, and then showed how far they had been modified by criticism and subsequent investigations. Copies of the drawings of his original paper from the *Medico-Chirurgical Transactions*, 1883, were submitted, and specimens were exhibited to illustrate the pathological conditions. I must not omit to say that in giving some account of the workers on the subject, Dr. Barlow did ample justice to America, from which he said the most striking evidence had come. He specially mentioned Drs. Northrup, Starr, Roche and others. It seems that the disease must be more common on your side the Atlantic, and it would appear to be on the increase with us, unless this apparent increase may be due to the increased knowledge which makes differentiation more general. Infantile scurvy is a disease of spoon-fed children. The spread, prevention, and cure are summed up in this statement. Still there are some fresh points in diet now and again cropping up. Thus the danger of proprietary foods is recognized, but it is not commonly suspected that sterilization of milk may be dangerous. Dr. Barlow spoke cautiously on the point, but suggested that prolonged high temperature might lessen the antiscorbutic powers of milk. The treatment is simple, appropriate diet and antiscorbutic remedies.

Antitoxin and diphtheria continue to occupy much attention, and one frequently hears of fresh cases in which the treatment by serum seems to have been most successful. It is now said that the British Institute will soon be able to supply the remedy. In the meantime supplies from the continent are falling off, and will soon be unobtainable. The Institute ought to have been ready before this, as I some time since suggested.

There was a good show of specimens at the Pathological Society on Tuesday, *e.g.*, rare examples of malignant disease, mediastinal tumor, peri-renal hemorrhage, carcinoma of kidney. Dr. E. W. Goodall read a paper on perforation of the soft palate in scarlet fever, and showed a preparation from a child of six months in which perforation was first observed four days before death. He had seen 14 cases, in 2 of which there were 3 perforations, in 3 cases 2, and in 9 only 1. They occurred at various periods, from the 9th to the 28th day. Generally they were by the side of the anterior arch. They might persist for weeks, and were probably the result of local sloughing. He had only seen perforation in diphtheria twice, and agreed with Dr. Fowler that the lesion is almost diagnostic of scarlet fever.

Dr. Octavius Sturges died this day week in consequence of injuries received a few days previously. He was knocked down by a cab in Cavendish Square, and though at first no internal injury was manifest, collapse set in and he died on the 3d inst. His chief writings were on chorea and pneumonia, and in connection with both of these his name will be familiar to many of your readers. He was senior physician to the Westminster Hospital, where colleagues and students alike held him in the highest esteem. At the Children's Hospital he held a similar position. At the Royal College of Physicians he was Senior Censor. In all directions regrets are expressed at his untimely death, mingled with admiration of his high character, unswerving loyalty to truth, faithfulness to conviction, and kindly sympathy with pupils and friends. As a *quondam* colleague, I would add my testimony to his upright conduct, and regret that so estimable a character should thus suddenly be removed from among us. We can ill afford to lose such examples. He was buried on Thursday, and a number of distinguished physicians attended the funeral service.

Small-pox continues to abate in London. Only eight new cases were reported last week. In the provinces, however, the returns are less favorable. In Dublin the disease continues. In Birmingham 69 fresh cases were reported. In Edinburgh there has been a fresh outbreak, to the extent of 50 cases in nine days, but I hear that the type is mild.

Diphtheria, which was rapidly falling in the number of its victims, has not declined further in the past week, in fact, the number of deaths went back from 49 to 54. At West Ham there were 12 deaths registered.

At last the committee of the Chelsea Hospital for Women have yielded to the voice of reason and resigned. There is no gracefulness in the act—it has been forced upon them by public opinion. I hope the governors who are to meet shortly will come in numbers and refuse to re-elect one of the old Board. I heard the medical staff will recommend the governors to appoint a special committee to deal with the subject of elections to the staff.

IS MALARIA A WATER-BORNE DISEASE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Anent the discussion on the sources of malarial infection between Drs. Daly, of Pittsburg, and Dalrymple, of New Rochelle—places where malaria is comparatively rare—perhaps a word from one who has spent six years in the Mississippi Yazoo Delta, where the infection is endemic, would be of value.

In the first place, both gentlemen are right. Malarial germs are earth-borne, water-borne, and air-borne; in fact are disseminated by every agency that circulates except excessive heat. Now, I have frequently known of a succession of cases of pernicious malaria in a family who drank water from the same source. To illustrate: In the summer of 1890, I had two cases of malarial hæmaturia, one of which was fatal, one case of malarial congestion fatal, one case of typho-malarial fever not fatal, and one case of severe intermittent; all occurring in one family of six members; the one escaping being a very old lady. Situated about three hundred yards from this residence was another family of three members. One of these had malarial hæmaturia and died. The other two had very severe attacks of intermittent. About fifty yards from the first-named residence was another family, numbers not remembered, which developed two cases of malarial hæmaturia, one of which was fatal, and several cases of intermittent and remittent fevers. There were several other families living contiguous to the first-named house in every direction, who were exposed to all the atmospheric and general causes, but remained healthy. It was found that the three infected families had used water from the same cistern, and this cistern was

cracked and full of sipage water. The families who had remained healthy had used a different water-supply.

Again, it has been observed repeatedly in that section, that during a protracted draught, when the stagnant ponds and bayous are all drying up, exposing their beds to the sun, which soon converts them to dust which fills the atmosphere, malaria is rife in all its forms; but let there come a good rain sufficient to bring down all atmospheric germs and fix them to the earth again, and there will be a sudden cessation of all acute cases. This is so invariable that its occurrence can be predicted with certainty. Of course, chronic cases and those which have undergone structural change will persist.

I have been told of severe epidemics caused by upturning the earth and by the exposure of large areas of the soil to the rays of the sun, by "deadening" the timber, but none have come under my personal observation.

Yours respectfully,

ISAAC J. JONES, M.D.

1603 SOUTH CONGRESS AVENUE, AUSTIN, TEX., November 15, 1894.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will Dr. F. W. Dalrymple, of New Rochelle, kindly answer the following questions for the information of the profession:

1. From what source does the Water Company of the village of New Rochelle get its water supply for distribution to the inhabitants?

2. If from wells, what is the evidence that there was no contamination in them from the land water?

3. If from a stream, what is the locality and character of the watershed drained by the stream which supplied the village water?

4. What was the storm-water fall amount and character for the two months previous to the outbreak of malaria?

5. What proportion of the people who suffered from malaria drank from wells in the village?

6. What were the sources of supply of lettuce, radishes, celery, etc., eaten by the persons taken sick; whether from muck lowlands or uplands?

7. What were the sources of the milk-supply of those taken sick?

8. What proportion of the men who worked in the sewer and cellar excavations were taken sick with malarial fever?

It is in no captious spirit that I ask the foregoing questions; I desire to get at all the facts for the sake of accuracy, and I sincerely hope, in replying, that no further epithets will be indulged in by the Doctor as to the views I advanced being "absurd;" for the Doctor will probably agree with me, that it is not difficult to mention now other well-accepted views in medical science that were previously more strange and unlikely than taking malaria into the system in the water we drink; and epithets are neither argument nor evidence, in this or any other discussion.

Yours,

W. H. DALY, M.D.

PITTSBURG, PA.

CIRCUMCISION—DO WE NEED LEGISLATION FOR IT?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: That delicate little procedure or operation, as Dr. Henry Levien would have it (issue of November 17th), circumcision, is again attracting the attention of our profession, and I believe there is no operation that has been so much discussed or spoken of for centuries as this rite of the Hebrews; and it is not surprising that it is the bête noire of our progresive Hebrew physicians imbued with the spirit of Listerism.

The chief fault that Dr. Levien finds with the Mohel (surgeon) is the ignorance of aseptic surgery, and he accordingly cites two cases, one of erysipelas and the other of excessive hemorrhage, that occurred as the result of the operation.

Those of our colleagues that practice among the Hebrews will admit that seldom, if ever, did they hear of complications after circumcision so grave as to cause death; it is of so rare occurrence, nay, so unheard of, that it is impossible to give any approximate data; it is infinitesimally small. Let the Board of Health statistics answer, how often do they contain reports of deaths as the result of circumcision. We do not attack modern surgery, with the great aseptic and antiseptic methods, but we venture to say that in the best modern hospitals, where Listerism is carried out in a most rigorous way, sepsis occurs a hundredfold more than in that small crowded room where the Mohel is the surgeon-in chief; and the surgeon of every hospital in the country would be proud should he be in position to point to as small a record of sepsis or other complications as the Mohel is able to. How to explain such a fact I do not undertake, but one feature of the Mohel's work is characteristic—his dexterity, the swiftness with which he performs the only operation he is able to, and which he has performed thousands of times, is so great that it only consumes one or one and a half minute, including time of dressing the wound, and, as I witnessed it the other day, it took at most forty-five seconds in all. The little time, say thirty seconds, which the wound is exposed might explain somehow why so few cases of complications occur in the Mohel's practice.

In conclusion permit me to state that: 1. As Dr. Levien himself admits the progressive Mohel employs antiseptics, he believes only the city Mohel does. I had an opportunity dozens of times to witness the country Mohel's armamentarium not complete without a bottle of carbolic and a strip of iodoform gauze.

2. There are licensed physicians, skilful and unskilful, and the same with the Mohels, but even the poorest Hebrew always seeks the services of the best, the one who is most popular as having the record of widest experience; for should the father be unable to pay the Mohel's fee, the invited guests respond to the Mohel's individual blessing of those present by voluntary contributions, thus paying for the opportunity to be present at a God-pleasing rite.

3. Circumcision, as practised by the Mohel on the infant, is no more of an operation than vaccination, opening an ordinary abscess, or severing a tongue tie.

4. As a custom and religious rite, circumcision cannot, and should not, be interfered with as carried out among them.

Permit me further to add that none of our most promiment surgeons ever attacked or ventured an adverse opinion in regard to circumcision, for we never see any evil results from it, and in many cases are sorry our patients have not been circumcised. As a patient of mine, an Arabian, aged thirty, upon whom I was compelled to perform circumcision about three months ago, for paraphimosis with extensive sloughing, exclaimed: "How ungrateful must I be to my father, who neglected his duty to me and left the work to be done by you thirty years afterward."

R. HOCHLERNER, A.B., M.D.

THE IMMUNE SERUM OF THE GOAT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: "C." in the MEDICAL RECORD, November 17th, suggests that "it may be worth while to test the natural and artificial immune serum of the goat in future experiments." He is speaking of tuberculosis. Let me inform your correspondent, that there are past experiments which he will find described in the *Tribune Médicale* of Paris. Unfortunately I cannot give the date of the articles, having sent the files of this French paper to the Tokio Medical Library; but the year was either '92 or '93. One article is entitled "Goat's Blood in the Treatment of Tuberculosis," by Bertin and Picq; the title of the other is "Transfusion of Goat's Blood in Pulmonary Tuberculosis," by M. Bernheim.

Yours truly,

ALBERT S. ASHMEAD.

Surgical Suggestions.

Gall-bladder. — The tongue-shaped projection, to which attention has been called by Riedel, is present in many cases of hydrops of the gall-bladder; it is not infrequently confounded with a floating kidney on the right side.—KEHR.

Appendicitis.—Surgical interference is not advised during an acute attack of appendicitis, except when grave symptoms intervene, unless a competent surgeon is at hand. Under these circumstances the case should be operated upon after the so-called recovery.—ASHTON.

Lacerated Cervix.—The kind of suture I use in operation for lacerated cervix is braided silk boiled in wax, and these sutures can be withdrawn with such ease that the patient is scarcely aware of the fact.—NILSEN.

Keep your nitric-acid bottle away from your steel instruments.

Do not carry nitrate of silver in the same case with instruments.

Control of Hemorrhage in Cases in which it is necessary to remove the Arm, the Scapula, and the Clavicle.—The methods that have been employed in these cases have been: (1) Simple compression of the subclavian artery; (2) compression of the artery after resection of the clavicle; (3) ligation of the subclavian prior to beginning the amputation; (4) resection of the middle half of the clavicle and ligation of the subclavian; (5) Wyeth first tied the artery, then formed his flaps, and, when the arm, clavicle, and scapula were connected with the trunk by only the veins and nerves, secured the veins and cut the nerves; (6) the artery and vein have both been tied after resection of the middle portion of the clavicle.—KEEN.

Empyema.—No operation is justifiable unless the presence of pus is certain; unless thorough treatment by medicinal agents, blisters, etc., has failed; or unless the symptoms, dyspnœa, etc., are so urgent as to demand immediate relief. (And the only way to be sure of the presence of pus is by the use of the aspirating needle.)—ASHHURST.

The man who intends to be a surgeon should not only make a special study of surgical anatomy, but should do a considerable amount of practical laboratory work in bacteriology, pathological histology, and experimental pathology and physiology.—BILLINGS.

The shock of being knocked down by an anæsthetic, as it is frequently administered, is very great indeed, extremely like that of a heavy blow on the top of the head.—ROSS.

We chloroform the patients in order to give them ether.—GORGAS.

Excision of Gasserian Ganglion.—Hartley improved on this operation by opening the cranium without incising the dura, raising the temporo sphenoidal lobe, exposing the ganglion, and removing it as it lies beneath the dura mater. This method seems to have the advantage over the method of Rose, in the precision with which the ganglion can, under favorable circumstances, be removed, and in the absence of such disagreeable, and sometimes unavoidable, accidents as wounding of the parotid gland or the seventh nerve.—STEWART.

Impacted Stone in the Ureter.—If the calculus is thoroughly squeezed between the thumb and fore-finger, the wall of the ureter being stretched tightly over it, a longitudinal incision will, after the removal of the stone, so contract that in many cases its site cannot be afterward discovered, except by a very careful search. The ureter should not be sutured.—COTTRELL.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 24, 1894.

	Cases.	Deaths.
Tuberculosis	142	103
Typhoid fever	14	5
Scarlet fever	88	12
Cerebro-spinal meningitis	0	1
Measles	47	2
Diphtheria	167	35
Small-pox	7	6

Pathogenesis and Treatment of Influenza.—It is well known how popular the quinine treatment of influenza was when that *maladie à la mode* visited our shores. So far as my knowledge goes this mode of treatment was strictly empirical, no laboratory experiments having been made on its action. The medical world will therefore be glad to know that the experiments of M. Mossé have confirmed the good opinion entertained of the value of this drug in combating "la grippe." Rabbits were inoculated with the blood of influenza patients, and then quinine was injected subcutaneously. Four out of six of these animals remained unaffected, while test rabbits unprotected by the drug became very ill. Again, rabbits inoculated with pure cultures of Pfeiffer's microbe (furnished by M. Roux) were quite capable of supporting this inoculation, provided subcutaneous injections of quinine had been previously practised. Of three unprotected rabbits, two were killed by the inoculation. Efforts to cultivate (on gelatine) the pathogenic bacillus from the blood of an influenza patient were always unsuccessful. In one instance the pneumococcus, and in another the staphylococcus were obtained. The blood of animals experimentally infected with influenza yielded the specific micro-organism only on one occasion. This culture was endowed with but feeble vitality, and proved to be non-virulent. M. Mossé arrives at the conclusion that the influenza bacillus is found only exceptionally in the blood, and that when so found its virulence is enfeebled. It is, moreover, unable to live in an organism in which the drug in question circulates, viz., quinine. It would thus appear that the exhibition of quinine as a prophylactic is justified; that it should be prescribed in large doses as an abortive agent; and that, finally, grave secondary infections, especially if due to the pneumococcus, call for hypodermic injections of quinine.—*Paris Correspondent of The Lancet.*

A True Story.—A correspondent sends the following, for the truth of which he vouches: A young doctor who began his practice in Texas, west of Houston, was called to a confinement case in which he, being green and nervous, naturally had some trouble, the patient seeming unable to make the supreme effort for final expulsion. The only other occupant of the wretched quarters was an old crone in a sun-bonnet who was silently but steadily rocking herself near the foot of the bed. Finally the old woman croaked out, "Doc, I wouldn't bother any longer with that woman, I believe I'd quill her and have done with it." The medical man not knowing what "quilling" meant answered that he did not quite see the necessity for that yet. The old woman repeated this suggestion several times until finally the nervous, exasperated man turned angrily on her and said, "Madam, I'll be d— if I will do it. If you want to quill her you can do so, but I won't." The crone took from the wall a turkey-wing and drawing a feather from it proceeded to fashion something like a long quill tooth-pick and, filling this with snuff from her own private stock leaned over the patient and as the next pain came blew the snuff into the woman's nostrils. Quick as a flash the woman re-

sponded with a giant sneeze and the child was born with the sneeze. "Thar," said the old woman, radiantly, "I knowed mighty well that thar bust would make her break her holt." And it did, to the great instruction of the attending physician.

The Doctor in Fiction.—Another bad doctor—bad rather through circumstances than of deliberate intent—is pictured in a new novel. The medicus discovers a specific for cancer (he is an Englishman, we hasten to say, and not a resident of New York) and cures a charming lady. Unfortunately she is soon after killed in an accident, and her husband refuses to permit an autopsy. This does not down the scientific enthusiast, however, for he goes to the cemetery after dark and digs up his former patient. But the husband of the deceased, unfortunately for himself, appears upon the scene and repeats his refusal to allow the autopsy to go on. Science stops at no such trifle as that, and the unreasonable husband is killed and buried in his wife's grave, the body of the lady being taken home by the doctor and dissected. The virtue of the cancer specific is triumphantly demonstrated in her body, which is then interred in the garden of the intrepid scientist. Twenty years now roll by in an uneventful way. The doctor prospers and his beautiful daughter cuts her second set of teeth and reaches womanhood. Now comes the son of the murdered man and dissected woman, and wants to marry the daughter of the doctor-villain. The latter refuses, the young man grows angry, makes inquiries, and discovers the crime. The wretched doctor becomes conscience stricken when found out, and dies. The young couple marry and are happy ever afterward.

The Value of Quarantine against Cholera was demonstrated pretty clearly last summer in Germany. In August and up to the middle of September it looked most decidedly as if the invasion of the scourge, which threatened Germany the whole length of its frontier toward Austria and Russia, could not be stayed. Two months ago the deaths by cholera in the thirty-one western provinces of Russia taken account of had already figured up three thousand one hundred, with more than double that number of cases, and in Galicia and Bukowina, in Austrian territory, there were one hundred and forty-six deaths per day at that time. But the state, with its severe precautionary measures—the latter going so far as to hermetically close the Silesian frontier for weeks—successfully stayed the spread of the disease in Germany. In every instance where cases of cholera occurred, or were only suspected as such, the sufferers were rigorously isolated. More thorough and comprehensive methods, too, were adopted to prevent travellers afflicted with the disease from penetrating into the interior of Germany than have ever before been employed. Quarantine stations were established at every point where the danger of imparting the disease could possibly lurk. The result of these strict quarantine regulations was that very few cases of cholera occurred in Germany, and most of those were along the banks of infected rivers, the source of infection of the water being in another country, beyond the control of the German sanitary authorities.

"Thyroidism;" its Relation to Exophthalmic Goitre and to Hysteria.—The *Gazette médicale de Paris* for October 20th contains a report of a recent meeting of the *Société médicale des Hôpitaux*, at which M. Béclère presented a woman, thirty-one years of age, who had recovered from myxœdema after treatment with the thyroid glands of sheep. She had taken, by mistake, at the beginning of the treatment, three ounces of the gland in eleven days, and this excessive dose had given rise to symptoms of thyroid intoxication. English authors, said M. Béclère, have described these symptoms as tachycardia, instability of the pulse, elevation of the temperature, insomnia, agitation, polyuria, glycosuria, albuminuria, and partial paraplegia, with a sensation of heat and sweating. M. Béclère had further observed an acceleration of respiration, transitory trembling in the arms, exophthalmia, and a staring expression of the eyes. Was there not, he asked, a striking resemblance between these symptoms and those of exophthalmic goitre? Was not their appearance in exophthalmic goitre allied, perhaps, to a supersecretion of the thyroid gland? Furthermore, M. Béclère had seen that, during the course of his treatment, the patient had had distinctly hysterical symptoms, although there had been no previous neuropathic symptoms, such as aphasia, monoplegia, and anæsthesia of the right arm. Might it not be concluded from this, asked M. Béclère, that the thyroid juice excreted in excess was one of the exciting agents of hysteria? Furthermore, he said, when thyroidism appeared in an hysterical person, it roused hysteria in her, as other intoxications did. M. Béclère thought that the syndrome of exophthalmic goitre denoted supersecretion by the thyroid gland, and that it acted like the poisonings that proved exciting causes of hysterical outbreaks.

Boiling Abscess Cavities.—The Paris correspondent of *The Lancet* describes a method employed by Jeannel, of Toulouse, in the treatment of localized tuberculous lesions, such as abscesses, ulcers, osseous, and joint troubles, with boiling water as a cauterizing and bactericidal agent. The method is applied as follows: After having freely opened the seat of mischief and slit up any sinuses that may exist, he excises if the lesion involves a joint. All the caseous detritus is then removed by curetting and thorough sponging of the parts, all bleeding being arrested. Then salt solution, maintained at the boiling point in a recipient (coffee-pot) is allowed to fill the cavity through a thick rubber tube. The cavity is then afterward filled and emptied until a sufficient degree of cauterization is effected. It will be seen that this *modus operandi* is only possible in the case of a funnel-shaped cavity whose sides can be raised and kept apart by tenacula and which is unprovided with counter-openings—a condition frequently met with in practice. A second and preferable procedure is also employed by M. Jeannel. This consists in first filling the foyer with cold or tepid salt solution, and then raising the liquid to boiling point by introducing into it the blade of a thermo cautery at a red heat. One minute suffices to fill a cavity the size of a pigeon's egg with boiling water in this way. The thermo-cautery method insures a constant temperature of 100° C., but it is applicable only in the case of an abscess cavity wide enough to allow the introduction of the blade without touching the parietes. General anæsthesia is, of course, necessary, except in cases of small abscesses, when cocaine, locally applied, is adequate. When the patient awakes considerable local pain is complained of, but this disappears the next day. The parietes of the cavity—or the abscess membrane, as this used to be designated—becomes gray, and yields a copious secretion of serous discharge, which renders frequent renewal of dressings a necessity. In a few days a detergent process is evident, granulations develop, and cicatrization rapidly ensues. Suppuration is rare; in certain cases, indeed, primary union is obtained. The boiling-water method is superior to ordinary cauterizing procedures in that it softens, disintegrates, and sterilizes the tissues to a greater depth.

The Corset in France.—A petition has been presented to the French Chamber of Deputies against wearing the corset as injurious to the health of the female part of the population. The Chamber solemnly received the petition, and passed it in committee. Meantime a Paris journalist has been gathering the opinions of notable women. A great many of them denounce the corset, declaring it to be unhealthy and ungraceful. They say it turns the figures into one commonplace mould, spoiling pretty ones and doing nothing to improve the ugly ones, yet most of the fair ones interviewed, who expressed themselves in this fashion, wore the objectionable garment.

REMINISCENCES OF DR. J. MARION SIMS IN PARIS.

BY EDMOND SOUCHON, M.D.,

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY, NEW ORLEANS, LA.

I HAVE often related to my friends the manner in which I happened to meet our surgical genius, Dr. J. Marion Sims, in Paris, and his first experiences in the French capital. They all were much interested in this as they were in everything pertaining to this great and good man, and they repeatedly asked me to write out the little story for the benefit of the profession at large. I, to-day, comply with this wish, regretting very deeply for all concerned that my pen is not more gifted, so as to do better justice to my hero and to my readers.

In the fall of 1860 I entered the old Charity Hospital on the rue Jacob as a benevolent student, in the service of the venerable and world-renowned Professor Velpeau. It was my first beginning in the study of medicine. Facilities to beginners over there are not so great as they are here, in our Southern hospitals especially, and in order to have a chance to come in close contact with the professor and the patients, a simple voluntary student of the service had to be over zealous with all, particularly the all powerful internes or lords of the service. After several months of trial I had succeeded in ingratiating myself with them all, and having been intrusted with the registration book of the in coming and out-going patients, with the number of bed, diagnosis, and dates, I had managed to be on as fairly good terms with Professor Velpeau as a little insignificant nobody like myself could be with such a magnate as was the great Velpeau in such a place as the great Paris at that period. This may seem rather hard to American students, but it is all true none the less.

Early one morning in the latter part of October, 1861, the year the War of Secession broke out, I was going to the hospital, and, as I was about to enter the gate, my attention was attracted at once by the face and appearance of a man who was coming toward the gate also, but from the opposite direction. That the face and appearance struck me at once will readily be believed by all those who have had the happiness of knowing our great American surgeon. Its characteristic soft and sweet expression, together with his deep-set, bright eyes and prominent, bushy eyebrows, the half smiling expression of his mouth, left uncovered by the absence of mustache or beard, made a much deeper impression on me than a glance ordinarily produces. I also at once recognized that he was a foreigner, and no Englishman at that, but surely and unmistakably an American, perhaps, hastily thought my young rebel heart, a Southerner; he must be that, I thought immediately afterward, because he looked so gentle and good, and yet, withal, so firm and self reliant. All this took but a few seconds, and I continued my course toward the ward to which I was assigned, walking through the yards with another student and the stranger coming up behind. When I reached the door of my ward I went through and closed it; it was soon opened again and closed; turning around I noticed my "American." The doctor told me later that at the foot of the stairs the other student went in another direction than I, and he was perplexed for a moment as to which one he would follow; after a little hesitation he said to himself: "Well, I think I will stick to the little one." The little one was myself.

I walked to the bed of the patient who took care of the white aprons the students wear over there, to protect their clothes, and, as I was putting it on the stranger came up to me, and after a most suave bow, said in a very slow and deliberate manner, that the Frenchman he thought he was addressing might have some chance of understanding: "Will—Professor—Velpeau—be—here—to day?" I burst out laughing and answered him in fluent English: "No, sir, Professor Velpeau is absent on his vacation and will not return before two weeks." The beautiful face brightened up at the sound of the English language where and when he so little expected it. "Where are you from," said he, "that you speak English?" "I am from the South, from New Orleans," said I, thinking that that would cool his enthusiasm if he was a Yankee. But far from it, he grasped my hand and pressed it so as to crush it. "Why," said he, "I also am a Southerner; I lived a long time in Montgomery, Ala." That made us friends at once. I showed the doctor around the hospital and finally asked him what he had come over here for.

"Well," said he, "I am Dr. Marion Sims, now living in New York, who has invented a method of operating for vesico vaginal fistula with almost invariable success." He looked at me to see if the name had made any impression on me, but it fell flat; we had never heard of Dr. Marion Sims in Paris. Furthermore, we all knew that nobody in the world knew anything about vesico-vaginal fistula except Professor Jobert de Lamballe, of the Hôtel Dieu, and, even under him, vesico-vaginal fistula was cured only exceptionally, even when using his procédé de glissement (sliding process), and the idea of this new man coming to Paris to teach French surgeons how to cure vesico-vaginal fistula almost infallibly, somewhat shook my faith in my new friend.

He said he had a letter for Professor Velpeau from Dr. Valentine Mott, of New York; that he was anxious to see the professor to get a case to operate on before him and thus to demonstrate his method. "Well," I said, "the professor will be here in some fifteen days," soon enough for your good, I thought to myself.

During that time the doctor was living in a little boarding-house in rue de l'Université, close to the hospital. He had invited me to dinner upon our very first meeting, and I went there once or twice to give him all the points about those men he was most likely to meet. He was all the time sanguinely confident and looked so sweet, so modest, so magnetic, that I began to feel a very strong drawing toward him, and by the time Velpeau was to return I was wound up to a high pitch and as eager as my friend that he should have a case soon.

Finally Professor Velpeau arrived, and I sent word to Dr. Sims immediately; he soon came to present his letter, which Velpeau read at once and fluently, but when it came to speaking to Dr. Sims he was at a loss to express himself and looked around for me. It was always the case when prominent English visitors came to the hospital. Although the Englishmen read and wrote French as well as the Frenchmen read and wrote English, a good deal better than I could then, yet when it came to talking they had the greatest difficulty in understnading each other, and I was always hunted up to help

them along. At that time Velpeau was nearing the end of a most hard-worked career, and, although age and success had softened him, yet he still bore the effects of his lowly, rough, peasant birth, and of his hard earned victory. At times the stiff haughtiness of the former years of struggle came over him. It did so to some extent at that time, and he was not to Sims exactly what he should have been, as I thought, and his coldness to him made my heart ache somewhat, as I took that to be of ill omen. The truth was that the name American at that time in Paris always evoked the name of Barnum, and the fact that a comparatively young surgeon posed as a successful operator on vesico vaginal fistula, when scarcely anyone, not even Jobert de Lamballe, ever succeeded in Paris, had rather prejudiced Velpeau against Sims.

After a few, very few words, Velpeau said to me, "Eh bien, que veut-il?" "Well, what does he want?" I translated the sentence to Sims, who at once modestly but firmly answered, "I want a case to demonstrate my operation, if the professor will be kind enough to procure one for me." "All right," said Velpeau, "I will get him one," in a way that showed he had but little confidence in the final result. Then he turned around without a hand shake or a word more to Sims and went on with his visit. I felt quite hurt, but could say, and said, nothing. Velpeau was the idol of all young aspiring surgeons, the demi god of the day. Nélaton was just looming up then, and had not as yet had his famous Garibaldi case which gave him world-wide fame.

For several days no case turned up. Sims was there every morning. I would introduce him to the younger surgeons who always swarmed around the old master, that he might not forget them. To every one who inquired about his object he said, "I want a case," and I myself would then also say, "He wants a case."

At last the case came! And, just as luck would have it, a case of moderate difficulty. "Thank the Lord," said I, with my American pride roused now to a high pitch for fear Sims should fail! When he told me he was sure to succeed it was a great relief.

By this time the whole of the old Quartier Latin had heard of the news, which had rapidly spread from hospital to hospital. On the day of the operation the famous little operating-theatre in the old Charity Hospital was overcrowded with students, and the arena below crowded also with the most distinguished professors of surgery of the French capital; Velpeau, Nélaton, Ricord, Malgaigne, etc., all but Jobert de Lamballe, who would not come.

Before beginning the operation Dr. Sims proceeded to demonstrate it graphically, by using a piece of thick and hard cotton batting, through which he cut a hole representing the fistula, then he pared the edges slantingly in one strip, next he passed the silk threads and the wires, etc. The doctor called on me to translate as he spoke. I was not expecting this, and before such an audience, and I felt shy and scared, but he so insisted with his sweet eyes and smile that I got up, trembling all over, and with a quivering voice would repeat in French each sentence as he uttered it in English. Gradually, however, I found that it was not so very hard, I became emboldened and went through the whole procedure with comparative comfort. After the demonstration Dr. Sims proceeded with the operation, which he performed with the skill and grace which characterized him. It was done in comparatively no time, closely watched and followed all the time by the French professors. When the doctor finally said it was done, a salvo of applause broke out from the benches; the professors rendered justice to the manner in which the operation had been performed, while reserving themselves mentally until the day when the sutures would be removed.

Dr. Sims attended to that case himself in the ward, and during the following days felt all along confident that it would be a success; and a success, a tremendous success, it turned out to be.

On the ninth day the same amphitheatre was again packed to witness the removal of the sutures; the case was pronounced cured, and this was confirmed by the French surgeons, who congratulated Dr. Sims.

The enthusiasm of the French students far exceeded their former outburst, and, since they could not very well carry Dr. Sims on their shoulders in triumph they took hold of me in his place, and the resident students carried me to their mess room to breakfast with them; a great and unprecedented honor in those days, for I was but a vulgar, simple, insignificant first-year student! I did more talking than eating, and the result of the excitement of mind and of heart was a very fine first-class headache that sent me to bed and lasted twenty-four hours.

However, some seemed to think that it might have been a chance cure. But these were soon to be set right. Immediately after the success of the first case, Dr. Sims started on the war-path for another, which was soon procured for him by a physician in private practice. But this case came very near being a Waterloo. It was taken to a private place, the Hôtel Voltaire, on the Quai Voltaire. The patient was a short, fat, stumpy little woman, and very obstinate. She, all of a sudden, absolutely refused to be operated upon unless she was given chloroform and put fast asleep. This much annoyed Dr. Sims, because in those days it was not thought quite safe to place a patient on the left side, the side of the heart, to give chloroform to the extent of keeping her perfectly still, since nothing could be done otherwise, and for such a long period as an hour or two. We were far then from the ideas of the present day. There was no overcoming her stubbornness and her will had to be done. It all went well for a while, a good while, but, all at once, the breathing became stertorous, the face blue, and the pulse flagged. The operation had to be suspended until she recovered. The operation was then resumed, but soon had to be stopped again, for the same reasons. Things were looking a little blue also, and as though the operator would not be able to complete the operation. But it was not to be so; it was to be completed, but it took Sims's whole nerve and skill to bring it to completion. During all that time the distinguished guests present said and did nothing, leaving Sims and his assistants to do all the fighting and get all the odium in case of failure, but all the credit in case of success. At one time I spoke to Velpeau to ask him what he thought of the condition of the patient, he shook his old silvery head and I imparted to Sims what I took that to mean, that he might make the best of it. Finally the patient rallied and was put to bed. At the end of the usual time this case was pronounced a success.

A couple of weeks later Professor Jarjavay secured another case, upon which Dr. Sims operated at the Hôpital St. Antoine. At the time of the removal of the sutures, a week or so later, Dr. Sims was not pleased with the appearance of the parts, and expressed his apprehension of some ulceration setting in and destroying the work done to a greater or lesser extent. Professor Jarjavay said that even if there was a fistulette (a small fistula) left it would not matter much. Although he seemed to say this in a good spirit, yet it occurred to some of us that some people would be glad to hail this as a failure of the so-called infallible American method. But no fistulette occurred, and that case was also placed on record as a complete success.

From that time on cases were quite frequent, and naturally so, since hardly any were ever cured before; the stock of fistulæ was very great, and cases were not wanting. It was specially in private practice that they appeared to be abundant, and Dr. Sims scored success after success with the greatest ease. However, he again struck another hard case, even a worse one than the one at the Hôtel Voltaire; it was the famous case of the "countess" out in the country, in a château, a patient of Professor Nélaton. She also insisted upon taking chloroform, and when the operation was about half

through she showed all at once most alarming symptoms. It was then that Nélaton uttered the legendary, cry "Head down," which everyone conversant with these matters must remember. After much and still more anxiety the poor illustrious patient was revived and the operation was safely completed. It turned out also a complete success.

Cases followed one another wherever the doctor went; in Paris, London, Germany, etc., he was kept busy with fistulæ and other female cases. It was he who then sowed the first seeds of true gynecological science and art throughout Europe, the science so eminently and thoroughly American.

Wherever Sims went he coined money, although he incessantly, willingly, and kindly did much charity work. He is the only man I ever knew or heard of who had such a vogue wherever he went. No French, English, or German surgeon could go to the capital of another country and have such calls and such success, no matter how great he was considered at home.

Dr. Sims made a host of friends among the surgeons of all countries, and it could not be otherwise, with his gentle, kind, unpretentious ways. However, some of his easy going American professional ways did not suit all of them, and some became a trifle cold and reserved toward him. Perhaps they were glad to find some flaw, ever so trifling, in such a beautiful gem. Surely, if they could have read thoroughly through his pure and simple heart and mind, they would have seen how unconventional were his ways, and how little he thought he was giving any offence or had any idea he was doing wrong.

Some time after all this the doctor brought his family over to live in Paris. From that time on the doctor's history is known to all Americans proud of the surgical genius born in our great land. One day he said in a burst of kindness: "How fortunate it was for me to have met you that morning I went to the old Charity. I was so thoroughly discouraged that I had about made up my mind to go back home!" Of course it was his goodness which made him express it that way and with such force, for he surely would have met some one else to play the rôle I was so fortunate and so happy to perform. He spent his money lavishly: all the needy Southerners and Northerners then in Paris were recipients of his generosity.

One day in his house, in the rue de Balzac, we were alone in his studio when he all at once asked me: "How are you getting along here, anyhow?" "Well," said I, "I am starving as slowly as I can. All resources from home have ceased since the war has begun, and but for a little position of $20 a month, which Professor Velpeau's influence secured for me, I would have succumbed to hunger and cold by this time." He replied, "Anything you need I will be glad to give you; I am making plenty of money now." I thanked him very much, but gratefully declined any assistance, because, if I borrowed, I intended to return it some day, and just then it was rather problematical if I should last to return and pay any indebtedness. However, he would not be contented unless I promised him to come to him if ever I needed any help. All this was said and done with a simplicity which was overwhelming, especially to one accustomed by recent education and association to the good but exuberant French people.

The following year, however, was the time for me to prepare my competitive examination for the "Internéship," *i.e.*, to be admitted a resident student in the Paris Hospital. That examination is, over there, the pons asinorum. It is held as the proof that there is something in the man, and in fact very few are those who attain any eminence in Paris who have not gone through that ordeal. It is really a very hard competitive examination, and it requires all the time of any student from early morning till late in the night to succeed. Very few succeeded the first time, usually it required two trials at one year's interval. I had to do it in one year or quit the study ot medicine. I needed, therefore, every moment of the days of the year of preparation, and therefore it was necessary for me to renounce my little situation. Now if I could not get Dr. Sims to assist me as he once proposed to do, what would become of poor me! Of course he had offered his assistance, but that was nearly two years ago, and perhaps he had changed his mind since, or could he still afford to do it, now that he had a large family to provide for in a gay and expensive capital?

I called at his house, then in the rue de Suresnes, so familiar to so many Americans, but he was out of town and would not be back for some time. When? No one could say positively: he was in London, they said, and very busy there! Yet time was flying and I had to take a decision, and no Dr. Sims! But at last he returned. I called in the middle of the day, thinking I had then a better chance of meeting him alone. He was in fact alone, taking his lunch; as usual, he greeted me with his kind look, sweet smile, and hearty shake hand. He invited me to lunch with him and I sat down to the table; but I could not swallow a morsel, my mouth was dry, my throat contracted, and my heart beating very fast. After a little trivial talk I summoned up all my courage and said to him: "Doctor, you once told me that if ever I was in need to come to you, and that you would help me along. Well, I am now in the greatest distress and upon you depends my whole future." "Why, what has happened, Souchon," said he, with concern in his dear face. "Well, sir," said I, "I have to give up my little situation in order to prepare for my examination for the residenceship of the hospital, and unless you give me today the assistance you offered two years ago, it will be impossible for me to do so and I must give up the study of medicine." "Oh, no," said he, "don't do that, I will help you certainly; how much do you want?" It was said with such natural kindness and simplicity that my heart sank within me: I felt as if a thousand pounds had been removed from my breast. "Thirty dollars per month will suffice," said I. "What," said he, "a dollar only a day. Oh no, take two." I thanked him very gratefully but consented to accept only one dollar and a half a day, remarking that I might never be able to return that little even. "All right," said he, "I will take my chances on that." He retired to his library and soon returned with a check for the first month in advance, and also for several hundred francs to buy some little furniture and clothing which he said I very likely needed. I should think I did need them! From that time the check came every month, no matter where he was—in France, England, Germany, Russia, Italy, or America. He never forgot it once, and when it happened, very rarely, that he was a few days behind, he would write a few words of apology.

When at last I was so fortunate as to succeed in my examination and I telegraphed to him in London, he immediately wired back that the news had sent a thrill of joy through the whole family; this in its turn sent a thrill of joy through me also.

The doctor's reputation had acquired such proportions that the French Government presented him with the decoration of Knight of the Legion of Honor, the highest ambition of all Frenchmen. It so happened that I was present in the forenoon of the day when the mounted dragoon from the State office brought the large, many-sealed envelope containing the brevet. It was the cause of great rejoicing in the family and among his friends. He himself did not believe very much in such trinkets, but he was happy because all around him were happy. I was despatched to go down to the Palais Royal to buy the ribbon worn in the button-hole. I chose it as nice and neat as I thought he would like, and brought it home, when I had the happiness of being asked to place it myself in the button-hole on the left side, over his noble and good heart.

Another notable instance of his great kindness is, when upon a visit through a London hospital, the physician in charge told him that he had in his ward a Confederate

surgeon who, heart-broken, had left the down-trodden South to seek rest somewhere. He had worked his passage through to London by acting as steward on board ship, but when he reached London his little money, his feeble health, his crushed heart, all had given way and he had stranded in a London hospital. Sims at once went to him, recognized a friend from the same grand State of Alabama, cheered him, saw him well, and brought him to his own house, and assisted him back home. All this I was told by the man himself, who, upon his return home became a most noted teacher of medicine in one of our famed Southern medical colleges.

I remember Dr. Sims in only one case of sickness. He was alone in the Grand Hotel in Paris, without any of his family with him, when he sent me word to come and see him. He had been suffering for some time from a repetition of an attack of pain and swelling in the right iliac region, and seemed concerned about his condition. Surely if it had been some years later he would have been appendicitized. But, thank God, he got well without the knife.

Alas! but that no human happiness is ever without a dark cloud! It was my distressing lot to be present at his house when the sad news came of the death of his eldest son, Granville. It was but a short message, quickly read, followed by a cry and a sob: "Oh God! Granville is dead!" Granville had torn himself away from Paris and his family and had gone to Havana to find a chance of running the blockade. He was there waiting for his opportunity, when he was attacked with yellow fever and succumbed very quickly.

Much more could be said of this great and good man during his stay in Paris, but it would require some one abler than I am to do justice to such a subject. He was surely one of the most magnetic men I ever met, and he made such a deep impression on me by his genius, energy, his courage, his goodness, his kindness, and his gentleness, that for many years ot the early part of my life he was the model and the guiding-star I strove to follow.

CHOLELITHIASIS.

By J. H. HOELSCHER, M.D.,

CHICAGO, ILL.

ATTENDING PHYSICIAN TO THE ALEXIAN BROTHERS HOSPITAL, AND MEMBER OF THE CHICAGO MEDICAL SOCIETY.

The history of gall-stones is imperfect. Reference to an old Latin work, known as "Lazari Riverri Praxis Medica," of the year 1653, gives an account of calculi which were found in the fæces and connected with symptoms of hepatic disease. Cullen's "Practice of Medicine," of 1792, contains considerable on the subject, and Watson's "Practice of Physics," of 1798, also contains statements which compare favorably with some of our present literature. This book contains the interesting statement that animals when stalled all winter become affected with gall stones, from which they recover when fed with green grass; this fact led an able physician to the belief that grass would cure gall stones and jaundice.

It is consistent with this paper to give a synopsis of the recent chemical analysis of bile and whatever pertains thereto. Secreted and excreted by the liver cells, it flows from the hepatic duct as a non viscous liquid, and when it comes in contact with the ducts and mucous membrane of the gall-bladder, an admixture takes place with a secretion from the ducts and gall bladder which gives it a certain viscidity. This secretion contains a substance known as mucoid nucleo albumin of bile.

Perfectly fresh human bile has a bright yellow and slightly reddish color, a bitter sweet taste, is generally odorless, of alkaline reaction, and a specific gravity of from 1.005 to 1.008. Chemically it consists of: 1, Sodium salts in combination with bile acids; 2, coloring substances known as bilirubin and biliverdin; 3, mucoid nucleo albumin. Other constituents are cholesterine, neutral fats, soaps, lecithin, mineral matters, traces of iron and gases, of which CO_2 is the most abundant. The bile acids and coloring matters are secreted by the liver cells. Cholesterine is excreted by the liver, and exists in the bile in a proportion of from ½ to 3 per 1,000. It is held in solution by a combination of bile salts and acids. Among the mineral constituents sodium salts are most abundant, and especially sodium chloride in the proportion of 5 to 1,000.

The quantity of bile secreted in twenty-four hours varies from a pint to a pint and a half; diminished during abstinence it increases immediately after meals, which increase is maintained about one hour. From three to four hours after meals it again increases.

This brings us to the consideration of the chemical composition, physical characters, and formation of gall-stones. They vary in size from a seed-like concretion to stones as large and larger than nutmegs; they may be irregularly rounded, smooth, faceted, polyhedral, and very rough and irregular. They vary in color from a light yellow to dark brown or black. A cross section reveals either a series of layers, or a homogeneous structure and a nucleus. The layers consist of cholesterine; the nucleus may consist of biliary pigments combined with calcium compounds, mucus, shrivelled epithelial cells, and sometimes foreign bodies; thus a case is on record where an ascaris lumbricoides formed a nucleus; Naunyn reports a case where a needle formed a nucleus, and cases of gall-stones in animals are on record where the distoma hepaticum formed the nucleus.

Chemically, gall stones consist of: 1, Pure cholesterine; 2, cholesterine and bilirubin-calcium; 3, calcium almost entirely; 4, bilirubin thirty per cent. and calcium; 5, a combination of all the ingredients.

This brings us to the study of the theories that have been advanced in explanation of gall-stone formation, and I shall adopt the following classification: 1, Causes located in the common duct; 2, those located in the gall-bladder; 3, those located in the bile; 4, those located in the liver.

The first class implies obstruction of the common duct and retention of bile; this latter condition has been cited as a cause. That this is inconsistent can be understood when we consider: 1, That the lymphatics absorb the biliary constituents; 2, chemical analysis of the fluid in a distended gall-bladder shows an absence of biliary constituents; 3, absence of bile ingredients precludes gall-stone formations; 4, practical observations have demonstrated the absence of gall stones in hydrops of the gall bladder, where the duct is obstructed by tumors, etc. Gall stones may cause retention and are to be regarded as a cause. Under the second class, or causes located in the gall-bladder, we have the presence of foreign bodies, such as ascaris lumbricoides, needles, distoma hepaticum, casts of intra hepatic ducts, and epithelial débris.

Naunyn has advanced the theory that gall stone formation is due to the entrance into the gall-bladder of the bacillus communis coli, which in connection with a retarded bile-flow causes a calculus forming catarrh; a condition wherein the mucous membrane of the gall-bladder secretes calcium carbonate. This theory is rather nullified by the fact that ligation of the common duct, followed by an injection of the bacillus communis coli into the gall-bladder, causes death rapidly on account of general infection; when, on the other hand, the duct is not obstructed, a similar injection causes neither local nor general changes; possibly because bile is sterile and aseptic, and thus assists in preventing pathological changes. It cannot be denied that the bacillus does enter the gall-bladder, because Naunyn and others have found it in cases of acute cholecystitis and suppurative lesions of the gall-tracts. These facts lead me to believe that it is not to be regarded as a cause of cholelithiasis, but rather as an agent in the production of complications; indeed, the presence of calculi may be looked upon as indirectly favoring the entrance of the bacillus communis coli. It is of great interest and importance to note the observations of Naunyn on individuals affected with gall-stones who died

suddenly. He found the epithelium of the gall-bladder to contain fat drops and a myelin-like substance. From some of these myelin-laden cells little masses protruded, which, becoming detached, were found to consist of cholesterine crystals. These he regarded as rudimentary gall-stones; other harder masses of similar composition had already developed into small calculi. Whenever this development of calculi from cholesterine masses was observed he always found minute stones containing a nucleus which consisted of bilirubin and calcium; these latter, it appears, are also associated with swollen epithelial cells, which break down into small granular masses and finally become surrounded by a deposit of cholesterine.

Of the causes located in the bile, Frerichs looked upon bile stasis as a cause, and believed that it resulted in decomposition of the bile salts and an acid reaction, with a precipitation of the cholesterine and bilirubin; these remaining in the gall-bladder caused a cystitis, a condition wherein the mucous membrane of the gall-bladder secretes calcium carbonate, which combines with the ingredients already mentioned and thus forms gall-stones.

This theory is rather disproved by the fact: first, that bile is sterile; second, no such chemical change is possible in the bile as it exists in the gall-bladder; and third, decomposition of bile and an acid reaction in consequence of exposure to atmospheric germs has not resulted in a precipitation of the ingredients already mentioned.

Of the causes located in the liver tissue nothing is known. In fact the lesions found in connection with gall-stones are to be regarded as effects.

If we will now consider the various causes of gall-stone formation, which necessarily involves more or less repetition, we are tempted to look upon Naunyn's observations as conclusively proving that the direct cause of gall-stone formation is located in the gall-bladder. I cannot assume this view as consistent with pathological processes, because there can be no change in the gall-bladder without an irritating substance, and it is only reasonable to suppose that the exciting cause is to be found in the bile itself. In order to support this opinion I will call attention to calculi formed in the pelvis of the kidney. From all that is known up to the present time, renal calculus is always due to an excess of some urinary constituent, such as urates, cystin, oxalate of lime, phosphates, etc. In excess these undoubtedly cause the so-called "calculus-forming catarrh" in the pelvis of the kidney; moreover, experience has demonstrated the existence of a certain diathesis which precedes or comes hand in hand with renal calculus; this tends to support the belief that there is an excess of some urinary ingredient.

I make this comparison in order to advance the theory that the primary cause of gall-stone formation, barring foreign bodies, is due to an excess of bilirubin and cholesterine, or to a diminished quantity of sodium salts and bile acids. I also believe that the excess or deficiency may be confined to any one of the essential constituents of bile, and just as an excess of urates or oxalates may cause a pyelitis, so an excess of cholesterine may cause a calculus forming catarrh in the gall-bladder, and give rise to the condition so well described by Naunyn, which undoubtedly plays the most important part in gall-stone formation.

It is impossible to say what changes in the human economy underlie an excess of essential bile constituents, and this is rendered more difficult when we consider that it affects individuals under all circumstances—the sedentary as well as the active, the glutton as well as the abstemious liver.

This brings me to the symptomatology of cholelithiasis; and since it is so varied and different in a series of cases I will place some stress on the symptoms as they are observed in connection with certain shapes of calculi. The most common and readily diagnosed cases are those where the gall-bladder contains the small, smooth, faceted calculi, which consist of bilirubin-calcium and a large proportion of cholesterine, etc. These may, as has been observed in autopsies, lie dormant in the gall-bladder and never give rise to symptoms. This is generally observed in old people, and may be accounted for by the fact that the gall-bladder's contractility is considerably lessened by certain pathological changes that accompany old age.

The symptoms of this class of cases ordinarily manifest themselves after a heavy meal, jolting in a buggy, or in consequence of sudden physical exertion, and begin with a violent, sudden, paroxysmal, and colicky pain in the epigastric or right hypochondriac regions, which radiates to the lumbar regions, right shoulder-blade, cardiac region, and sometimes to the opposite side. Owing to the intensity of the pain the pulse becomes weak, the skin is covered by a cold perspiration, there is a feeling of oppression across the chest, there may be nausea, and sometimes vomiting, which generally becomes biliary; this condition of shock may be accompanied by epileptiform seizures and syncope; the latter has proven fatal. Within twenty-four hours after the onset of the attack jaundice develops, which first appears in the sclerotic of the eye and rapidly involves the skin of the whole body. Coincident with this jaundice the urine contains bile pigments, it usually deposits an abundance of lithates, and the fæces are acholic. Palpation of the gall-bladder always reveals tenderness, which persists for two or three days, and sometimes longer. Owing to the tenderness it is generally impossible to feel the gall-bladder. The pain ceases suddenly, which signifies that a calculus has passed through the common duct and entered the duodenum, or has fallen back into the gall-bladder.

Examination of the fæces during a number of consecutive days will bring to light the presence of one or more faceted calculi. I wish to emphasize the importance of properly examining the fæces a number of days after the attack; the reason for this precaution becomes apparent when we consider that foreign bodies may remain in the intestines two or three weeks, and I do not see why gall-stones should be an exception to this fact. The gastric disturbance gradually diminishes in the course of a few days; with the cessation of jaundice and returning appetite the patient resumes his daily duties. Generally more or less gastric disturbance, always manifested by a tendency to gaseous distention, eructations, anorexia, and often constipation, remain to remind the victim of his illness; in fact, this latter condition may be so persistent that the patient gradually becomes exhausted, loses in weight, and is rendered unfit to fulfil ordinary mental and physical exertions; this condition I look upon as a strong indication for operation.

The colics may be of daily occurrence, or months and years may elapse before any more make their appearance. In typical cases calculi will be passed with the colics. The number that may be passed varies from one to several hundred.

The diagnostic features of these cases are: 1. Colicky, sudden, and violent pain, beginning in the epigastric or the right hypochondriac regions, and radiating to the lumbar, cardiac, and hypochondriac regions. 2. Tenderness on pressure over the dividing line of the epigastric and right hypochondriac regions. 3. Jaundice following the colic. 4. Bile in the urine. 5. Acholic fæces. 6. Calculi in the fæces. 7. History of previous attacks. 8. Palpation of gall-bladder may reveal the presence of calculi. All except tenderness and tumor may be absent.

These are the typical cases where a diagnosis is readily made. I shall give a few histories:

Case I.—Mrs. A——, aged twenty-nine; two children; history good; was suddenly seized with hepatic colic, with all the symptoms already given. The colics appeared every three or four days, each one accompanied by the passage of small faceted calculi. This condition existed six weeks, during which she passed twenty-four calculi, and then recovered fully. It is now five years since her illness, and there has been no return up to date.

Case II.—Merchant, of temperate habits and well nourished, had attacks of colic during a period of five years; not oftener than every two or three months. Calculi were passed each time, with typical concomitant symptoms. He refused an operation, and during one attack the duct ruptured. An operation performed by Dr. J. B. Murphy verified the diagnosis; the patient died.

Case III.—Colics had existed for a period of eight years. They occurred after long intervals at first, but finally became so frequent that the patient was forced to a life of invalidism. All the concomitant symptoms were present. The patient passed over two hundred calculi, one of which finally became impacted in the common duct, intensifying all the symptoms, with complete jaundice and a severe degree of cholæmia. There was no distention of the gall-bladder in this case. Dr. Parkes (deceased) performed the operation of cholecystotomy and found the duct thickened and obstructed by a calculus. The patient died on the third day after operation.

I wish also to call attention to cases where the symptoms persist two or three months. They are accompanied by a decided tenderness and increased resistance in the right hypochondriac region, increase in temperature of from two to three degrees, complete anorexia, intense jaundice, and daily colics.

Case IV.—In this case this condition was noticeable. She recovered after three months' illness and then had attacks of hepatic colic only four or five times in three years. I attended her and witnessed three attacks of hepatic colic which were accompanied by all the concomitant symptoms. Seven calculi were passed. Examination revealed the presence of a resistant, illy-defined, and tender mass in the region of the gall-bladder. I advised operation, to which she consented. Dr. J. B. Murphy operated, assisted by Dr. Lee and myself. The gall-bladder was found to be contracted, and surrounded by a mass of connective tissue with firm adhesions. Thirty-two calculi were removed, and the long button was introduced and removed on the seventh day. She made an uninterrupted recovery.

Case V.—The history corresponded to that of the fourth case. She had hepatic colics for ten years. Two years ago, in 1892, she was confined to bed for a period of four months with daily attacks of hepatic colic, and a constant pain and tenderness in the right hypochondriac region; she also had chills and fever, with decided gastric disturbances, such as nausea, vomiting, constipation, and anorexia; these, together with decided jaundice and cholæmia, made the case a serious one. She always passed calculi after one or more hepatic colics. When I saw her, in 1894, she had had colics ten days, and passed only three faceted calculi. The gall-bladder could be distinctly felt and was tender on pressure. Operation by Dr. J. B. Murphy. Found a purple, congested, and moderately distended gall-bladder; finding that it remained in the incision without support, a tampon was introduced and removed on the eighth day. I then incised the gall-bladder, and in the course of a week removed three hundred and eighty-five calculi of the bilirubin-calcium variety. No bile escaped through the incision, leading me to believe that the cystic duct was obstructed by calculi. She is recovering at the present time.

I cite these two cases because both give a history of prolonged disturbance covering a period of three months, during which time the pathological changes already mentioned must have taken place. To recognize this condition would assist in arriving at a conclusion when the question of an operation presents itself.

Differential Diagnosis.—In renal colic the pain begins in the lumbar region and radiates down into the thigh, testicle, and hypogastric region. After an attack the urine contains blood and pus. Concretions may also be passed. In the absence of urinary changes the history of the case will reveal the occurrence after active and passive motion, and there will also be vesical tenesmus. Tenderness over the kidney will invariably be present; finally, the absence of jaundice, bile in the urine, and acholic fæces will make the diagnosis positive. Here I will interpose the possibility of a renal and hepatic colic being present at the same time; and can best illustrate this occurrence, by citing the history of a case which I witnessed in my own practice:

A lady, aged thirty four, married, gave a history of four weeks' illness with symptoms of nausea, vomiting, chills and fever, vesical tenesmus more or less constant, and violent colics every three or four days, followed by a moderate jaundice. Physical examination revealed the presence of a movable kidney, which was tender on pressure; the gall-bladder was tender, but could not be felt; fæces were acholic. The urine contained bile, lithates, and pus-cells; no albumin nor sugar, and was diminished in quantity to about twenty-two ounces in twenty-four hours. I observed several colics, and found the first to be an hepatic colic which gradually terminated in a nephritic colic, or a violent boring pain in the right lumbar region, accompanied by vesical tenesmus. After such an attack the urine contained bile, pus, blood, indican, and was diminished in quantity. The final outcome of this case was favorable, recovery being complete after the passage of two cholesterine calculi.

Intestinal colic may be differentiated from hepatic colic by the following symptoms: 1, Pain begins in the umbilical region; 2, pressure relieves the pain; 3, pain is distinctly intermittent; 4, there may be tympanites, or contraction of the abdominal muscles; finally, the seat of the pain is an important differential symptom; and the absence of hepatic disturbance will establish the diagnosis.

Carcinoma of the pancreas should be considered, because there are cases where the common duct has been obstructed and given rise to decided jaundice, bile in the urine, and dropsy of the gall-bladder. The symptoms are: 1, Rapid emaciation and cachexia; 2, occasionally the nodules can be felt; 3, there may be fatty stools; 4, the jaundice is persistent, and there is no history of hepatic colics, which fact would materially aid in removing the diagnosis of gall-stone occlusion of the common duct. Absolute differential signs are: 1, The presence of a fixed tumor in the umbilical region; and, 2, the concomitant symptoms which always accompany carcinoma.

Catarrhal jaundice is readily diagnosticated from cholelithiasis by gastric disturbances followed by a jaundice, which remains more or less constant from two to six weeks; it is accompanied by temperature and sometimes chills; finally, it is never accompanied by hepatic colics and the passage of calculi The history is important.

Acute appendicitis begins suddenly with a sharp pain in the epigastric region, nausea, chills, and temperature, sometimes diarrhœa. Finally, in a short time pain becomes localized in the right iliac region, with decided tenderness, local tympanites, increased resistance, and an indurated mass makes its appearance in the right iliac region. Appendicitis can be diagnosticated from hepatic colic: 1, By the previous history of the case; 2, by the absence of jaundice, acholic fæces, and bile in the urine; 3, the tenderness in hepatic colic is generally (though not always) most marked in the region of the gall-bladder. It is oftentimes difficult to make a differential diagnosis. I had a case recently, where the patient was seized suddenly with acute and violent pains in the right hypochondriac and iliac regions, with nausea, vomiting, and a temperature ranging from 100° F. to 102 5° F. There was obstinate constipation. I saw the case about four days after the onset, and found the following condition: A large, fixed, indurated, extremely tender mass in the right iliac region, extending upward toward the liver; there was decided tenderness over McBurney's point; the bowels had resisted all efforts at evacuation, which, together with the persistent vomiting, indicated bowel obstruction. Here, then, the symptoms of appendicitis were well marked. She gave a history of having had periodical attacks of gastralgia for ten years or more, not

accompanied by jaundice or any conclusive sign of cholelithiasis. A closer examination disclosed that the tumor in the right iliac region had a round shape, and extended upward toward the liver; it was resistant and fluctuating. From the shape, size, and apparent origin of the tumor, as well as the bodily temperature and chills, together with the previous history, I diagnosed impaction of calculi and suppuration in the gall-bladder. With the assistance of Dr. Lee I performed a cœliotomy, and found the tumor already described to be the gall-bladder intensely distended. Suspecting its contents to be purulent, I adopted the procedure of placing an iodoform tampon in the incision, taking care to properly place the peritoneum in contact with the gall-bladder. Ten days later I incised the gall-bladder, evacuating twenty-five large biliary calculi, and about ten ounces of pus; I introduced a large drainage-tube. About two weeks later ten large calculi were removed, which, I believe, had been encysted somewhere in the gall bladder. Bile flowed through the tube immediately after the operation, and all symptoms of bowel obstruction disappeared. The obstruction was undoubtedly due to the large size of the gall bladder and pressure on the intestines. The progress of the case was favorable up to the eleventh week, when she became comatose and died in four days, with symptoms of cerebral abscess.

This brings me to the consideration of gastralgia. The importance of properly understanding what we mean by gastralgia becomes very apparent when we recall the similarity between it and hepatic colic; indeed, it appears to me that it is oftentimes a decided symptom of cholelithiasis. Gastralgia, pure and simple, is typical neuralgia, and generally makes its appearance after prodromal symptoms, such as gastric disturbance, neuralgic pain in other parts of the body, and general lassitude. The pain comes on suddenly, is intensely acute and paroxysmal, of a boring, lancinating, and burning character; it always begins in the epigastric region and radiates to the shoulder blades, hypochondriac, and umbilical regions. The pulse is weak and sometimes irregular; the skin is covered by a cold perspiration, the abdominal muscles are generally contracted, and pressure relieves the pain. There may be concomitant pains in other parts of the body. This condition may last from a few minutes to several hours or days. The urine may be diminished in quantity, or be very abundant when hysteria is a causative agent. There may be nausea, and sometimes vomiting terminates the attack. The symptoms of gastralgia will vary with the cause or causes. It occurs in conjunction with menstruation, gouty diathesis, ulcer of the stomach, carcinoma, malaria, nervous lesions, displaced kidney, etc. Since gastralgia is a symptom of so many lesions it becomes apparent that a process of diagnosis by exclusion must be adopted, and this applies with special force to cholelithiasis.

I shall have to base the description of gastralgia as it occurs in cholelithiasis on cases in my own practice. The attacks were extremely irregular, and rarely appeared oftener than once every two or three months; or a series of attacks covering a period of three or four years were noted, when they disappeared and did not return for several months.

I have noticed that they become more frequent when the pathological changes in the gall-bladder, such as thickening and contraction, are far advanced. Gastralgia occurs most frequently where the calculi are too large to enter the common duct; naturally the symptoms of bile obstruction, such as jaundice, bile in the urine, and acholic fæces, are always lacking in this class of cases. Here gastralgia and a very persistent gastric catarrh, which usually resists treatment, are the prominent symptoms.

In every case of cholelithiasis where this symptom was present, I observed that the pain commenced in the epigastric region; it was intensely acute and always accompanied by signs of shock. Local examination showed marked tenderness in the region of the gall-bladder, most acute during and immediately after the attack; it generally subsided and almost disappeared in three or four days. This symptom I have never found in these cases. I believe the pain is due to irritation of the opening at the cystic duct. Recently I introduced a blunt sound into the gall-bladder where cholecystotomy had been performed. The moment the sound entered the cystic duct the patient complained of acute pain in the epigastric region, which immediately ceased when the instrument was withdrawn. The injection of sterilized water into the gall-bladder, with slight force, elicited the same pain, or reflex gastralgia.

I will now cite a few cases wherein gastralgia was a prominent symptom:

Case I.—Married lady, has several children, and no history of lesions, except chronic gastric catarrh and gastralgia. These attacks had appeared about five or six times a year, but more frequently in the last year, and led her to consult Leube, of Germany, who made the diagnosis of gastralgia. In 1888 I was called to relieve an attack. She had a violent pain in the epigastric region and marked tenderness over the gall-bladder. The attack lasted four days, and was accompanied by a very slight jaundice, most noticeable in the sclerotic coat of the eye. There was no bile in the urine, and the fæces, which were thoroughly examined, were normal. There was an apparent enlargement in the region of the gall-bladder. Dr. Parkes (deceased) operated and removed two large calculi from the contracted and thickened gall bladder. She made an uninterrupted recovery.

Case II.—A well-nourished, married lady was suddenly seized with a violent attack of gastralgia accompanied by vomiting and obstinate constipation. The history revealed chronic gastric disturbance and attacks of chronic gastralgia every three or four months; she never had jaundice, bile in the urine, or acholic fæces. Local examination revealed the presence of a tumor which extended downward from the liver into the right iliac region, and backward into the right lumbar region. It was tender, fixed, rounded, fluctuating, and very resistant. Urine was diminished in quantity and deposited lithates in abundance. There was no bile in the urine, no jaundice, and no acholic fæces. Constipation was obstinate. The tumor was immobile, and apparently separated from the liver by a distinct depression. On account of its apparent origin in the right lumbar region I suspected a nephritic tumor, though the history did not justify this belief. Dr. J. B. Murphy made an exploratory incision and found a distended gall-bladder of a dark-red color, which was apparently œdematous. Calculi were felt, and a large sized Murphy button was used to make an anastomosis with the duodenum. Seven or eight days after the operation two calculi were passed per rectum; the largest measured one inch in its longest diameter, its shortest seven-eighths of an inch. The smallest measured seven-eighths of an inch longest diameter, and three-fourths of an inch short diameter. The button was passed on the eighteenth day. The operation was performed October 7, 1892. The patient has been perfectly well and free from all physical ailment up to date.

Case III.—Mrs. C——, married, illy-nourished; has had three children. History gives the following symptoms: Chronic gastric catarrh for twelve years; attacks of violent gastralgia about every three months; each attack lasted about four days. One physician advanced the opinion that she would not survive another attack. This state of affairs, coupled with a severe degree of atonic dyspepsia, brought about an extreme degree of anæmia, emaciation, and inability to perform ordinary housework. She had never had jaundice, bile in the urine, acholic fæces, and no calculi were passed. I observed her in two attacks of gastralgia. The pain was intense and distinctly located in the epigastric region, and radiated to both hypochondriac and lumbar regions, with syncope, a very small and weak pulse, and cold extremities. Morphine always gave relief. Local examination

revealed acute tenderness in the region of the gall-bladder, which could not be felt on account of tenderness. In four days the pain had ceased, no concomitant signs of gall-stones were noticed. At a second examination I found both kidneys movable and displaced. She had never had renal colics, and the urine presented no evidence of kidney lesion.

(It is said that gastralgia is often due to a movable kidney. This I have not observed in a series of nineteen cases. To be sure, there are reflex gastric disturbances of a neurotic type, but I have yet to see gastralgia due to movable or displaced kidney.) Pushing the right kidney back I felt a small, resistant tumor in the region of the gall bladder, which moved with respiration. Repeated examinations always resulted in finding this tumor. After the exclusion of other abdominal lesions, I made the diagnosis of cholelithiasis. Dr. Murphy examined the patient and agreed to the diagnosis Dr. Murphy removed two calculi—as large as nutmegs—from the gall-bladder, which was thickened and had contracted down around the calculi, thereby forming a distinct sac for each calculus—giving it the appearance of an hour-glass. Anastomosis was made with the duodenum by means of the Murphy button. The progress of the case was interrupted by an attack of acute dry pleuritis on the tenth day, which subsided rapidly and terminated in acute bronchitis. The button was passed on the twentieth day. The patient has been well since the operation. Her appetite has returned and the gastric catarrh underwent rapid improvement.

This completes a synopsis of three cases, wherein the gall-stones were as large as nutmegs, and gave rise to attacks of gastralgia, cholecystitis, constant gastric disturbances peculiar to chronic gastric catarrh, constipation, and general physical debility in consequence of defective digestion. The indigestion was not limited to any particular kind of food; indeed all foods, either liquid or solid, caused distress. Therapeutic remedies gave only slight relief.

The indications for operation in these cases were: 1. Gastralgia. 2. Persistent gastric disturbance. 3. Emaciation and physical exhaustion. 4. The possibility of complications, such as carcinoma and suppurative lesions. 5. The safety of operative procedure, and the improvement of health that invariably follows.

I also wish to report two other cases of cholelithiasis wherein the calculi were large, polyhedral and tetrahedral in shape, with large, smooth, faceted sides.

Case I.—Had been ill for a period of twelve years, with the following symptoms: Constant gastric disturbance, anorexia, general debility, exhaustions, and emaciation. She gave a history of having had one distinct hepatic colic, and claimed that she passed some small sand-like concretions. She never had jaundice, and according to her own statement no bile in the urine or acholic fæces. She also gave a history of slight chills followed by fever. The most constant symptom was pain in the right hypochondriac region whenever she worked in a stooping posture, or simply stooped. During all this time there was habitual constipation.

Local examination revealed the presence of a pear-shaped, smooth, and painful tumor in the region of the gall bladder. It moved synchronously with respiration, and could not be fixed by holding it between the two hands, something that always can be done with a movable kidney. It could be moved slightly from side to side, and since it appeared to be distinctly connected with the liver, and located in the region of the gall-bladder, as well as its smooth, globular shape, I made the diagnosis of gall-stone impaction. Dr. Murphy operated. Upon incising the gall-bladder a puriform fluid made its appearance and several calculi of the shape already described made an escape through the opening. Anastomosis with the duodenum was made by means of the Murphy button. Owing to the carelessness of the nurse I was handicapped in making thorough examinations of the stool after the operation; at all events the patient made a good recovery, gained in weight, regained her appetite, and was able to attend to her household duties when I last saw her. It is now over a year and a half since the button operation was performed.

Case II., which I mentioned in connection with appendicitis, gave a history of attacks of gastralgia every four or five weeks, but sometimes months elapsed before an attack made its appearance. Every attack was instantly relieved by vomiting. She had never had jaundice, bile in the urine, or acholic fæces. Here the calculi were unusually large; there were thirty-five, three of them were rounded and almost as large as nutmegs, the rest were of the same shape already described.

The details of this case have already been mentioned.

Among the cases of interest, I have in mind two where the calculi consisted of cholesterine entirely. One I have already mentioned in connection with renal colic, and therefore will not repeat it. The second case occurred in a lady, aged fifty-five years. She gave a history of having had colics five or six years, not oftener than once every three or four months. All the concomitant symptoms, such as bile in the urine, acholic fæces, and jaundice, followed the colics. When I saw her she had been sick two weeks. There was moderate jaundice, a large quantity of bile in the urine, acholic fæces, and colicky pains had persisted steadily, the constant use of morphine being necessary to subdue the violence of the pain. Beyond tenderness localized in the region of the gall-bladder, nothing abnormal was found in the abdominal cavity. Considering the history, the occurrence of jaundice within twenty-four hours after a decided hepatic colic, the constant presence of bile in the urine, and acholic fæces, together with the persistent colics, I diagnosed obstruction of the common duct, and recommended operation. Dr. Murphy operated, assisted by Drs. Lee and Hartmann and myself. The gall bladder was normal and contained no calculi. The cystic and common ducts were so obstructed by calculi that they felt like a string of beads. Dr. Murphy made an anastomosis with the duodenum, using his button for this purpose.

The colics ceased immediately after the operation. On the sixth day three round, semi-transparent cholesterine calculi were passed, each one about three sixteenths of an inch in diameter. These were passed without pain or colics, which substantiated Dr. Murphy's opinion, "that the calculi would fall back into the gall-bladder after the anastomosis was made."

On the seventh, eighth, and ninth days more calculi were passed, making a total of thirteen pure cholesterine calculi which had obstructed the bile ducts. The patient passed the button on the twentieth day after the operation, and never had an unpleasant symptom since. It is nearly a year since the operation. Here the Murphy button operation was certainly superior to the more difficult and dangerous procedure of cholecystotomy.

Owing to the rarity of pure calcium calculi in the gall-bladder, I shall give the history of one of two cases which I observed.

Mrs. X——, aged thirty-six, married, had never been sick and gave no history of hepatic colics. In 1888 she was suddenly seized with a distinct hepatic colic, followed within twenty-four hours by all the concomitant symptoms of cholelithiasis, such as jaundice, bile in the urine and acholic fæces. Local examination revealed tenderness in the region of the gall-bladder, which organ could not be felt. The hepatic colics were intense and continuous for a period of three weeks. During this time there was nausea and vomiting, and rather decided cholæmia. Finally, at the end of three weeks, I found an irregular, rather hard, white calculus in the fæces, which consisted almost entirely of calcium. Following its appearance the patient made a rapid recovery, and has had no recurrence up to the present time.

The other case resembled this in all respects.

It will be observed, from the histories given, that the classical symptoms of cholelithiasis, such as jaundice, bile in the urine, acholic fæces, and the passage of cal-

culi, were lacking entirely in five cases, and one case gave a history of twelve years' illness with only one distinct colic. These facts render a diagnosis extremely difficult, and sometimes impossible. The symptomatology therefore deserves special attention. In these five cases the most constant symptoms were gastric disturbance, such as gaseous distention, nausea, fermentation of foods during digestion, a constant sensation of pressure and slight pains in the epigastric region, and constipation. This condition may be so marked that the patient becomes emaciated, exhausted, and unable to perform ordinary physical exertions. This, together with attacks of gastralgia every two or three months, in conjunction with decided tenderness in the region of the gall-bladder during the attacks, completes the picture of subjective symptoms in these cases. A diagnosis by exclusion must be adopted and all other causes of the symptoms mentioned eliminated. Local examination is of the utmost importance, and must be practised in a suspected case. Where the calculi are large and patience is used, one can often feel a distinct rounded enlargement in the region of the gall-bladder, which is slightly tender and moves synchronously with respiration. A tumor in this region must be differentiated from carcinoma of the pancreas, echinococcus cysts, fecal accumulations in the colon, renal tumors, movable and displaced kidney.

In carcinoma of the pancreas we have cachexia, rapid emaciation, and sometimes fatty stools, an irregular tumor deeply seated in the epigastric region, and sometimes metastatic deposit in other organs. The tumor is generally fixed, and on auscultation one may hear a bruit due to transmitted pulsations from the underlying vessels.

When the common duct is obstructed in carcinoma of the pancreas, there will be intense and constant jaundice, bile in the urine, and acholic fæces, coincident with a distended gall-bladder, which can be distinctly felt as a rounded, smooth, fluctuating, and pear-shaped tumor, encroaching on the anterior margin of the liver; sometimes atrophy of liver tissue takes place at the point of contact. This tumor moves with the respiratory movements and is distinctly connected with the liver. In order to determine the cause of hydrops of the gall-bladder in these cases the history is of importance, and in connection with it the symptoms mentioned will make a diagnosis possible. It should not be forgotten that cholelithiasis may also be present.

Echinococcus cysts rarely originate in the region of the gall-bladder. When by reason of extreme size or central origin in the liver they occlude the bile-ducts, we will observe that, first, the jaundice developed without pain; second, it is persistent; third, the gastric functions are generally undisturbed; and fourth, other physical signs of echinococcus cyst would exclude cholelithiasis.

Fecal accumulations in the transverse colon present the following symptoms: An irregular mass, superficial, non-fluctuating, and freely movable, coupled with a history of bowel obstruction, intestinal colics, and constipation. Cases have been observed where diarrhœa was present. The treatment with purgatives will remove all doubts.

Renal tumors, when smooth and symmetrical, may simulate a largely distended gall-bladder to such an extent that a diagnosis is made with difficulty. Renal tumors are of slow development and are always accompanied by changes in the quantity and quality of the urine, which may contain albumin, blood, pus, casts, and be diminished in quantity. There may also be a history of renal colics and vesical irritability. In a large hydrops of the gall-bladder the onset is generally sudden and painful, and by reason of its size gives rise to symptoms of bowel obstruction. This I observed in two cases. The distended gall-bladder is generally fixed, smooth, rounded, fluctuating, and pear-shaped, and very tender on pressure when the distention is acute.

Renal tumors when large are more resistant, have an irregular surface, and generally the colon overlies the tumor. In hydronephrosis the enlargement is smooth globular, and fluctuating, and bears a striking resemblance to hydrops of the gall bladder.

Especial attention must be directed toward ascertaining: 1, A history of sudden increase in the quantity of urine voided and a corresponding diminution in the size of the tumor; 2, diminution in normal quantity of urine; 3, the presence of renal colics and lumbar pains; lastly, it may depend on pelvic enlargements which have occluded the ureter on the right side.

Movable kidney differs from distention of the gall-bladder as follows: 1, It is bean-shaped; 2, it is freely movable and can be replaced to its normal location; 3, it does not move with the respiratory movements; 4, it can be fixed between the hands in spite of the respiratory movements; 5, there may be a history of renal colics; and lastly, there is no history of jaundice, bile in the urine, and acholic fæces. It should not be forgotten that movable kidney and cholelithiasis may exist together. I have given the history of two cases. In case the kidney is displaced and fixed under the liver, the diagnosis is more difficult. Careful analysis of the symptoms and history will always render diagnosis possible.

It is important to mention the physical characteristics of gall-bladders which have become elongated and divided in two or more sacculi, each one containing a calculus. A local examination reveals the presence of a rounded elongated tumor which admits of being freely moved from side to side. It can be traced to the region of the gall-bladder and is attached to the liver. In connection with the history of the case a diagnosis can be made.

This brings us to the complications of cholelithiasis. They are: 1, Obstruction of the common duct; 2, impaction of gall-stones and suppuration in the gall-bladder; 3, hydrops of the gall-bladder; 4, contraction and almost entire obliteration of the gall-bladder, and a deposit of connective tissue with adhesions to the surrounding organs; 5, carcinoma of the gall-tracts; 6, obstruction of the cystic duct; 7, cholecystitis with thickening of the gall-bladder and its division into several diverticulæ: 8, hepatic abscess; 9, rupture of abscess in the colon, kidney, stomach, duodenum, and through the abdominal wall; 10, rupture of the gall-bladder or bile-ducts; 11, obliteration of the common and cystic ducts.

It is not out of place to say a few words about the symptomatology of the complications. Rupture of the gall-bladder or its ducts generally occurs suddenly during an attack of hepatic colic. I can best describe the symptoms of this accident by citing one of two cases which I treated. A merchant, whose case has been mentioned in this paper, was seized with an ordinary hepatic colic; feeling a desire to evacuate his bowels he went to the closet, and while straining felt something give way suddenly. Thereupon the hepatic colic immediately ceased and was replaced by syncope, cold sweats, and a feeling of extreme weakness. Two hours later I saw the patient and found his condition to be as follows: Rapid, weak, and thread-like pulse, cold extremities, dyspnœa, and decided abdominal tympanites; in fact the patient was apparently dying. Dr. Murphy performed cœliotomy in the hope that drainage would save life. The abdominal cavity was full of biliary fluid; the intestines floated on the latter. Death occurred on the third day and an autopsy was refused. The second case was almost identical with the first. An operation by Dr. Murphy substantiated the diagnosis.

When carcinoma of the gall-tracts develops in the course of cholelithiasis the patient rapidly loses in weight, and ordinarily the jaundice becomes intense and persistent, with all the concomitant symptoms of bile obstruction. Local examination reveals uniform tenderness over the gall-bladder and along the liver-margin. Sometimes it is possible to feel carcinomatous nodules which completely obstruct the bile-ducts. The following case will be of interest and serve as an illustration:

Dr. Allaben, of Rockford, Ill., to whom I am indebted for the history, and who referred the patient to me, had

made the diagnosis of cholelithiasis. The case was a typical one, and accompanied by jaundice, bile in the urine, and the passage of calculi after every hepatic colic. Suddenly jaundice developed without a preceding colic, it was persistent and accompanied by rapid emaciation, occasional vomiting of mucus and undigested food. There was no recurrence of hepatic colic. He also had chills and a temperature rising from one to three degrees. This, together with decided tenderness in the region of the gall-bladder and along the liver margin, as well as the presence of a nodular mass in the region of the gall-bladder, completed the picture of this case.

Owing to the intense jaundice and its time of occurrence, as well as the concomitant symptoms, the diagnosis of gall stones with carcinoma and probably suppuration was made. Operation by Dr. Lee found the gall-bladder contracted and shaped like an hour glass. The outer portion contained a large calculus firmly fixed, and consequently it could not be removed. The inner portion contained a greenish puriform fluid. A nodule was also felt. Death followed in twelve hours. Autopsy brought to light what has already been mentioned. The common duct was completely obliterated and surrounded by a carcinoma as large as a hickory-nut. Metastatic deposits were found in the liver and elsewhere.

It is not possible to predict the pathological changes in many cases of cholelithiasis. Sometimes those where the symptoms have been comparatively mild present the most decided pathological changes, and *vice versa*.

We now come to the treatment of gall-stones, which can properly be divided into two classes, viz.: Therapeutic and surgical. It would not be consistent with the present medical knowledge to give the details of every remedy which has been used. Among those which have claimed the greatest attention are such as olive oil, arsenic, iron succinate, the mineral acids, and saline laxatives. It cannot be claimed that any of these, and others not mentioned, act as solvents of gall stones. Moreover, were it possible to dissolve them as contained in the gall-bladder, we would not cure but merely remove the effect of a cause which is yet a mystery. No doubt the medicines are of value in relieving concomitant conditions, such as constipation, gastric disturbance, etc.; thereby temporary improvement is procured. Laxatives probably encourage the elimination of calculi by reason of their action on the intestines and bile secretion. Diet and the regulation of living have a good effect, as they do in other diseases.

Since it would be useless to say more about the therapeusis of cholelithiasis, I will discuss the surgical procedures and the indications for interference. When we would operate, is a question that admits of much argument, particularly so when the patient has been made to believe that this, that, or the other medicine will dissolve the stones. I recall a case where olive oil had been administered; the patient passed a number of soft greenish masses consisting of fatty substances. And lo! the people and others declared that they were gall-stones which were partially softened by olive oil; that mistake is sometimes encouraged by the attending physician.

The indications for operation are: 1. Hepatic colics, coming on every four or five days for a period of several months, with passage of calculi. 2. Obstruction of the common duct by a calculus, with cholæmia and gall-bladder dropsy. 3. Hydrops of the gall-bladder, of acute development, with obstruction of the cystic duct. 4. Persistent gastric disturbances with occasional attacks of gastralgia, physical exhaustion and anæmia, and the presence of tumor in the region of the gall bladder. 5. Suppurative cholecystitis, due to gall stones. 6. Continuous daily hepatic colics, with signs of bile-duct obstruction, and the absence of calculi in the fæces. 7. The possibility of dangerous complications, such as rupture of the gall tract, carcinoma, adhesions, etc. 8. Hepatic abscess, due to gall-stones. 9. Impaction of gall-stones in the gall-bladder. 10. The comparative safety of operative procedures.

Among the operations ordinary cholecystotomy is most generally practised, and with the present methods has given good results. The ideal operation consists in making an anastomosis between the gall-bladder and the duodenum, called cholecyst-duodenostomy. By this method we imitate to an extent the normal physiological conditions, and meet the usual indications of cholelithiasis. The gall-bladder is drained thereby, and the bile flows into the intestine when the cystic duct is not obstructed. There is no fistula left. In my own practice that useful and ingenious contrivance, the Murphy button, has been used four times in making an anastomosis. These cases have been under my observation over a year and a half, and are in the best of health to-day.

I believe that sufficient time has elapsed to demonstrate the safety of the operation as it is done with the Murphy button, and recommend it wherever the condition of the organs will admit of its use.

I wish also to add that the four cases under my observation were of a widely different type. In Case I., the gall-bladder was enormously distended and œdematous; in Case II., the gall-bladder was normal in size, its walls thickened, and contained a purulent fluid; in Case III., normal gall-bladder with calculi obstructing the common and cystic ducts, which subsequently fell back into the gall-bladder; Case IV., thickened and sacculated gall-bladder.

Another point in favor of this operation is the impossibility of a return of gall stones, and the certainty that all the calculi will escape from the gall-bladder.

In cholecystotomy it is possible to leave calculi in the gall-bladder which may occasion considerable trouble. Someone made the statement that the operation of cholecyst-duodenostomy with the Murphy button favored infection of the gall tracts; this is not possible; first, because bile being aseptic and sterile, would to an extent overcome this danger; second, infection with the bacillus communis coli (which is generally found in suppurating lesions of the gall tracts) is harmless when not confined, as has been amply demonstrated by Naunyn.

In any of the cases under my own observation, where the Murphy button was used, no infection occurred.

I wish to add that, up to the present date, I have the reports of thirty-four cases of cholecyst-duodenostomy done with the Murphy button for gall-stones; of this number one died, making thirty three recoveries and one death.

LANDMARKS OF VISCERAL DISEASE, WITH A NEW THEORY.

By BYRON ROBINSON, M.D.,

CHICAGO, ILL.

Useful works on applied anatomy and pathology of the abdominal viscera are very scarce. I do not know any subject in medicine of which the general student and practitioner is so lightly supplied. It must be acknowledged that the abdominal cavity is filled with a complicated mechanism which holds body and soul together; it is the assimilating laboratory of life, the location where food is worked into blood, bone, and tissue. This cavity is less generally known than the cerebro spinal cavity.

In this article I wish to speak of what one sees in opening the abdomen in dead bodies. One has not the right to attempt to study very much on the viscera while laparotomy proceeds. I also think that by disseminating some real, practical knowledge of the abdominal viscera unnecessary laparotomies may be spared. To-day there are too many laparotomies done by unskilled physicians without proper facilities. In speaking of the landmarks of visceral disease I mean the points of the viscera where disease is apt to arise. Probability is the rule of life, and when we find in autopsies that certain viscera and certain localities are liable to show pathological conditions it is wise to look after these same points during life. The comparison of the pathology found in the dead abdomen

with that of the living gives ample rewards to the thoughtful surgeon and physician. The great phenomenon in the dead abdomen which leads one to the origin of disease is peritonitis. Inflammation of the serous sac may refer one back a quarter of a century to events long forgotten, but the "blaze" on the peritoneum, like that of the surveyor on the tree, remains to tell the story of invasion. If one will carefully examine at least twenty-five adult bodies as regards the abdominal viscera he will be liable to observe the main common visceral disease. It will require at least twenty-five autopsies to be impressed with the idea that, after all, visceral disease has a peculiar similarity, a liability to be alike in each body. Visceral disease has common grounds to start on and common organs to attack. It persists in definite localities and has many common symptoms. Visceral disease is much like meals, which are generally composed of a few common articles. Meat, bread, and potatoes are the common articles found in most meals. So, for example, one can find with a similar commonness that autopsies reveal peritonitis in the pelvic, appendicular, and gall-bladder region. On first opening the abdomen one will soon generally observe whether peritonitis has existed by the position of the omentum—the surgeon's friend, the patient's man-of-war. If peritonitis has existed the omentum, or a part of it, will generally be found trying to quell the fire by covering it up with adhesions. The omentum has covered up the infectious invader and buried the slain of the battle. It has guarded the parts where infection is liable to enter. In seventy-five per cent. of bodies the omentum tends to the left and reaches to the pelvis. In some it is rolled up around or behind the transverse colon. Sometimes we find the omentum so thick and large that scarcely a viscus is in sight. Now, there are greater and lesser districts of peritonitis in the abdomen. All peritonitic districts depend on certain weak points of viscera. These peritonitic regions are places where disease arises in viscera, for peritonitis is a secondary matter. The great peritonitic districts are—*a*, the pelvis; *b*, the appendix; and *c*, the gall-bladder. These are the three great regions of peritonitis in man. I have scarcely posted an adult body which has not some trace of peritonitis in one of these three major regions. In these peritonitic districts is where abdominal surgery has made progress and where life has been many a time and oft saved or snuffed out. These three regions have tolerated infectious invasion so long that they resist it and almost always save life by producing a peritonitis which buries the invaders in exudate forever. It must be remembered that peritonitis is a life saving process, while it is infection that kills. Peritonitis is nature's method of repair. If it were not for peritonitis the people would soon be swept from the earth. Peritonitis produces exudates which bury and starve the invading deadly germs. Now, there are other regions of peritonitis which I call minor districts. We have inflammation around the sphincters (pylorus and ileo-cæcal valve and anus), which is common in adults, though limited in extent. Again the flexures of the colon suffer (hepatic, splenic, sigmoid) from inflammation. Peritonitis is common around the colonic flexures. The reason is that as the solid fæces, containing sharp, rough, foreign bodies pass around the acute angles of the flexures the mucous membrane becomes abraded and torn so that the way lies open for germs and infection to pass into the gut-wall and peritoneum. At these sphincters and flexures malignancy as well as cicatricial strictures are apt to arise. The hernial orifices are very apt to catch some portion of the gut and inflame it, starting up peritonitis. Also we have what I designate as accidental peritonitis, *i.e.*, from some perforation or trauma in some portion of a viscus outside of what has been designated as a distinct peritonitis district (major or minor).

What I wish to present in this paper as original, as I have never seen it in a book nor heard it from anyone, is the peculiar inflammation or peritonitis which occurs around the cæcum and under the sigmoid, as it crosses the psoas muscle. For a long time in autopsies I have been carefully observing local peritonitis, and particularly my attention has been called to two points whose explanation did not seem satisfactory. The peculiar, apparently benign inflammation which one can so frequently see around the cæcum, and just under the sigmoid as it crosses the psoas muscle, cannot be wholly due to appendicitis nor to the acute angle of the sigmoid. First, the pericæcal adhesions are entirely out of reach of the appendix. In fact, it is the most distant from it. I admit that the appendix is often movable and may create inflammation in a locality and then leave it to lie in another region. But physical circumstances were such in many cases that it appeared unreasonable that the appendix could produce such old adhesions. Really there is a kind of pericæcal adhesion and a kind of appendicular adhesion. These kinds of adhesions may be totally separate and distinct by physical spaces. Now, how do I account for the inflammation around the cæcum which is not appendicular? The answer is that it is due to the relaxation and contraction of the psoas and iliac muscles. The majority of cæca lie partly on the psoas muscle and partly on the iliac muscle, and in walking these two muscles are continually contracting and relaxing. Should the cæcum be congested or even inflamed the irritation produced in these muscles would cause an exudate which would organize and result in bands. Again, as the sigmoid crosses the psoas on the left side, I have seen the peritoneum or its mesentery inflamed so often that I looked a long time for a cause. The cause, in my opinion, is due to the contraction and relaxation of the psoas and iliac muscles. This is a clearer case than the cæcal region, for the old peritoneal inflammations are so frequent and entirely isolated from all other fields and sources of inflammation. The old bands, dense adhesions, and thick, new cicatricial tissue so frequently found just under the sigmoid as it crosses the psoas muscle can be accounted for, so far as I can see, only by an irritation arising out of the psoas and iliac muscles. It must be chemical or mechanical peritonitis due to irritation. This explanation will give a new view to all the isolated adhesions around the cæcum as not being due to rupture of the appendix.

In nineteen autopsies made by me in special reference to the abdominal viscera, where every point was observed in regard to peritonitis and an attempt made to measure almost every viscus, I found over seventy-five per cent. of old adhesions resulting from peritonitis existing around the cæcum. I can say that many of the adhesions were entirely isolated from the appendix. In the same autopsies we found thirteen cases out of nineteen with distinct old peritonitic adhesions under the sigmoid as it crosses the psoas muscle. In many cases the peritonitic adhesions under the sigmoid were entirely isolated from all other fields, and many were in men, so that the tubal end could not empty its infection there, just exactly on the psoas, immediately under the sigmoid bend.

It cannot be explained by the flexure in the sigmoid, for it is not sharp enough. In these very cases the sigmoid was almost straight over the adhesions, and therefore could not become angular. When Albers, of Bonn, said, over two generations ago, that the cæcum was the disturbing element in man's trouble in the right iliac fossa, he had a grain of truth on his side, for there do exist old adhesions around the cæcum separated from the appendix which do not appear connected with the appendix. It must not be forgotten that about all fatal pathology lies in the appendix. I am mathematically investigating one hundred cases of autopsies on the abdominal viscera. So far I have done with as much care as possible nineteen autopsies of this proposed one hundred, and many interesting revelations have arisen. Further investigation will either confirm or deny this theory.

The Death-rate of Montreal has fallen from 37 per 1,000 in 1872 to 24 per 1,000 in 1892.

ELECTRIC LIGHT AS A DIAGNOSTIC AND THERAPEUTIC AGENT.[1]

By MARGARET A. CLEAVES, M.D.,

INSTRUCTOR IN ELECTRO-THERAPEUTICS, NEW YORK POST GRADUATE MEDICAL SCHOOL.

The attempt to illuminate the less accessible cavities of the human body had its origin as long ago as the beginning of the present century. Bozzoni, in 1805, first conceived the possibility of throwing light into the bladder, but without much success. In 1853 Desormeaux exhibited the first endoscope before the Paris Academy of Medicine. Julius Bruck, of Breslau, is said to have first employed the platinum loop as a source of illumination for medical work. In 1867 he exhibited a stomatoscope designed to assist in examining the rectum and bladder. These old instruments were cumbersome and inefficient, but Nitze and Leiter have constructed a cystoscope which has achieved remarkable success.

The use of the electric light in medicine now covers a much larger field and has become an important aid in diagnosis. By it the dentist can detect spots of decay in the tooth which without it would escape his observation. The nose and throat specialists are able to search the minutest recesses, while the physician who is in doubt regarding certain diseased conditions of the stomach and abdomen, may literally study his obscure cases in a new light.

In 1885 Dr. Louis J. Lauterbach, of Philadelphia, published an account of the use of the incandescent electric light in examinations of the eye, ear, and throat. He recommended for illumination of the ear the use of a tiny lamp placed close to the speculum and enclosed in a shield having a small circular opening in it.

In 1890, Theodor Heryng was able to illuminate the antrum of Highmore by using a five-volt incandescent lamp attached to a tongue depressor. He was able in more than thirty cases to diagnosticate latent empyema without exploratory puncture, and this diagnosis was corroborated by the subsequent removal of the pus.

About two years ago Davidsohn called attention to the value of illuminating the eyeball by an incandescent lamp in the mouth. Quite recently Burger has claimed that luminous sensations in the eyeball were far more distinctive tests than illumination, as a very feeble light was sufficient to excite the subjective sensations.

On November 1, 1893, the writer had the pleasure of demonstrating this point to a number of medical persons by introducing an incandescent lamp into the mouth. On the lamp being illuminated the pupils of the eyes were seen as blood-red apertures, and it was also shown that if the person so illuminated cast his eyes upward at an angle of 45° he could discover the same phenomenon. Mr. N. Stevenson has called attention to the curious fact that when light is thus introduced the pupils do not contract.

Dr. D. Braden Kyle, of Philadelphia, has recently introduced some improvements for examining the nasal cavity. The essential feature of his method is the placing of the lamp within the post-nasal space so that the parts are seen by direct instead of by reflected light. He also recommends that the lamp be protected with a cap of aluminum, by the aid of which it can be used continuously for thirty seconds without inconvenience from heat. This lamp was furnished by Charles Leutz, of Philadelphia.

Within the past few months Dr. Charles W. Caldwell has published an article in which he has considered the subject of transillumination of the mastoid cells as a means of diagnosis of mastoiditis interna suppurativa. The examination must be made in a perfectly dark room. When the lamp is inserted well into the external auditory meatus and the current turned on, the healthy mastoid is illuminated with a red glow, extending from the apex to the lateral sinus and to the limits of the cells above. By placing the lamp on different parts of the mastoid the limitation of the cells and the position of the lateral sinuses may be accurately mapped out, and pathological conditions demonstrated if present. If there is a purulent condition in the cells this portion will appear dark. Comparison with the opposite healthy side renders the diagnosis of pus in the mastoid cells complete, whether or not the usual symptoms are present.

The same observer has also described a method of transilluminating the accessory sinuses of the nose, by which he was able to detect a large mucous polypus by its translucency, higher refraction, and globular form, which concentrated the light, and increased the brilliancy of the illuminated area.

Dr. Chevalier Jackson, of Pittsburgh, has also practised transillumination of the nose successfully for some time past. His method differs somewhat from that previously described, as he uses a fifty-candle-power lamp and a hollow silvered glass rod.

As an instance of the great clinical value of electric illumination in diseases of the nose and throat a case of tubercular laryngitis has been reported in which no tubercle bacilli could be found in the expectoration, but on passing an applicator deeply down into the passages under the guidance of a brilliant electric light, some secretion was found, which on removal proved to contain innumerable tubercle bacilli.

The work of Dr. Max Einhorn in connection with the transillumination of the stomach is well known. His "gastrodiaphane," first described in November, 1889, consists of a soft rubber stomach tube containing wire conductors and having a small Edison incandescent lamp mounted at the gastric end of the tube. By its aid the examination is performed so quickly that there is no danger of the lamp becoming too hot, especially as the water in the stomach (swallowed by the patient just previously) exerts a cooling action upon it. Dr. D. D. Stewart, in the *Medical News* for February 18, 1893, speaks of the value of gastrodiaphany as follows: "The actual utility of gastrodiaphany over other methods of outlining the stomach lies especially in the application of the diaphanoscope to the differentiation of gastroptosis and gastrectasia, as by it the determination of the site of the lesser curvature is far more readily made than by inflation."

Theodor Heryng has succeeded in transilluminating the anterior walls of the vagina. With the help of a Ferguson speculum he was also able to insert an electric apparatus into the rectum and so transilluminate the posterior wall of the vagina as far as the posterior fornix.

With reference to apparatus, it is a matter for regret that much of the intended experimental work has not been done on account of the great difficulty experienced in securing suitable lamps.

The W. F. Ford Surgical Instrument Company have furnished a lamp for transillumination of the frontal sinuses, also one for the transillumination of the antrum of Highmore, and a head lamp. The Galvano-Faradic Manufacturing Company have furnished a small mouth lamp for general use. The use of a lamp has also been secured for the transillumination of the bowel, known as Hertyng's lamp, and a lamp for the transillumination of the pelvic tissues devised by myself. These lamps have all been personally tested, with the following results:

Ford's head lamp requires 10½ volts and 1 ampère, and gives 3-candle power. For use with a street current, it should be placed in circuit with one 16 and one 24-candle-power lamp. Ford's lamp for the transillumination of the frontal sinuses requires 8 volts and .8 ampère and gives about 2-candle power. For use with street current two 16 candle-power lamps should be placed in circuit. Ford's antrum lamp requires 8 volts and .8 ampère and gives a little over 2 candle power. For use with the street current, one 16 and one 24 candle-power lamps are needed. The lamp supplied by the Galvano-Faradic Company, requires 5½ volts and .8 ampère and

[1] Read before the American Electro-therapeutic Association, September 27, 1894.

gives a little over 1-candle power. For use with street current it requires two 16 candle-power lamps in circuit. Hertyng's lamp for transillumination of the bowels has a shield or cap over it with an attachment to a fountain syringe so that water is allowed to flow about the lamp and also through the terminal opening into the bowel itself. It requires 9 volts and .7 ampère and gives a little over 2 candle power.

The lamp for the transillumination of the pelvic tissues, devised by myself, requires 32 volts and .8 ampère, giving about 8-candle power. It was intended to be a 20-candle-power lamp, but as it passed through a chapter of accidents, it is at present only an 8 candle power, but will be replaced shortly by one of 20 candle power. The lamps variously used and the results obtained from them have already been indicated in the report. The Edison lamp or condenser for direct illumination of the different cavities of the body has also been tested. It is best suited to positions in which the direct rays of light may be used and is also satisfactory where the light has to be reflected.

So far as the transillumination of the bowel is concerned, nothing has as yet been done. A number of observations have been made in transillumination of the pelvic tissues. As a result of these it is found that wherever there is morbid material, either in the form of exudative matter or abnormal growths, as fibroid tumors, sarcoma, etc., the tissues of the anterior pelvic and abdominal walls are not transilluminated but remain absolutely black. In the abnormal conditions which have been examined the pelvic cavity has been pretty well filled, so that there has been no transillumination. Of course with the morbid material on one side only, the other side should be transilluminated. In so far as the writer has done any work in this direction, she regards transillumination of rather doubtful utility. The conditions can be much more accurately determined by means of the educated finger than by any candle power of electric light that has yet been used.

I have been able to obtain translucency of the tissues within two inches of the umbilicus, but have demonstrated nothing save the course of blood-vessels.

The foregoing statements give a fair idea of the use of electric light in diagnosis, but they by no means compass all the methods by means of which electric light is helpful in therapeutics. One of the recent adaptations is known as the electric-light bath, and is based on the proposition that the properties of electric light are similar to those of sunlight. By means of a suitably constructed cabinet, patients are subjected to the rays of a number of incandescent lamps. The temperature can be regulated by passing the current through a resistance coil and may vary between 90° and 150° F., with a result equivalent to a combined light and vapor bath. The skin is browned as if by sun-burn and the effect is claimed to be most salutary.

The writer has had placed in her hands for use an apparatus furnished by a manufacturer of Newark, which is worthy of attention as a means of experimental work. It is a cabinet with an arc light arranged in front of a large tin reflector which can be raised or lowered at will. This and a lamp with a very strong lens and reflector for localization of the rays of light are the only apparatus which have been placed at my disposal. It is impossible, therefore, to say which form of apparatus is best. No observations have yet been made as to the efficacy of the light used through glass or similar substances, nor have investigations been attempted which would enable me to arrive at any conclusion as to possible difference in therapeutic effect between electric light and solar light.

Turning now to a consideration of the effect of light on living organisms we find that plants have been forced into rapid growth by exposure to the rays of the electric light. M. D'Arsonval has made many investigations on the effect of both sunlight and electric light on various bacterial growths. He found that cultures exposed to the white rays were not colored while those exposed to the red rays had developed pigment. He also expressed the opinion that light exerted a more powerful influence over bacteria than ozone or even oxygen.

Dr. H. Marshall Ward in a paper read before the Royal Society showed the effect of light on bacilli from the Thames, and found that in all cases both solar and electric spectra exerted no perceptible action whatever in the infra red, red, orange, or yellow region, while all the bacteria were injured or destroyed by the rays from the blue or violet spectrum. The intervention of a thin piece of glass resulted in cutting off a large proportion of the effective rays. The most distinctive rays, *i.e.*, those at the end of the blue and beginning of the violet, were to some extent effective even after reflection from the inner faces of a quartz plate covering the film, and the glass on which it was supported. This investigator goes on to say that these results evidently suggest that the naked arc light may prove to be a very efficient disinfecting agent for use in hospital wards, railway carriages, and other places where the rays could be projected directly on the organisms.

Theodor Geisler in 1892 found no qualitative difference between sunlight and electric light, only a quantitative difference. In the course of some experiments on the typhoid bacillus, he found the most decided effect was produced by the rays from the violet end of the spectrum.

P. A. Khmelevsky, of St. Petersburg, after prolonged experiments, concluded that both solar and electric light have an undoubted inhibitory influence on the growth of microbes.

Klebs-Loeffler has discovered that diffused light does not prevent the development of cultures of diphtheria at ordinary temperatures or at a temperature as high as 95° F., but that sunlight arrests this development, and after an exposure of several days sterilizes bouillon. This bactericidal power of light toward the bacillus of diphtheria is due almost exclusively to the rays of greatest refraction, those at the other end of the spectrum having little or no action of this kind.

Some years ago experiments were made with Jablochkoff candles in the Paris sewers, with the result that considerable purifying action was noted.

In 1881(?) Mr. Harold P. Brown, E.E., of New York, while using Brush arc lamps for lighting the basement of a store in Chicago, noted that within an hour after turning on the current, the odor from the closets, which at first was very offensive, became entirely neutralized.

The writer, who has an arc-light apparatus in her office such as has been described, made the following observation on a recent excessively hot day. The refuse barrels which had accumulated over Sunday in the basement and had not yet been removed Monday morning, emitted a very unpleasant odor, which filled the office. The arc light was turned on and the writer left the room for half on hour. On her return she found that every evidence of odor had disappeared and that the air seemed perfectly pure, while in another part of the house which was not near enough to be affected by the light, the odor still persisted as before. This action was undoubtedly due to the ozone.

In an article in *The Medical Week* for August 17, 1894, Dr. R. L. Boqles gives some interesting facts regarding the influence of solar rays on the skin and concludes that some other principle must be at work beside heat. Some observations of M. Charcot tend in the same direction. The phenomenon appears to be due to the action of the chemical rays in the ultra violet end of the spectrum. Mr. H. B. Hewetson, in the *British Medical Journal* for 1893, cites five cases in which eyes became inflamed after watching the operation of electric wiring by the arc light, unless the observer was protected by a shield of thick ruby glass. It was found that the skin of the face and neck would become tanned and would peel off just as if it had been exposed to the rays of the sun. This was evidently not due to heat but to the chemical rays.

M. Gautier has recently investigated a curious phenomenon, namely, that substances which have been submitted to the action of electricity or which have been exposed to the direct rays of the sun, are in a peculiar state of excitement which renders them much more active as regards one another than are the same substances prepared by the ordinary methods of the laboratory.

Such being the admitted facts, one is prepared for the assertion that electric light may be made a potent therapeutic agent. Dr. Gatchkowski, St. Petersburg, 1892, reports twenty-seven cases, chiefly of rheumatic and neuralgic pain, which he had quickly cured by the electric light, and Stanislaus von Stein also reports good results.

Few observations have yet been made by the writer as to the therapeutic value of electric light. Something, however, has been done, as the following particulars will show. In one case of cervico-occipital neuralgia of great severity, coupled with supra-orbital neuralgia, the application of the electric light was found to be exceedingly grateful to the patient and resulted in relief from pain for several hours. In a case of intense pain in the roots of the cervical cord, an extension of neuritis, the only way the patient was able to get sleep, without hypnotics, was by having an electric lamp placed directly over the cervical cord. In this instance, however, it is believed that the heat only produced this grateful result.

The following experimental observation is reported somewhat at length:

J. C——, twenty-one years of age; suffering from anæmia and enuresis. The electric arc-light bath was given for twenty minutes. The patient was placed upon a stool with the entire body exposed to the rays of light, special attention being paid to localizing it at the lumbar and sacral plexuses. The treatment was entirely experimental, but with the expectation of, at least, improving the nutrition. The writer felt willing to undertake it, as she was confident of being able, later on, to cure the enuresis by long percussive static sparks. The patient had suffered from nocturnal enuresis as far back as she could remember. Menstruation was established at seventeen and was perfectly regular. All the conditions were normal save that the patient was decidedly anæmic, and suffered from facial acne. The pupils were always dilated, and there was a tendency to constipation, the bowels often moving but once in two days—rarely two or three days consecutively. The wet nights were slightly variable; she would sometimes go in summer two or three nights without trouble, but rarely for this time in winter. In all, sixteen treatments were given, extending over a period of one and a half months, three times weekly. Careful examinations of the urine were made at first, and the pulse, temperature, and skin were carefully watched. Thirteen observations were taken of the temperature and pulse. In eleven instances the pulse dropped, and it was always of better volume after the bath. In two instances the pulse remained unchanged but its volume improved; while in every instance (thirteen times) there was a rise in the temperature of from one to eight degrees. The skin always became moist under the applications, and during the last treatments was very profuse. There was a general sense of well-being expressed by the patient after each application. Soon after coming under treatment the bowels became regular, and there was no trouble during the time she was under care, nor since then, a matter of nearly six months, excepting for a few days at one time after discontinuance of treatment, when very much hurried making preparations for leaving the city. The urine was analyzed from time to time, and showed a steady increase in the amount of urea eliminated The patient gained a pound and a half during the first two weeks, and since that time has gained seven pounds more, and is in better health than for several years. The temperature of the bath varied on different days, being affected by the outside temperature, but it ranged from 90° to 100° F., and the patient left the office feeling much better. No drug of any sort was given or allowed the patient during the time she was under observation.

Arrangements have just been made with a dermatologist to have observations made as to the value of arc light in parasitic skin disease, and, in fact, to carry out a systematic series of scientific experiments bearing upon these points. The writer is well aware that the value of one or two experimental cases is open to question, but under the special circumstances already referred to has thought well to mention the few cases quoted, wishing it to be distinctly understood that she considers the investigation very incomplete in its present stage.

It is interesting to note that Dr. Dawson Tyner, of London, commenting upon the well-known treatment of goître by smearing the part with red iodide of mercury ointment and then exposing the surface to direct sunlight, suggests that the effect is due to the power of iodine to cut off the visible rays of the spectrum. The fact that red iodide is the more efficacious points in this direction, for it would serve to transmit the heat rays only. In this way the part is subjected to the full blaze of the calorific rays without the vibrations of its molecules being altered by the visible rays. If this theory be correct we could expose diseased parts to sunlight or to a fire after the application of iodine. May not this suggestion give us a valuable hint in connection with the use of the electric-light bath.

And now, after studying this novel and interesting subject until we have begun to form some adequate conception of the potency of light, we are confronted with the rather startling announcement, from no less a physicist than Professor Dolbear, that there is no such thing as light—that there are no peculiar waves which can be called light. In proof of this assertion he describes a method of taking a photograph of an object in absolute darkness by means of the ether waves set up by working an electrical machine. We have already seen how similar are the effects of sunlight and the electric light, but lest there should still be a lingering doubt in the minds of some individuals regarding this point, that distinguished experimenter, Nikola Tesla, comes forward and produces a faint glow of light in a dark room with alternating currents of 800,000 voltage, by means of atmospheric vibrations to such an extent that the phenomenon would no longer be electricity, but light!

68 Madison Avenue, New York, October 30, 1894.

Who Fed Fevers?—The story of the physician who wished to have as his epitaph, "He fed fevers," has been told, the saying being usually attributed to Stokes. Dr. Julius Althaus writes to the *British Medical Journal* that it was Graves who said this. In the biographical notice of Graves which precedes his edition of the latter's "Studies in Physiology and Medicine," Stokes says: "Graves was going round the hospital, when, on entering the convalescent ward, he began to expatiate on the healthy appearance of some who had recovered from severe typhus. 'This is all the effect of our good feeding,' he exclaimed; 'and lest, when I am gone, you may be at a loss for an epitaph for me, let me give you one in three words:

"'He fed Fevers.'"

Trousseau has alluded to this point in his introduction to the French translation of "Graves's Clinical Lectures," where he says: "Graves's maxims relating to the regimen of fever have become the guide of practitioners of all countries; yet when he inculcated the necessity of giving nourishment in long-continued pyrexias, the Dublin physician assailed single handed an opinion which appeared to be justified by the practice of all ages. Had he rendered no other service than completely reversing medical practice upon this point, Graves would, by that act alone, have acquired an indefeasible claim to our gratitude."

MAY THE SHOCK OF A RAILROAD ACCIDENT EVER BE BENEFICIAL TO THE RECIPIENT?[1]

By RICHARD C. NEWTON, M.D.,

MONTCLAIR, N. J.,

SURGEON TO THE NEW YORK AND GREENWOOD LAKE RAILROAD; ATTENDING SURGEON TO THE MOUNTAINSIDE HOSPITAL; PHYSICIAN TO THE ESSEX COUNTY PENITENTIARY; LATE CAPTAIN AND ASSISTANT SURGEON UNITED STATES ARMY.

My excuse, if one be needed, for selecting the above subject for a paper before this learned body is that a brief consideration of the possible benefits of a railroad accident may prove of interest and profit, if for no other reason, simply because we have been made so familiar with the injuries, both immediate and remote, which a railroad accident may inflict upon its unfortunate victims, that it may be worth our while to consider the other side of the question, and to dwell for a few moments upon the benefits, if any there be, which may follow such an accident.

The great variety and extent of railroad injuries afford to this branch of surgery an interest peculiarly its own. The railroad surgeon is called upon to treat lesions more variable and complex than those that usually come under the care of the military surgeon. In war it is true that men are horribly wounded by missiles and explosives of different kinds, are cut by sabres, trampled by horses, stabbed by bayonets, etc. They are, however, seldom or never scalded by escaping steam, burned or drowned in wrecked cars, or crushed under heavy bodies. Moreover, soldiers are picked men in the prime of life, and are, by their training and surroundings, inured to danger. They look upon wounds, sickness, and even death, as some of the contingencies of their profession. In battle, especially, they are nerved up to a high pitch, and often suffer willingly for the cause in which they are enlisted. It is not so with the victims of a railroad accident. These unfortunates are of all ages and stations, of both sexes, and of every degree of bodily strength and mental calibre. Furthermore they are injured when totally unprepared for an accident. They are taken entirely by surprise, and the shock and fright complicate and increase their injuries, and bear a considerable relation to the ultimate result. The nervous and psychic lesions following railroad injuries have for years engaged the attention of the alienist and neurologist, as well as the surgeon, and various and far-reaching have been the results of their studies. In these respects I think that you will agree with me that railroad surgery covers a wider field than military surgery.

Who, indeed, ever heard of a military spine? Perhaps this is one of the discoveries now in the womb of the future which only awaits some bold accoucheur for its delivery and addition to that already numerous family of disabilities for which enterprising patriots may draw pensions from a grateful country.

A surgeon of this city has described typhoid spine, and it seems probable that, following in the steps of Erichsson, other writers will, from time to time, increase the present stock of spines indefinitely.

So far as the scope of this brief paper is concerned, it will simplify matters to consider our subject under two heads, as follows: 1. May a person suffering from some bodily ailment be benefited by the shock of a railroad accident? and 2, May a person suffering from some nervous or mental disorder receive benefit in a similar manner?

The literature relating to railroad injuries does not provide as many cases illustrating these questions as could be wished. Yet some quite striking ones may be found, and doubtless the number would be largely increased if railroad surgeons generally would report cases of which they may be cognizant. Probably nearly every one in this room can recall cases in which disease has been checked or even cured by the shock and excitement of a railroad or other serious accident.

Hack Tuke, in the preface of his book, "Influence of the Mind upon the Body," relates the following case which he had found in a newspaper under the heading "Curative Effects of a Railroad Collision." I quote *verbatim*: "Allow me to confirm all that your two correspondents have related with respect to the alarming collision on the 17th inst. on the Midland line. Nothing needs to be added either to their description of the circumstance or to their just condemnation of the reckless negligence which brought us so near to death; but the shock produced so curious an effect on myself—an effect perhaps unparalleled in the history of railway accidents—that you will perhaps excuse my troubling you with the details.

"At my hotel in Manchester I was seized with all the symptoms of a violent attack of rheumatic fever, in fact, my condition so alarmed me and my dread of a sojourn in a Manchester hotel bed for two or three months was so great that I resolved to make a bold *sortie* and, well wrapped up, start for London by the 3.30 P.M. Midland fast train from the London Road terminus. From the time of leaving that station to the time of the collision my heart was going at an express speed; my weak body was in a profuse perspiration; flashes of pain announced that the muscular fibres were under the tyrannical control of rheumatism, and I was almost beside myself with toothache. Crash! smash! bump! and bang! and from side to side of the carriage I went like a billiard-ball under a hard cushion hit. The compartment was soon seen to be sprinkled with the blood of a hapless victim whose face had come into crushing contact with it." Dr. Tuke continues—"The rest of this paper was unfortunately wanting, but I learnt from other sources that, as the heading intimated the patient was cured of his rheumatism."

I can relate a somewhat similar case of serious accident on shipboard which undoubtedly prolonged for years the life of the young man who received the injury.

L. M——, aged about twenty, came of a highly phthisical family. His father and mother, and all of their children, were consumptive. The latter all died, soon after reaching maturity, of this disease. When L. M—— was approaching his majority, similar symptoms began to manifest themselves in him to those that had appeared in the older members of his family. He was sent to California in a sailing vessel in the hope that the voyage might be of benefit to him. When the ship was returning to New York, the young gentleman, having climbed into the rigging, lost his hold and fell from a great height on to the deck, striking the keel of an upturned boat. He sustained fractures of both legs and other serious injuries. In one leg at least he had a compound comminuted fracture. He was laid up for months, and it was supposed that this accident to one in his delicate condition would surely prove fatal. For a long period one or more open sinuses in his leg discharged freely pus and bony detritus. Contrary to the general expectation, however, the young man finally recovered from his injuries, although he walked with a limp from shortening of one leg. As he began to get about it was observed that his pulmonary symptoms had disappeared. He grew stouter and stronger. He was able to engage in business and married and had a family. Whether his death, which occurred a number of years afterward, was due to tuberculosis or not, I have not been able to ascertain. It seems fair to assume, however, that his life was prolonged by the accident.

A case of gout suddenly cured by fright is given in Tuke's work already cited. I quote *verbatim*: "Peter Fether, the person cured, is now alive, a householder in Reading, seventy-three years of age, a native of Germany, and a very hearty man. The first fit of gout he ever had was about the year 1773, and from that time until 1785 he had a regular attack in the spring of every year. His feet, hands, and elbows were much swollen and inflamed. The fits lasted long and were excruciating. In particular the last fit in 1785 was so severe as to induce an apprehension that it would inevitably carry him off, when

[1] Read before the Erie Railway Surgeons' Association, at the Academy of Medicine, New York City, January 5, 1894.

he was suddenly relieved by the following accident: As he lay in a small back room adjoining the yard, it happened that one of his sons in turning a wagon and horses drove the tongue of the wagon with such force against the window, near which the old man lay stretched on a bed, as to beat in the sash of the window and to scatter the pieces of glass all about him. To such a degree was he alarmed by the noise and violence that he instantly leaped out of bed, forgot that he had ever used crutches and eagerly inquired what was the matter. His wife, hearing the uproar, ran into the room, where to her astonishment she found her husband on his feet bawling against the author of the mischief with the most passionate vehemence. From that moment he has been entirely exempt from the gout, has never had the slightest touch of it, and now enjoys perfect health, has a good appetite and says he was never heartier in his life." The reporter of this case, who was no less a person than Judge Rush, brother of the famous surgeon, goes on to say, "To you, who have long been accustomed to explore diseases, I leave the task of developing the principles on which this mysterious restoration from the lowest decrepitude and bodily wretchedness to a state of perfect health has been accomplished. I well know that toothaches, headaches, hiccoughs, etc., are often removed by the sudden impression of fear and that they return again. But to see a debilitated, gouty frame instantly restored to vigor, to see the whole system in a moment, as it were, undergo a perfect and entire change, and the most inveterate and incurable disease radically expelled, is surely a different thing, and must be acknowledged a very singular and marvellous event. If an old man, languishing under disease and infirmity had died of mere fright nobody would have been surprised at it, but that he should be absolutely cured and his constitution renovated by it, is a most extraordinary fact, which while I am compelled to believe by unexceptionable evidence I am totally at a loss to account for."

A case of the relief of ascites due to an accident is recorded by Dr. John Pennington, who says: "A sailor in an ascites fell off the end of the yard into the sea; the weather being calm he was taken up unhurt, but to use the sailor's words who told me the story, he was frightened half to death and as soon as he was taken out of the water he discharged a gallon of urine or more." Dr. Pennington observes, "the sedative operation of fear was no doubt the cause of the cure."

I cannot forbear to give one other case which was related to me in my boyhood. An Irish peasant had suffered for a considerable time with fever and ague and the ordinary remedies having failed to arrest the disease, an extraordinary one was employed, some human ordure was concealed in a bowl of milk, which the patient was made to drink to the bottom. The intense disgust and horror which the dregs of this dose caused, it was alleged, entirely 'broke the chills.'"

I have given these cases at some length because they appear to me remarkable, and because their recital answers the first of the two questions that were asked in the beginning of this paper, viz.: "May a person suffering from some bodily ailment, be benefited by the shock of a railroad accident?" There is no doubt that a favorable result may follow in certain cases. Naturally we should hear of such results far oftener, were it not for the fact that the proportion of people injured in railroad accidents to the whole number of travellers is exceedingly small; and of the injured a very small percentage are suffering from illness at the time of the accident.

As to the second division of our subject, I find that the time allotted me is already about exhausted, and that the field for discussion upon the effects of shock upon the nervous system in health and disease is almost without limit. I could multiply cases almost without end, to show that the emotions—fear, anger, and excitement—can, and frequently have benefited or even cured the most severe nervous maladies. From the nature of such complaints such a result seems reasonable enough. It is well known that such grave nervous lesions as chorea, paralysis agitans, asthma, epilepsy etc., are frequently brought on by fright or other strong emotion and are also cured by similar means.

I will not take up your time by citing cases of which a number are given in Tuke's work already referred to. Professor Goodell, of Philadelphia, in a recent lecture, has related some remarkable cases of coccyodynia and other nervous affections of which the cause was mental or emotional, and which were apparently cured by anger, fright, or excitement.

I cannot forbear to quote one case, which is given in Professor Norton's "Life and Letters of James Russell Lowell," recently published. It seems that while Mr. Lowell was minister to Spain, his wife's health was apparently in quite a precarious condition. He received a letter from the State Department at Washington, offering him the mission to England, which he was desirous of accepting, but felt obliged to decline, as it did not seem possible that his wife could be moved. In fact she was confined to her bed and seemed perfectly helpless. After Mr. Lowell had despatched his letter declining the English mission, his wife's bedclothes took fire; whereupon she jumped up with the greatest alacrity and for the time being at least found herself quite well. Mr. Lowell then sent a telegraphic message to Washington, in time to anticipate his letter of declination, and accepted the mission.

That intractable and discouraging disease epilepsy has occasionally been cured by a fall or blow, or by fright. It would seem that the nervous elements that have been disarranged by one shock might be shaken back into place by another. I would explain the beneficial results that have followed most of the surgical operations for epilepsy by saying that they are caused by the fright or excitement of the operation.

I believe that enough has been said to prove that a railroad accident, horrible as it is apt to be, may be of benefit to those concerned in it. As a therapeutic measure fright or shock, produced by such a means is of course entirely out of the question.

How far a physician may be justified in shocking or frightening a recalcitrant or hysterical patient is a problem requiring the nicest discrimination and the highest diagnostic acumen. Such a course has sometimes succeeded in doing good. It has often done harm. Of practical results our discussion may have been barren, but I venture to hope that it has not been entirely uninteresting.

A Strange Disease in Dublin.—A number of the inmates of the Richmond Insane Asylum at Dublin have been attacked with a disease resembling beriberi in many of its features. The symptoms are a general œdema, beginning in the legs and spreading thence to the whole body, followed by peripheral neuritis and paralysis. There is no fever, and albumin has been found in the urine in a few cases only. The heart is weak and dyspnœa is complained of. After a while the œdema diminishes and signs of neuritis appear; then atoxic symptoms set in with loss of the patellar reflex and muscular atrophy of the extremities. Post-mortem examination has shown hydropericardium, œdema of the lungs, ascites, and fatty degeneration of the heart and kidneys. Over a hundred inmates of the asylum have been attacked with the malady.

Porous Glass for Windows.—The latest hygienic craze in Paris is the use of porous glass for windows. This is declared to possess all the advantages of the ordinary window-framing, and, while light is as freely admitted as through the medium of common glass, the "porous" further admits air too, the minute holes with which this is intersected being too fine to permit of any draught, while they provide a healthy continuous ventilation through the apartment.—*The Hospital.*

TUBERCULOSIS—ITS ETIOLOGY AND PROPHYLAXIS.[1]

By F. A. BOTTOME, M.D.,

NEW YORK.

BEFORE the discovery of the tubercle bacillus by Koch in 1881 there existed a great difference of opinion as to the etiology of pulmonary tuberculosis; since then all the study expended upon the subject has but strengthened the position of Koch, and in this present year our Health Board expresses the universal belief when it states: "Tuberculosis is a communicable disease and is distinctly preventable, and acquired by the direct transmission of the tubercle bacillus from the sick to the well."

Indeed, we are all so familiar with this view of the etiology of tuberculosis that it would be presumptuous on my part to go over this well-beaten ground. Our Health Board has distributed among the physicians of this city a circular from which I have just quoted, and which expresses the latest views on the subject in a clear, concise way, and moreover gives the most practical methods for destroying the tubercle bacillus and thus preventing the spread of the disease.

As you are all doubtless familiar with this circular I shall not take up your time to read it, but call your attention simply to one paragraph, which reads as follows:

"It is a well-known fact that some persons, and especially the members of some families, are particularly liable to tuberculosis. So marked and frequent is the development of the disease in certain families that the affection has long been considered hereditary. We now know that the disease itself is very rarely hereditary, but that there is inherited a liability to the disease which renders the individual a more easy prey to the living germs when once they have gained an entrance."

This "liability to the disease" is a phase of the subject which, it seems to me, is often lost sight of in the consideration of tuberculosis. We think of the disease as being caused by a specific micro-organism, the tubercle bacillus; but we forget that this germ is powerless unless there is a coincident peculiar state of the system—"a liability to the disease."

Without depreciating in the least all that the Health Board is doing to eradicate this disease by the destruction of the tubercle bacillus, I would emphasize the fact that there is another way of accomplishing this end, which should go *pari passu* with the former, and which is the peculiar province of the practising physician, *i.e.*, removing the peculiar state of the system which constitutes a liability to the disease. Indeed until the great work which the Health Board has undertaken in this line has succeeded in lessening to a very great extent the countless numbers and universal distribution of this dread germ, it would seem as if the removal of the liability to the disease was easier than the eradication of the germ. And yet there should be no relaxation on our part in carrying out the former while we endeavor to accomplish the latter, since carelessness in so doing may result in the occurrence of the disease in the individual before we have succeeded in removing the "liability."

It will not be amiss, then, if we spend some little time in considering what constitutes this liability and the means for its removal.

This peculiar state of the system is variously designated tubercular habit, tubercular predisposition, tubercular diathesis. That it is this diathesis which is inherited and not the disease itself has been quoted above; but not only may it be inherited, it may also be acquired, and this will account for the cases of tuberculosis occurring in those whose family histories show no trace of the disease for generations back; in other words, this diathesis may be inherent in the constitution of an individual.

Children of tuberculous parents are frequently, during the early period of their lives, to all appearance perfectly healthy and may remain so till the first symptoms of the disease appear in the cough, hectic flush, and malaise; while in others we recognize at an early period certain physical conditions which warrant us in predicting the advent of tuberculosis at a later period. Thus they may exhibit the slight build, contracted chest, and delicate complexion. But if it is true that in both these classes of cases the diathesis exists, we must look for this diathesis in some defect deeper than in a gross physical malformation visible to the eye.

S. Solis Cohn, in speaking of this condition, says: "It is a negative, not a positive, state; an absence, not a presence. . . . That which is wanting in individuals who become tuberculous is the life force, the vital energy, an energy which we know to exist because of its manifestations as fully as we know electric energy to exist."

Vital energy we know is an inherent quality of the individual cell, so that, if Cohn's view is correct, this deficiency in vital energy must be inherent in the individual cell, and whether this be absolutely true or not it at least serves as a working hypothesis and is consistent with many of the peculiar phenomena of this condition. For instance, we know the cell contains not only sufficient energy to meet the ordinary demands made upon it, but is continually storing up surplus energy (potential energy) to be used in time of extraordinary demand, and this would explain those cases of tuberculosis developing in persons apparently healthy, the fact being that in these the individual cells possess sufficient energy for ordinary circumstances but succumb under an unusual, though, perhaps, slight demand, and, sinking below a certain point, are in the proper condition to constitute a suitable nidus for the development of the tubercle bacillus.

At the present time this germ is so widely distributed and exists in such numbers that it would seem as if there must be a constant warfare between the germ and the cell, the former laying siege to the latter, and waiting patiently till the cell shall be sufficiently reduced in strength to warrant an easy victory.

This comparison is not a bad one, for it indicates the proper line of treatment. The vital point with a besieged army is to keep up the supply of food, and the same is true of the cell in its warfare against the tubercle bacillus. If the cell is sufficiently fed, so that its vital energy remains above par, it can defy the tubercle bacillus and hold it at bay till the bacillus itself dies, for the tubercle bacillus cannot multiply unless it feed upon the animal cell, and also its period of vitality and virulence outside the animal body has a limit.

In the use of this term, vital energy, it must be remembered that it includes that energy which is expended in nutrition, heat-production, growth, development, repair, etc., and also the stored-up or potential energy which is held in reserve for some unusual demand which may be made upon the system.

There is one objection, it seems to me, in this theory of the deficiency of vital energy in the individual cell as the distinguishing characteristic of this diathesis, and that is the fact that if lowered vitality were all that is necessary to make the cell a suitable nidus for the growth of the tubercle bacillus, then we should expect to find tuberculosis developing in all individuals whose vitality had been greatly reduced by some outside cause, as by some one of the wasting diseases. This, however, is not the case.

It would seem as if there were some deeper defect in these cells, to which, if there is added a deficiency of potential energy, the cells are vulnerable to the tubercle bacillus; while in a cell not subject to this diathesis such a lack of potential energy would not make it more vulnerable. In other words our theory is that it is this, at present, undefined defect of the cells, to which if there is added a lack of potential energy, they become vulnerable to the tubercle bacillus. This view does not conflict with the recognized methods or results of treatment, for it recognizes the fact that the safeguard of the cell, subject to this diathesis, is the maintenance of potential energy, while in cells not subject to this diathesis such a

[1] Read before the Harlem Medical Society, November 7, 1894.

safeguard is not necessary, since they are not vulnerable to the tubercle bacillus under any conditions.

Treatment.—In the treatment of this condition or diathesis it must be remembered that we are dealing not with patients who have already developed tuberculosis, but with those who simply have the diathesis, usually inherited; since with our present knowledge we are hardly able to diagnose the inherent cases before tuberculosis itself has developed, and then only by inference in the absence of family history.

To put it in a more practical way, what can we do for those cases which give a strong family history of tuberculosis, and whose friends, if not themselves, ask our advice as to the means of preventing the development in them of this dread disease? Such a question is a very common one, which the practitioner is asked to answer.

If it is true that the safeguard in these individuals against the disease is the maintenance of potential energy, then the problem of treatment resolves itself into the consideration of the best methods of supplying this potential energy to the cells. The more we study the subject, the more shall we be impressed with the fact that the treatment of this condition embraces the whole subject of hygiene, and doubtless it is owing to the vastness of the subject that the above question is so often answered by the busy practitioner in the few words, "Keep the patient strong and well."

So far as it goes the answer is correct, but its accomplishment will not be attained unless we go into explicit detail, and treat each case individually, for we shall find a great difference in individual cases, and in the same case at different times, and each of these indicate special treatment.

Of course it will be impossible for me to do more than indicate the line of treatment, with perhaps special emphasis placed on certain points, but we shall be greatly aided if we keep well in mind the object of our treatment, the increasing of potential energy. In supplying this energy three means naturally suggest themselves, in food, air, exercise, and by regulating these we can accomplish a great deal even among those who must of necessity remain in the city, where these cannot be so easily regulated as in the country, and in special climates.

Food.—In the classification of food we find that different classes serve different purposes in the animal economy. Thus the nitrogenous elements serve principally the purpose of tissue-building, and the storing up of potential energy, while the hydrocarbons and carbohydrates are concerned principally in heat production, and from this fact it is evident that the food-supply in these subjects should contain a large proportion of nitrogen. Unfortunately it is in this very class of patients that we find a marked perversion of appetite, a liking for sweets, a distaste for meat, and it will require all our powers of tact and persuasion to regulate properly the diet of these cases. Some experimenters claim excellent results from an exclusive meat diet, but aside from the difficulty of carrying this out, among private patients at least, the general consensus of opinion is in favor of a mixed diet composed largely of nitrogenous foods.

If we are fortunate enough to have the patient under observation from the time of birth, the problem is less difficult, providing we can enlist the co-operation of the parents. The fact that the child of a tuberculous mother should not be fed from the mother's breast, on account of both mother and child, is universally conceded, but in addition to this, would it not be wiser that a mother who inherits merely this diathesis, although she may not have developed tuberculosis, should not suckle her offspring?

At the present time when the subject of bottle-feeding has been placed on a scientific basis, so that cow's milk can be made almost identical with human milk, the removal of the child from the breast is no longer such a serious question, nor is there the unpleasant alternative of a wet-nurse.

It is possible in this city to order a milk containing the albuminoids, sugars, and fats in whatever proportion the physician may desire, and by taking advantage of this fact we can increase the albuminoids or nitrogenous portion in these cases and watch the effect.

I do not know whether this has been done by anyone as yet; but is there not here a field for investigation to find out the effects of a larger proportion than is usually given, of the nitrogenous elements in the diet of an infant of tuberculous parents?

As the diet of the child increases in variety it should still consist of only plain wholesome food, largely of a nitrogenous character. The child should not be permitted to develop an appetite for sweets and pastry. The custom of giving a child candy as a reward or bribe is a bad one, aside from the questionable moral effect, and especially is it true in the cases under consideration, for perfect digestion is a *sine qua non* in their successful treatment, and in these subjects (the) sugars are very apt to cause digestive disturbances.

As the child grows older the diet, of course, varies somewhat; but the same principle holds good. And in the selection of articles of diet, with the aim of giving a large proportion of nitrogen, we shall find a large number from which to choose, for aside from meat we find other articles containing a large proportion of nitrogen; thus eggs contain about thirteen per cent. of proteids, fish, eighteen per cent., oatmeal twelve per cent., peas twenty two per cent., cheese thirty-one per cent. I mention these simply to emphasize the fact that meat is not the only nitrogenous food, and that in regulating the diet, to prevent sameness, we can select food-stuffs which will still aid in accomplishing our aim.

Air.—The necessity for fresh air is as important as the necessity for proper food. The rôle which oxygen plays in the metabolism of the body is a well-known physiological fact, but is more often disregarded in practice than remembered in theory.

It would, of course, be better for persons subject to this diathesis to live in some region where the air is absolutely pure, and where the tubercle bacillus is not present, but this is not often practicable nor is it necessary. If we breathed nothing less pure than the out-door air of this city we should have little cause for complaint. It is the air in our dwellings that is impure, and the fault is our own.

When the patient is old enough to look out for himself we can advise him, as far as possible, to lead an out-of-door life, and in the case of a young man to select a business or profession where this will be possible; but if the patient is an infant or young child we must be explicit in our directions to those in charge of the child, and teach them a few lessons on the subject of ventilation.

We must show them how perfectly possible it is to ventilate a room without the presence of draughts. That it is only necessary to have a communication between the outer and inside air, and by the law of diffusion of gases, and the law which relates to the difference in weight of masses of air of unequal temperature, the warm, impure air of the room will pass out, and the cool, pure, outer air will come in and take its place, and that the process can be made to take place so gradually that the temperature of the room remains stationary.

We can tell them that the simplest, and yet one of the most delicate means of testing the purity of the air in a room, is that by the sense of smell; that on entering a room to be tested we should notice no difference in point of freshness between the out and inside air, remembering that warm air is not necessarily impure, and that in this test the question of temperature is not to be taken into account.

These are homely truths and it would hardly seem necessary to mention them, and yet is it not true that the majority of sleeping-rooms have a disagreeable, stuffy odor before they are aired in the morning? This odor is due to the organic matter exhaled from the lungs and skin, and if not removed from the air of the room is taken into the lungs with each respiration and constitutes

a positive poison. Such a condition is bad enough for healthy subjects, but for the cases under discussion, in whom the amount of vitality is below par, is a serious drawback to our efforts in overcoming this diathesis.

Exercise.—As the child grows older, and especially during the period of youth, exercise is important as a prophylactic measure. In considering the subject of food we pointed out the necessity of increasing the nitrogenous elements; but this is only possible as it is combined with active physical exercise. The nitrogen assimilated is stored up, principally in the muscular tissue, and as this is increased and developed a correspondingly large amount of nitrogen is stored up.

In considering the different forms of exercise it will be well to select, as far as possible, those which, of necessity, must be performed in the open air, as fresh air is thus obtained at the same time. Bicycle riding is an excellent form of exercise, providing a faulty position is not adopted; also brisk walking, especially when taken with some definite purpose other than for its own sake. Swimming, horseback-riding, and, in short, all recognized forms of healthy out-door exercise will accomplish the desired end.

Besides these there are special forms of exercise which apply particularly to these subjects in whom there are frequently found a poor chest development and deficient lung expansion. Perhaps one of the best means for overcoming these defects is the exercise of swimming, in which there is, of necessity, a forced inspiration and a special development of some, if not all, of the muscles of respiration.

In addition to these there is the exercise with the so-called chest-weights, and how much can be accomplished by these and other forms of gymnasium apparatus has been recently shown in a paper read before this Society by Dr. Gardner Smith. The only objection to exercise in the gymnasium is the poor ventilation frequently found there, but this is a fault easily remedied. A simple yet practicable means of increasing the lung expansion, including the apices, which, in these cases, are so apt to be partially collapsed, is that in which the subject, when walking in the open air, inhales slowly and deeply, and then retains the air in his lungs for a few steps, when he gradually exhales. In this way I have seen the lung capacity markedly increased. To some of these patients, on account of business, daily open air exercise or that in the gymnasium is an impossibility. In these cases I advise the purchasing of a chest weight apparatus, which is placed in the bath-room and used every morning for a short time, followed by a cool plunge-bath and brisk rubbing. The latter serves the purposes of cleanliness, an active tonic, and a means of hardening the skin, thereby lessening the liability to "catch cold." The interest of the patient in his increasing muscular development removes the sense of irksomeness from the exercise, and the after effects of the cool bath are such that it soon becomes a great pleasure, and not to be foregone by one who has become accustomed to its use.

These are a few of the salient points in the hygienic treatment of this condition. I have made no mention of drugs because, in the majority of cases, they are not called for, though often their treatment is dismissed with a prescription for cod-liver oil. Any intercurrent disease must be treated on its own merits, and this includes the surgical measures indicated in diseases of the respiratory tract, to which we should pay special attention.

In closing, let me again emphasize the fact that the etiology of tuberculosis is twofold, and that in the prophylactic treatment we should pay as much attention to the diathesis as to the tubercle bacillus.

My excuse, if one is needed, for confining myself in this paper to the consideration of the diathesis, is that I feel that this side of the question is too often neglected in practice, and that while the exact nature of this diathesis is theoretical, the treatment based on this theory is highly satisfactory.

Progress of Medical Science.

The Surgery of the Gall-bladder and Bile-ducts, with Brief Notes of Seventy Eight Cases.—Dr. Robson speaks of the most prominent symptoms and complications of cases of cholelithiasis which have come under his observation: 1. Spasms or biliary colic without jaundice, the attacks being repeated at longer or shorter intervals. 2. Collapse due to the intensity of the pain. 3. Spasms followed by evanescent jaundice. 4. Pain followed by persistent jaundice and enlargement of the liver. 5. Hydrops of the gall-bladder without jaundice. 6. Ileus due to atony of the bowel. 7. Acute intestinal obstruction due to paralysis of the gut from local peritonitis, volvulus of the small intestine, or impaction of a large gall-stone in some part of the intestine.

In the majority of these cases, where medical treatment has failed, surgical procedures hold out very good hope of success in nearly every complication, if the patient be not too much exhausted. Cases complicated with malignant diseases are very unfavorable for operation. First, because the subjects of cancer are, as a rule, cachectic and worn down by disease before the surgeon is called in; and, secondly, because such patients are prone to hemorrhage at the time of the operation or subsequently. The author claims that there is considerable risk in operating on patients that are markedly jaundiced, on account of hemorrhage, but more especially as the jaundice is frequently associated with malignant disease. In order to avert the danger of hemorrhage in jaundiced patients the author has found that the administration of chloride of calcium for a few days before the operation makes the blood more plastic and lessens the tendency to bleeding both at the time of operation and subsequently. In jaundiced cases he prefers ligating all bleeding points rather than trust pressure forceps. In all of the cases operated upon by the author, in which there was malignant disease with jaundice, the gall-bladder formed a perceptible tumor, whereas, when the jaundice was dependent upon gall-stones, no marked tumor was present. A valuable diagnostic point, the author claims, is tenderness on pressure over some point between the eighth or ninth costal cartilage and the umbilicus. The so-called diagnostic operation of sounding for gall-stones and aspiration of a distended gall-bladder the author believes to be futile and dangerous, and is much better replaced by a small exploratory incision, when treatment can at the same time be carried out, if required. The indications for operating in these cases the author gives as follows: 1. Frequently recurring biliary colic, without jaundice, with or without enlargement of the gall-bladder. 2. Persistent jaundice ushered in by pain. 3. Empyema of the gall-bladder. 4. Peritonitis starting in the region of the liver. 5. Purulent collections about the gall bladder.

If the bladder and ducts can be cleared without much difficulty, the opening in the gall-bladder can be sutured to the aponeurosis and drained. If the ducts cannot be cleared, one of the following procedures may be carried out: 1. Cholelithotrity, the stone being crushed between the finger and thumb or by padded forceps. 2. Choledodectomy, opening the duct, removing the stone, and suturing the duct afterward. A drainage-tube should always be inserted in the right kidney pouch in these cases. 3. Cholecystenterostomy. This operation may be easily performed if the gall-bladder be dilated. The author prefers the decalcified bone bobbin, as only two sutures must be applied. 4. The daily injection of fluids after an interval of some days, through the cholecystotomy opening, which will either soften or dissolve the concretion. For this, hot water, or a solution of taurochlorate of soda, may be used, or, as the author prefers, injections of olive oil or a five per cent. solution of oleic acid. 5. Cholecystectomy may be required as

a secondary operation in cases of stricture of the cystic duct, the common duct being free. With but very few exceptions a vertical incision along the upper part of the right similunar line gives ample room.—*The British Medical Journal.*

The Treatment of Obstructive Jaundice.—Dr. Dujardin-Beaumetz divides this condition into three classes with reference to its causation: 1. Obliteration from a calculus. 2. Obliteration from inflammation. 3. Obliteration from compression by tumors—the last belonging exclusively to the domain of surgery.

Hepatic calculi are more frequent in women, and it is probable that the corset is an important factor in their causation, which is further aided by the usual costo-superior type of respiration. In these cases systematic massage can do much in relieving the causative factor. Of the cholagogues, the watery alcoholic extracts, as podophyllin, cascarillin, and euonymin, and even sodium salicylate, can be of service. To these should be added alkalies, as the waters of Vichy or Vals. For the treatment of hepatic colic two agents have recently been introduced—oil and glycerine. The oil has been the subject of numerous papers, and has achieved considerable success, but it possesses the marked inconvenience of being repugnant to the patients, and they swallow with considerable difficulty, at one time, the large amount (seven ounces) which is required. Glycerine in much smaller quantity, two and one-half to five drachms, appears to be equally effective, either given clear or mixed with water. If the latter fails, then it is necessary to resort to anodyne suppositories, ether sprays over the hepatic region, hypodermatic injection of morphine and atropine, or even of chloroform if the pain is acute. The obliteration from inflammatory action, which is usually the consequence of a duodenitis, requires different treatment. The duodenitis may be the result of an excessive alimentation in quality and quantity, or an incomplete mastication. It is necessary to regulate and increase the number of meals—for each meal, by giving rise to reflex phenomena, produces an increased flow of bile. Irritant foods must be avoided—those which increase the gastric acidity, especially alcohol and liquids containing it. In the advanced stages it is necessary to resort to intestinal antiseptics, of which the most in use are salol, benzonaphthol, and the salicylates. Salol, usually the best of all, is here unavailing, because the bile being arrested, the contents of the duodenum are acid, and no decomposition of the drug occurs. To obtain antiseptic effects from benzonaphthol one drachm or more each day is required. Of the salicylates, bismuth salicylate is the best. Since this colors the fæces it is difficult to arrive at a true understanding of the patient's condition; to avoid this inconvenience asaprol has been substituted with advantage. Calomel is useful because it is at the same time a purgative and an antiseptic; but it should be used with caution if the treatment is to be prolonged. Constipation is always an important symptom, and the use of Rubinat, Carabana, Villacabras, and even Carlsbad is advisable. Pancreatin may be useful in some cases.—*American Journal of the Medical Sciences.*

Stomach-reefing.—This operation has been performed by Dr. Brandt for dilatation of the stomach. It is well known that the stomach becomes enlarged in cases of pyloric stenosis due to new growth, cicatricial contraction, or bands of adhesions. The rational treatment of this stomach trouble is the removal of the cause. This is accomplished by pylorus resection and excision of pyloric cicatrices, which have been so successfully done during the past few years. It sometimes happens, however, that after opening the abdomen no such a cause is found for the dilatation. If the wound is closed, the laparotomy has been nothing more than an explorative operation, and the patient continues to suffer from the disease, the case being then regarded as a medical one and a subject for medical treatment. It has occurred to Brandt to treat these idiopathic cases by diminishing the size of the stomach by folding in its wall and suturing it through the serosa and muscularis. The patient upon whom he operated was a woman, twenty-six years of age. The gastric sound could be introduced till it struck the pubes and left Poupart's ligament. Palpation revealed no tumor of the pyloric or other region, nor even an abnormal resistance. The patient was poorly nourished and greatly reduced in strength. She was treated medicinally by faradization and lavage of the stomach, with little improvement. After this treatment had been carried on for two months, Brandt made an opening into the abdomen parallel with the left costal arch, and explored the stomach and other abdominal contents. The pylorus was especially examined, and nothing found. The organ was found enormously enlarged. He then proceeded to fold in the anterior wall and suture it by two rows of transverse sutures. The same was done on the posterior wall through holes torn through the great omentum. More than two hundred sutures were applied. The patient made an excellent recovery, without any disturbance of digestion, and was able to leave her bed on the tenth day. Brandt has published this case as preliminary to a more exhaustive communication upon the subject. The same operation has been described under the head of "gastrorapie" in the same periodical.—*Annals of Surgery.*

A New Method of Resecting the Rectum.—Dr. Routier described (Chirurgical Society, Paris) a method of resecting the rectum as devised by Moulonguet, a modification of Kraske's operation. The first step is the same as in Kraske's operation; the sphincter is then dissected out, and even though the lower portion of the rectum is found healthy, it is cut away instead of being preserved, as in Kraske's operation. The sphincter, after having been dissected out, is lined by the upper portion of the rectum, which is pulled down for this purpose and sutured to the edges of the wound at the anus. The perineo-sacral wound is then sewn up, with a drain in the lower portion. In Dr. Routier's estimation the usefulness of the operation is rather limited, especially to cases in which the cancer is not situated high up, and in cases in which the sphincter is intact.

The Inoculability of Cancer.—Dr. Gratia reported, at the Academy of Medicine, Brussels, a series of experiments, in which he had employed grafting and inoculation, with the object of proving or disproving the inoculability of cancer. The result of his experiments led him to conclude that cancer does not seem to be inoculable even between individuals of the same species. He likewise feels justified in making the following statements: 1. The parasitic nature of cancer has not been satisfactorily proved. 2. The direct or indirect contagiousness of this neoplasm has not been proved; the most that can be admitted, in the present state of our knowledge on this subject, being the possibility of ingrafting, that is to say, transplanting cancer, and that only in individuals exhibiting exceptional predisposition such as cancerous patients themselves. 3. The etiology and pathogenesis of cancer are still undetermined.

Myxœdema and Thyroid Therapy.—Ewald presented to the Medical Society of Berlin a woman, aged fifty-two, who had been treated for myxœdema by the use of the thyroid gland in tabloid form. The three points to which he called attention in the report of the case were: 1. The complete failure of all other forms of treatment. It was also peculiar that the hypodermatic use of the thyroid extract had been fruitless. 2. Investigation of the products of retrograde and constructive metamorphosis showed, in contradiction to what has been reported by English and Danish observers, that the urinary constituents were not increased. 3. The presence of a considerable quantity of sugar in the urine. He was unable to decide whether this was due to the method of treatment or an intercurrent complication.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, December 8, 1894.

A NATIONAL BOARD OF HEALTH.

THE President of the United States, in his recent message to Congress, formally and forcibly recommends the establishment of a National Board of Health, or National Officer, having under his control or advice matters pertaining to the protection of the country against pestilence and disease.

It can be easily seen, by the wording of his recommendation, that the establishment of a new Department of Government is not intended or considered at present necessary. This is the view which has been taken by leading sanitarians all over the country, and is the one that has been voiced by the Academy of Medicine in its carefully prepared bill.

There is little doubt that, with the generous and united support of the profession, the Academy bill, or one of similar tenor, could soon be made a law. It is equally certain to all acquainted with the feeling at Washington, that the attempt to establish at once a new department and a new cabinet officer would fail. No such thing has ever yet been done since the foundation of the Government. The Department of Agriculture, for example, for many years was simply a Bureau, and had its usefulness tested in this way.

If medical opinion cordially supports the project for a Bureau, it will get it; the rest will come in good time.

THE ORAL EDUCATION OF THE DEAF.

THE *Churchman* for December 1st contains an illustrated article by S. Millington Miller, M.D., on the above topic. The writer defends, with a considerable array of facts, the superiority of the new oral system of educating those congenitally, or otherwise, afflicted with dumbness.

The particular facts which he employs with most telling effect are, first, that the intermarriage of deaf men and deaf women, necessarily thrown together by the manual sign-alphabet system, produces children a large proportion of whom are congenitally deaf; and, second, that orally educated deaf persons can mingle without disability with the world at large, while the manually educated cannot. He also points out that all Europe is oral, and that America is lagging instead of leading.

It seems that some eleven years ago that very distinguished physicist and inventor, Dr. A. Graham Bell, announced that a series of investigations pushed in all directions, and as exhaustive as he could make them at that time, showed that one-third of the total number of children of deaf and dumb parents were congenitally deaf. This means that they are also dumb, so far as articulate speech is concerned. In other words, he had been forced to the conclusion that the method of instructing the deaf then mainly in vogue (by the manual alphabet-sign system), isolated deaf men and deaf women from society in general, facilitated their intermarriage, and was therefore developing a deaf and dumb species of the human race.

Since that paper appeared, statistics bearing on this subject multipled exceedingly, and they have all been sent to a gentleman who is an instructor in a manual institution, Dr. Fay, of the Gallaudet College, in Washington.

Those interested in such matters have been long expecting the publication of these reports, but their appearance has been most persistently delayed.

Within the past few weeks, however, Dr. Fay has written to the *Philadelphia Press*, stating that he is now busily engaged in sorting out and arranging this interesting matter, and will publish it at the earliest possible moment. It was decided by those who advised the placing of it in Dr. Fay's hands, that he was the person most competent to handle the subject.

According to conservative authorities there is one deaf person in the United States to every fifteen hundred units of population. Others place the proportion as high as one in every twelve hundred. We take it for granted, therefore, that there are some fifty thousand deaf persons in round numbers, in a total population of sixty-five million people. As there are at least ten persons more or less directly interested in the welfare of each deaf person, we have a total of half a million people to whom the method employed in educating a person so afflicted is a matter of vital interest. Two-thirds of these fifty thousand deaf persons were either born deaf or have become so under the age of two years. They are, therefore, dumb as regards articulate speech.

There have been various systems invented for the education of the deaf. One of the earliest references to the treatment of the deaf occurs in Bede's History, where Bishop John is spoken of as curing "a dummy man by blessing of him." The earliest schools for the instruction of the deaf were those of Pedro Ponce de Leon, in Spain, and of Jerem Garden, in Italy. Both of these men flourished in the sixteenth century, and their method of instruction in both cases was oral.

The cure of the deaf was universally regarded at that time as a miracle, and its instances were sedulously fostered as such by the Roman Catholic Church.

Jean Paul Bonet introduced and taught the single-hand alphabet in Spain in the first half of the seventeenth century. In the latter part of the eighteenth century three great schools were started: that of the Braidwoods, in Edinburgh; that of Samuel Heinecke, in Germany; and that of the Abbé de l'Épée, in France. The Braidwood system was a mixed sign and oral education, and was carried on by the family of that name for years as a sort of trade monopoly. Samuel Heinecke taught pure oral speech. The system of the Abbé de l'Épée consisted entirely in a series of conventional and pantomimic signs. Among the latter were included the drawing together of

the shoulders and shivering to indicate "feeling cold;" nodding the head to express assent, and shaking it as a sign of dissent. Besides such natural signs as these, the benevolent Abbé invented a number of conventional or arbitrary signs to express certain ideas. The most primitive races of mankind conversed in signs, and some of these earliest pantomimic signs still survive among civilized people, and are likely to last forever by reason of their terse expressiveness.

So it occurs that some of the most natural and forcible of the Abbé signs are still taught in connection with the one-hand alphabet. The letters of this alphabet are formed by the rapid juxtaposition of the fingers of one hand. They are arbitrary letters, not at all like the stately and rounded capitals of the copy-book, but still the child learns by their combination to spell out words and form sentences, and so to converse with other deaf children similarly instructed, and with its teachers. In a manual-sign school, speech is regarded as an accomplishment. The graduate of a manual school can only communicate with those unacquainted with his language—signs—by means of a writing pad.

But *revenons à nos moutons*. It was the general belief of continental Europe at the time when these great schools began their career, that mentality, or thought, could not be successfully carried on by any other medium than that of articulate speech. The system of l'Épée was therefore a startling innovation, as he had taught the oral system previous to his elaboration of the sign method.

The first American mover in this same benevolent purpose to remedy a prevalent affliction of humanity was Francis Green, who flourished in the latter part of the last century in Boston. He secured statistics showing the existence at that period of at least seventy deaf folk in Massachusetts. And he made strenuous efforts to start a school for them in Boston, but unsuccessfully.

Early in the present century Col. Bolling, of Virginia, two of whose children were deaf, made arrangements with the Braidwoods to send one of their number to this country who should found a school in America, and thus allow two continents the privilege of their monopoly.

In 1817, Dr. Thomas Gallaudet was sent abroad from Boston to study the Braidwood system, but its founders were so economical of their monopolistic right that the Doctor wended his way to France, visited the manual school of the Abbé de l'Épée, then conducted by his successor, the Abbé Sicard, spent several years in Paris, and brought back with him the deaf-mute Laurent Clerc as an assistant in the school then opened in Hartford, Conn.

The oral method was never introduced into America until 1887. In the following year the president of the National Gallaudet College in Washington called together in that city a meeting of the American manualists to take action against the new heresy. But the seed had been planted in a good soil and grew.

In 1880, a great convention was held in Milan, Italy, to settle forever in Europe the question of how the deaf should be taught; to arbitrate between Purist (oralists) and Non Purists (manualists). Dr. E. M. Gallaudet was present at that convention. Since that day every child in Continental Europe who is deaf has been taught by the pure oral system. The very school of de L'Épée has become an oral school.

But matters were by no means so easily cut and dried in England, until some five years ago, when a Royal Commission was appointed by the Crown and experts summoned to London at the expense of the English Government. Dr. Bell and Dr. Gallaudet went from America. The decision of this Commission was that every child who was thus afflicted in Great Britain should be taught for one year by the pure oral method. And only then be turned back into the manual sign system if it was clear that the oral system was not suited to its individual requirements. This country is therefore now going through the same scientific birth-pangs as did Continental Europe before the 1880 convention of Milan. "Verbum sapientibus" would seem to be the only criticism needed.

There are practically only two methods in vogue at the present day for teaching the deaf—the oral method (teaching by and through articulate speech), and the manual-sign alphabet method. Under both methods the child is taught writing, composition, arithmetic, spelling, geography, and all the English branches. The methods differ distinctly in that the oral system endows its graduate with articulate speech, and that the manual-sign system does not.

THE MODERN TREND OF GERMAN MEDICINE.

It used to be the reproach of medical science in Germany that it was not practical, that its students concerned themselves little with what should be the end and aim of the physician, namely the cure of disease, the relief of suffering, and the saving of life. Once the diagnosis made, all interest in the patient ceased, unless indeed he chanced to die, when he again became an object of interest for pathological purposes. The reproach was not undeserved, although it was somewhat exaggerated. But now things have changed, and a question of therapeutics arouses as great interest as did formerly one of pathology. This change is well illustrated by the comparative sale of two subscription works now being issued in the German language. One, edited by Penzoldt and Stintzing, devoted chiefly to the treatment of disease, is having, so we are informed, a very large sale, while the work edited by Nothnagel, the tendency of which is chiefly pathological, is meeting with but indifferent success. The cause for this change is doubtless the hope of cure that has been aroused by discoveries in bacteriology. Formerly it was nearly all guess-work and empiricism, but now there is a basis upon which to build a science of therapeutics, and inspired with the hope of success, the German shows that he is just as willing to save his patients as is anyone else, provided he has an incentive for trying.

Garbage Cremation.—According to the *Inventive Age* there are now fifty-five towns and cities in England which destroy their garbage and solid refuse by burning, using an average of about ten furnaces each for that purpose. The combustion of the material is used for the generation of steam, by which the streets are electrically illuminated, and other cities are reported to be considering the propriety of reducing their municipal expenses by this means.

News of the Week.

President Cleveland's Recommendation of a National Board of Health.—President Cleveland, in his message to Congress, makes the following recommendation: "I am entirely convinced that we ought not to be longer without a national board of health or national health officer charged with no other duties than such as pertain to the protection of our country from the invasion of pestilence and disease. This would involve the establishment, by such board or officer, of proper quarantine precautions, or the necessary aid and counsel to local authorities on the subject, prompt advice and assistance to local boards of health or health officers in the suppression of contagious disease, and in cases where there are no such local boards or officers, the immediate direction by the national board or officer of measures of suppression, constant and authentic information concerning the health of foreign countries and all parts of our own country as related to contagious diseases; and consideration of regulations to be enforced in foreign ports to prevent the introduction of contagion into our cities, and the measures which should be adopted to secure their enforcement. There seems to be at this time a decided inclination to discuss measures of protection against contagious diseases in international conference, with a view of adopting means of mutual assistance. The creation of such a national health establishment would greatly aid our standing in such conferences, and improve our opportunities to avail ourselves of their benefits. I earnestly recommend the inauguration of a national board of health or similar national instrumentality, believing the same to be a needed precaution against contagious disease and in the interest of the safety and health of our people."

The Cause of the Czar's Death.—We have received a copy of the official notice giving forth the nature of the malady to which the Czar succumbed. The diagnosis made by the physicians in attendance, Drs. Leyden, Zakharin, Girsh, P. Popoff, and Weliaminoff, was confirmed in the main by the results of the autopsy performed the following day. This diagnosis was "chronic interstitial nephritis with secondary disease of the heart and vessels, and hemorrhagic infarction of the left lung with secondary pneumonia." The following is a translation of the report of the autopsy: On October 22, 1894, at 7.30 o'clock in the evening, we, the undersigned, upon the occasion of embalming the body of the Emperor Alexander Alexandrovich, asleep in God, found the lesions described below. There was considerable œdema of the subcutaneous connective tissue of the lower extremities, with a punctate redness over the left leg. In the left pleural cavity was 200 c.c. of serous effusion of a reddish color; in the right cavity 50 c.c. of a similar fluid. There was an old fibrous cicatrix at the apex of the right lung, and this lung was somewhat œdematous; in the left lung there was œdema of the upper lobe and a hemorrhagic infarct in the lower lobe, and this lobe was also congested and contained very little air. The infarct was situated at the upper edge of the lower lobe and presented a triangular form on section, measuring 1½ ctm. in length by 1 ctm. on cross section. In the pericardium there was 50 c.c. of a blood-stained serous effusion. The heart was considerably increased in size, measuring 17 ctm. in length and 18 ctm. in width. In the subserous cellular tissue there was a large amount of fat (lipomatosis cordis). The left heart was dilated and the wall of the left ventricle was hypertrophied (2½ ctm.); the muscular tissue was pale, flabby, and of a yellowish color (degeneratio adiposa myocardii). The muscular wall of the right ventricle was thinned (6 mm.), and of the same yellowish color. The valvular apparatus was perfectly normal. In the abdominal cavity was about 200 c.c. of serous fluid. There was a large collection of gas in the stomach and intestines. The liver was slightly enlarged and greatly congested. The kidneys presented the following measurements: left, 16 ctm. in length, 7 ctm. in width, and 4 ctm. in thickness; right, 15 ctm. in length, 6½ ctm. in width, and 4 ctm. in thickness. The capsules were of ordinary thickness and not adherent. The surface of the kidneys was finely granular and of a dark-red color. The organs were not noticeably hardened. The cortical substance was reduced in thickness (6 to 7 mm.) and yellowish, the medullary portion was dark-red in color (nephritis interstitialis cum atrophia substantiva corticitis venum granulosa). In addition there was a serous cyst 3 mm. in diameter in the left kidney. Upon a basis of what has been above described, we conclude that the Emperor Alexander Alexandrovich died from paralysis of the heart due to degeneration of the muscle of the hypertrophied heart, and interstitial nephritis (granular atrophy of the kidneys). The report is signed by Drs. Klein, Zernoff, M. A. Popoff, Altukhoff, and Bielousoff.

Professor Baginsky and Antitoxin.—Professor Baginsky, of Berlin, writes concerning his article in October 6th issue, and desires the following correction:

Instead of: "It was difficult to ascertain the cause of the disease: Twenty-five cases which had been exposed to diphtheria were carefully examined a number of days, and all developed diphtheria. As they were examined daily, they were attended when the first symptom appeared. Not one of these developed nephritis nor cardiac trouble. Their sisters and brothers, who had been previously admitted to the hospital, some as severe cases, died. All twenty-five cases were discharged cured."

The above should read thus: "It was extremely difficult to ascertain the real cause of the disease from the relatives. We have had a number of children, twenty five in all, brought to us on the same day that their brothers and sisters were admitted as diphtheria patients, carefully examined them, and found these children perfectly healthy. These children were brought to us for inspection daily, and took sick some on one, two, or several days afterward. So that in these twenty-five cases we are really depending on proper statistics in the beginning of the disease. All of these latter patients got well and were discharged cured. In not a single case did any symptom of cardiac or nephritic complication manifest itself. Whereas, the brothers and sisters that were first brought to us developed not only severe types of diphtheria, and some proved fatal."

Statistics in the Medical Department of the Navy.—The new form of statistical report recently issued by Surgeon-General Tryon will not only be appreciated by the medical corps of the navy, but by the profession at

large. The nomenclature of diseases (adopted by the Royal College of Physicians and Surgeons, England) in use in the navy for many years has been abolished, and a classification substituted on the basis of modern requirements. The new system, commencing January, 1895, will enforce interesting statistics rendered valuable on account of their accuracy.

Charles T. Chase, M.D., of Brooklyn, died on November 5th, aged sixty-three, the cause of his death having been chronic interstitial nephritis. He was a well-known practitioner of forty years' standing in Brooklyn, and the son of Dr. Charles Chase, of the United States Navy.

Dr. Hedges's Paper on Diphtheria.—By an oversight of the printer the article of Dr. Hedges, on page 682, was not indexed.

Football at Springfield.—We must confess to a distinct disappointment at the way in which the Harvard-Yale game of football at Springfield was conducted this year. The promise of reform in rules and discipline has not been kept. The number of disabled men was unusually great, and there were several serious injuries; that these were in every case the result of "accidents" it seems to be difficult to admit. The rules may be amended to any extent, but it profits nothing if they are not or cannot be enforced. The penalty for slugging, or for purposely attempting in any way to injure an antagonist cannot be too severe or too severely enforced, if this game is to be continued as a competitive sport among college men. That a player may with impunity jump on an antagonist prostrate on the ground with the ball, after the whistle has been blown, and dislocate his victim's clavicle, should be an impossibility. What the umpire does not see, however, is supposed not to occur. In so far as the umpire is blind he may, at least, in that particular, be said to be a representative of justice; the best pair of eyes may really miss some of the incidents of the gridiron. Had the penalty of disqualification, however, been rigidly enforced from the beginning of the first half of this game, there would, we are convinced, have been fewer subsequent "accidents."—*Boston Medical and Surgical Journal.*

Dr. William Gay Brockway died November 28th, at 181 West 134th Street, New York, aged thirty-four. He was graduated from the University Medical College in 1887, and practised in Harlem until December last, when he went to Florida for his health.

Dr. George R. Brush, of Sayville, L. I., died of diabetes on November 29th, at Colorado Springs, aged fifty-nine. Dr. Brush was born at Smithtown, L. I. After his graduation from the College of Physicians and Surgeons in 1858, he practised in this city and Sayville until September, 1861, when he entered the navy as assistant surgeon. He passed through the successive grades until he became Medical Inspector in 1889, which rank he held at the time of his death. He was detailed to the Brooklyn Navy Yard in 1892.

A New Woman's Hospital.—The authorities of the Woman's Hospital, at Park Avenue and Forty-ninth Street, New York, are to erect a new hospital in Central Park West, having acquired the block between Ninety-second and Ninety-third Street, the plot extending back two hundred and fifty-nine feet in Ninety second Street and two hundred and fifty in Ninety-third Street, with the exception of one parcel of twenty-five feet in the latter street. Most of this property has been actually purchased and the remainder is under contract. The cost of the plot is $331,000.

St. Mark's Hospital, New York.—Dr. H. J. Schiff has been appointed attending surgeon to St. Mark's Hospital.

The New Surgeon-General of New York State N. G. is Dr. M. C. Terry, of Utica. He is a graduate of the Cleveland, O. Homœopathic Hospital College in 1872.

The Montefiore Home for Chronic Invalids.—The new wing of the Montefiore Home was formally opened on November 29th. The occasion was also the tenth anniversary of the founding of the institution.

Bequests to Hospitals.—The late Henry Keney has left $50,000 for the Hartford Hospital.

The Manhattan Dispensary, of this city, is the fortunate recipient of a bequest of over one hundred thousand dollars.

There seems to be Considerable Trouble in the National Association of Railway Surgeons. The association issues a special proclamation warning its members against the proposed American Academy of Railway Surgeons. Certain members of the N. A. R. S., in their efforts to establish a rival society, says the resolution, "have used fac-similes of letterheads of the railway surgeons for the purpose of producing a false impression as to their standing with the members of this (N. A. R. S.) association and its official organ and with railway surgeons, etc." Gentlemen, this is a N. A. R. S——ty trick, and, in the words of another, "You shouldn't ort to have done it." We believe in fair play if you are going to fight.—*Medical Examiner.*

A Year's Immigration.—The annual report of Herman Stump, United States Superintendent of Immigration, shows that during the fiscal year ended June 30, 1894, 288,020 immigrants arrived in this country, of whom 285,631 were landed and 2,389 debarred from landing because of being under contract to perform labor made previous to their arrival. Of the immigrants landed, 96,000 were destined for New York State, 42,000 for Pennsylvania, 25,000 for Massachusetts, and 22,000 for Illinois, the others being scattered throughout the United States, no other State receiving a greater number than 10,000. Immigrants destined for southern States, all told, did not exceed 12,000. Of the immigrants over sixteen years of age, 41,000 could not read or write.

A German Temperance Society.—The German Society Against the Abuse of Alcohol held its annual meeting on September 18th and 19th, at Cassel. Among the subjects discussed were Sunday afternoon closing and the influence of women in the temperance movement.

Dartmouth Medical College held its annual commencement November 20th, graduating a class of twenty-seven.

An Epidemic of Diphtheria prevails in Yonkers, N. Y. On November 23d there were fifty-six cases in the city.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, November 20, 1894.

W. H. Porter, M.D., Chairman.

Specimens illustrating varieties of biliary calculi were presented by Drs. George P. Biggs and Morris Manges.

A Résumé of the Subject of Biliary Calculi.—Dr. Thomas Southworth read a paper on the above subject, and in opening the discussion, Dr. Kinnicutt said that the chemistry and symptomatology of biliary calculi had been described very thoroughly in Dr. Southworth's interesting paper. He had little or nothing new to say, yet it might be useful to refer to some of the difficulties of differentiation between certain lesions of the larger ducts and gall bladder, produced by impacted calculi. He would first refer to the differentiation between hydrops in the sense of a dilatation of the gall-bladder through obstruction in the cystic duct, and empyema of the gall-bladder on the one hand, and a catarrhal cholangitis produced by impacted biliary calculi in the common duct, also causing enlargement of the gall-bladder.

A differential diagnosis was very desirable, as in the case of empyema, at least, prompt surgical interference was indicated, while in dilatation with catarrhal cholangitis, complete recovery frequently occurred without operation. Although both hydrops and empyema of the gall-bladder, as a rule, were produced by impacted calculi in the cystic, rather than in the common, duct, and hence were unattended with jaundice, nevertheless impacted calculi in both cystic and common ducts were not of uncommon occurrence.

In both empyema and catarrhal cholangitis, paroxysms of chill, fever, and sweating of an irregular, or quotidian, or tertian, or quartan type might be present. It was important to bear in mind that such symptoms occurred, as a rule, in catarrhal cholangitis from impacted stones. The fever often rose to a very considerable height. In a case which was recently under his observation, a severe chill was immediately followed by a rapid rise of temperature to 105° F., and again succeeded by profuse sweating. Similar paroxysms of a quotidian type occurred over a period of three weeks, and on operation several large stones were found impacted in both the cystic and common ducts, without either a trace of suppuration or the evidence, on the closest scrutiny, of any lesion of the mucous membrane. The autopsy, the patient dying of uræmia, rendered a very careful study of the ducts possible.

The true nature of hepatic fever associated with catarrhal cholangitis yet remains unsettled. It very certainly is not of a septic character. On the other hand, an empyema of the gall-bladder may exist with an entire absence of chill, fever, and sweating. An interesting case of this kind recently has been reported by Dr. Osler, in which 150 c.c. of pus were removed from the gall-bladder. A possible sign of differentiation between hydrops and empyema of the gall-bladder, on the one hand, and dilatation from an impacted calculus producing catarrhal cholangitis and hepatic fever, on the other, may be looked for in the much greater enlargement of the gall-bladder in the former instances. It is a clinical fact, moreover, that in obstruction of the common duct, even when the dilatation of the gall bladder is found to be very great, the physical signs of its enlargement are frequently unappreciable. The explanation I am not prepared to give, unless it be that through the distention of the smaller ducts with bile in these cases, and the consequent enlargement of the liver, the relations of liver and gall-bladder are somewhat altered. A second point of differentiation in favor of a catarrhal cholangitis with dilatation, is in the persistence of the ague-like paroxysms over a very considerable period of time; cases are not uncommon where such symptoms extend over an interval of weeks, and even months.

In conclusion, Dr. Kinnicutt expressed his views in regard to the indications for surgical interference in the different conditions he had referred to. In simple hydrops from obstruction in the cystic duct or neck of the gall-bladder, the indications were not very apparent, although the passage of a large stone through ulceration into the duodenum, and possible intestinal obstruction, should be borne in mind. In empyema of the gall-bladder, speedy surgical interference was demanded. In impaction of a calculus in the common duct, the presence of hepatic fever, even extending over a long period, did not indicate operation in his judgment and from his experience, unless the health seriously suffered thereby. Complete recovery was entirely possible in such cases, even after many months of persistence of these symptoms. A number of cases with this outcome had passed under his personal observation.

Dr. W. Gilman Thompson said that he was pleased to see the specimens presented, for in addition to their general interest some of them, by their great size, showed that it was possible to exist in health without the use of a gall-bladder, as they entirely occupied its cavity—a fact that had also been demonstrated by the removal of the gall-bladder without serious results. In the treatment of gall-stones it was possible that glycerine and ether might dissolve the stone to a slight extent, but he had not secured favorable results from the use of olive oil; and as the oil is not taken up by the blood-vessels, but by the lymphatics, one must conclude that the oil never reaches the gall-bladder. Most of the "gall-stones" found in the stools after giving oil, have turned out to be nothing but inspissated oil. The subject of dietetic treatment was one worthy of careful investigation, but one on which little had been written. It is a matter of interest to find whether cholesterin is a force-producer that can be used in the system, or is only a waste product. It seemed to him that it is not essentially a waste product, for it exists in substances where we would not look for waste matter. It is found in eggs, in pulses, and other vegetables, in red blood-corpuscles, and in the brain, and because it is present in these substances it could reasonably be claimed that it is not a waste product. The fact that it is found in the fæces and rarely in the urine, might be cited to prove that it is waste material, but the probability is that it never appears there in any greater quantity than is taken into the system with the food. As cholesterin is the substance from which gall-stones are chiefly formed, it seems desirable to avoid foods containing it, in the ordering of dietetic treatment.

Dr. Thompson further said that in explanation of the formation of gall-stones he did not see any need of a bacterium, for we look to the precipitation of certain ingredients of the bile as the true factor, and lime salts in excess will do this. A large quantity of water should be drunk, as it dilutes the bile and prevents further precipitation.

Dr. Beverley Robinson said he thought that many cases were diagnosed as gall stones that were not such; that there might be a distention of the gall-bladder and severe colic without the presence of stone in the gall-bladder or the ducts, and that such distention was often wrongly attributed to gall-stones. He further said that he did not believe gall stones occurred in young people, unless in exceptional cases; also that there could be spasms of the gall-bladder and hepatic duct, producing pains similar to those of biliary colic.

Dr. Robert Abbe said he believed that the surgeons were as conservative as the physicians, though they were often looked upon as less conservative. He was confident that patients were sometimes operated upon for the removal of gall-stones who would recover without the operation, yet there were cases in which an operation

was a necessity. He had operated on about fifteen very bad cases, and cited others in which an operation seemed demanded, but the patients got well by passing the stones. The operation was a comparatively simple one, for there was no danger of a hernia, and drainage could be secured without trouble. Dr. Abbe emphasized the point that, opening the abdomen and examination of the gall bladder was not enough for a sure diagnosis of stone, for the gall-bladder was always found to contain considerable bile, and this would interfere with the discovery of the stones. The operator could not be certain until he had opened the gall-bladder itself. He had seen a case that had been operated upon and no stones found, but on a second operation and opening the gall-bladder seven stones were found. He said that he would hesitate most in operating on the aged who had suffered from pains for a number of years, and also in operating upon the young. He cited a case of an expert cook who was accustomed to serve in wealthy families, but biliary colic became so bad every few weeks that it was impossible to retain a position. He thought that in such a case it was very advisable] to perform an operation. Dr. Abbe also thought that dietetic treatment was very important. Manipulation was often of service, and in one case, that of a man sixty years of age, the use of an ice enema and manipulation caused the patient to pass a number of stones, and thus gave relief.

Dr. Leonard Weber gave the history of several interesting cases, and said that he had used an enema of cold water with very good results, but had never used ice for that purpose. One patient had passed four or five hundred stones; in another patient he had found a stone surrounded by cancer, and in another there was a cicatrix encircling the cystic duct.

Dr. Southworth, in closing, said that glycerine was supposed to act by increasing the action of the hepatic cells; that olive-oil probably reduced the size of the formed stone; that it was believed the cholesterin stone was formed from the mucus of the bile-duct and gall-bladder; and that a stone could grow to large size in a duct in a few days.

Clinical Department.

A CASE OF CYSTIC DEGENERATION OF THE CHORION.[1]

By L. W. ZWISOHN, M.D.,
NEW YORK.

On January 3d, I was called to see Mrs. R. S——, who gave the following history: aged twenty-three; married three years; has one child living, aged nineteen months; is greatly emaciated, has headache, sleeplessness, and great debility. She was suffering from severe vomiting and thought she felt life; on bimanual examination I found the uterus very much enlarged and the os closed —to all appearances a normal pregnancy. I advised perfect rest, and prescribed an anti-emetic. On January 10th I was summoned in haste to see the patient. A hemorrhage had occurred and I deemed it necessary to tampon the vagina; I made cold applications and the hemorrhage was controlled; the vomiting still continued and I ordered moderate diet with cold drinks, which afforded the patient some relief. On January 25th a second hemorrhage occurred. I tamponed again, and six hours later the os was well dilated. On introducing the finger to examine the condition of the uterus a sudden and rather severe hemorrhage occurred. I had no time to prepare a proper tampon, but seized the nearest piece of cotton at hand, and packed it into the vagina. Two hours later an hydatidiform mole was removed piecemeal, with the fingers of one hand in the uterus, and the other hand making pressure from above externally. The friends would not allow the use of instruments, and as there was no elevation of temperature I left the case to nature, merely watching developments. Two days later the mother of the patient presented to me the placenta, which was expelled during the night. Since then the patient has been doing well. Now the main points of interest are:

1. Is vomiting one of the main symptoms of hydatid cyst? Thomas, Schroeder, and Tait do not mention it. Playfair says there is constant vomiting, and Polk has reported a case which is similar to the case under consideration.

2. Do we have positive signs to help in the diagnosis of hydatidiform mole? and what are they?

3. Do they reappear in the same individual, and if so, how frequently? for how long a period is the mole retained in the uterus? Tait reported a case in which five moles were removed from the same individual at different periods. He says a mole is rarely retained more than five months.

4. Is curetting advisable in cases of hydatid mole? Thomas, Schroeder, and Tait do not mention this operation; Polk performed it in the case he reported, but in that case he says the mass had a decided odor of decomposition.

5. Is it possible that hydatidiform mole should occur independently of conception?

To answer these important questions, I believe we have to consider the etiology of the hydatid mole. The chorion remaining attached to the uterine walls after the expulsion or death of the embryo sometimes undergoes a peculiar metamorphosis; it differs, however, from the true hydatids in absence of the acephlocysts and is also unlike it in appearance and form; the uterine hydatids consist of little sacs in a series as if strung together, hence their grape-like appearance; the true hydatids are closed sacs, one within another. Giers and Graily Hewitt say it always follows death of the fœtus. The fact that the morbid growth may owe its inception to fœtal disease seems demonstrated by the cases[1] where a healthy fœtus may be developed at the moment with the hydatid mole. Virchow thinks it originates in a morbid state of the decidua, while others attribute it to some blood dyscrasia on the part of the mother, such as syphilis. The latter believes that it may occur more than once in the same person, and that the exciting cause of the hydatid mole is a morbid maternal condition. The probability is that both views may be right, the disease sometimes following the death of the embryo and at others being the result of obscure maternal causes.

McClintock says that hydatids may be retained in the uterus for many months or years, or a portion only may be expelled and the residue may throw out a fresh crop of vesicles to be discharged on a future occasion. This may be important from a legal point of view, for instance, in the case of a widow or a woman living apart from her husband. It is possible, as Playfair points out, that true entozoa may form in the substance of the uterus, which being expelled per vaginum might be taken for the result of cystic disease. Hewitt also relates a case of an unmarried woman in whom true hydatids from the liver had extended to the peritoneum and burst through the vagina.

In such cases the woman's reputation may demand that a careful examination of the cyst and its contents should be made.

Symptoms.—The first physical sign is the rapid increase of the uterine tumor, which does not correspond in size to the supposed period of pregnancy. Leishman attributed much importance to the unusual hardness or density of the uterus. The uterine tumor is often irregular, and constant vomiting may be present. None of these are, however, positive signs except the presence of cysts in the watery and bloody discharge.

Dr. Holperin related to me two cases that came under his observation in which there was hemorrhage in both,

[1] Read before the Harlem Medical Association.

[1] Spiegelberg, Lehrbuch, p. 332.

and vomiting in one. In the second case he was unable to tell, as he was called to deliver the mole and could not obtain the history of the case.

Treatment.—The uterus should be cleared of its contents as soon as possible, and on account of the occasional firm adhesions of the cystic mass to the uterus too energetic attempts at complete separation should be avoided.

Summary.—From the different opinions above quoted we are justified in coming to the following conclusions: 1. Persistent vomiting is one of the principal symptoms, but not a certain sign. 2. The only positive sign we have is the presence of the cysts in the watery discharge. 3. They frequently reappear in the same individual, but for what period they are retained in the uterus it is impossible to say. Although Tait says it is rarely retained more than five months, it is quite possible, as McClintock points out, that a portion may be expelled and the residue may bring out a new crop. Thus the five different periods in the same person of Tait may all be from the first mole. 4. Curetting is advisable only where the hemorrhage continues, and then with a dull curette, as the parenchyma of the uterus may be affected and its walls very thin. 5. Hydatidiform mole is essentially connected with pregnancy.

326 East Seventy-eighth Street.

MENSTRUATION AND PREGNANCY — IMPACTION OF A FOREIGN BODY IN THE ŒSOPHAGUS.

By R. H. PHILLIMORE, M.D.,

COOKSHIRE, CANADA.

The following two cases are perhaps deserving of record:

Case I.—On October 5, 1893, I was hastily summoned, at 2 A.M., to attend Mrs. C——, an anæmic, hard-working woman, aged thirty nine, and the mother of eight children. She was suffering from severe pains, with uterine hemorrhage. Examination showed the organ to be considerably enlarged, with tenderness on pressure. Naturally the first question to present itself was, was the patient pregnant, and were the symptoms those of threatened abortion? She emphatically declared that she was not pregnant, notwithstanding that the sapient matrons in attendance were unanimous in their belief that she was. Suitable agents were administered, and the vagina was tamponed. I continued treating her almost daily, up to the end of January, 1894, when the severe hemorrhages, which had returned periodically, ceased; and, though the menstrual epochs continued regular, they were always attended with pain and considerable constitutional disturbance.

From this time until the end of September, 1894, I saw Mrs. C—— only on a few occasions, when she informed me that the condition of the uterus remained practically unchanged—it was still enlarged and tender, and menstruation was regular. Toward the latter part of this month she consulted me in regard to swelling of the extremities, with puffiness of the eyelids. Examination of the urine exhibited only a trace of albumin.

On October 6, 1894, I was again hastily summoned. "Mrs. C—— was flooding again." Upon examination I found the uterus apparently in the same condition, and the patient considerably "bloated." Menstruation, as I have previously observed, had been perfectly regular, and not so painful as on previous occasions. She complained, as before, of pains in the back and legs. External examination showed no change in the size of the uterus, but an internal examination revealed an os slightly dilated, with a tumor presenting. I informed the friends of the condition of the patient, but they, being well acquainted with the previous history of the case, ridiculed the idea of pregnancy, as also did the patient herself. On the morning of the 7th she was delivered of a female fœtus, measuring 8½ inches in length.

The following points in this case are interesting: 1, Signs suggestive of pregnancy on first visit, eventually proving erroneous; 2, pregnancy present when not suspected; 3, uninterrupted menstruation during pregnancy.

Case II.—On September 18, 1894, I was summoned to attend a child, aged eighteen months, who at 11 A.M. had swallowed an English farthing. Having placed the patient under an anæsthetic, an examination of the throat was made, but no obstacle was discovered, though a horse-hair probang was employed. The following day persistent vomiting ensued.

Patient was ordered milk with raw egg beaten up, solid food being persistently rejected. On this diet the child thrived. The parents having refused to allow another examination—although I repeatedly expressed the opinion that the coin was lodged in the throat—liquid diet was daily administered. On October 7th, nineteen days after the accident, the patient ate a quantity of grapes in addition to its liquid diet. This was followed by emesis, and the coin, considerably worn, was suddenly expelled. The patient at once partook of a hearty repast, consisting of solid food, and has now entirely recovered from the effects of its financial embarrassment.

That the coin was impacted in the œsophagus there can be no reasonable doubt, and the case is instructive as indicating the difficulty of detecting foreign bodies in this situation, and also the length of time which may elapse without injury to the tube in which they are lodged.

THE TREATMENT OF CARBUNCLE, WITH REPORT OF A CASE.

By J. MORTON HOWELL, M.D.,

WASHINGTON COURT HOUSE, O.

In the month of May of the present year, I was called to see Mr. R. S. S——, a man little past three score of years. I had been treating him for some months previous, for a severe prostatitis and functional albuminuria. There had been but little loss of flesh as a result of the diseases named, but the patient complained of weakness, and was noticeably void of that vitality which was so characteristic of him in former days. When I arrived, he told me that he was suffering much pain in the small of his back, and described it as a dull, heavy ache with intense burning.

Upon examination, I found a circumscribed, oval, and highly inflamed induration, situated immediately to the left of the spinal column, at the juncture of the dorsal with the lumbar vertebræ. It measured 5.75 inches in its longer diameter, and was discharging pus from a half dozen different openings. The sieve-like appearance presented by the skin surface, together with the form of the neoplasm and the character of the pain, made the diagnosis one of ease.

Owing to the age and debility of my patient, together with kidney and prostate trouble alluded to, the prognosis could be but grave. To adopt a form of treatment which would be most sure to land my patient upon the side of recovery, was my desire.

An examination of authorities shows that comparatively little is written upon this subject, which furnishes the mortality that it does.

The modes of local treatment, as suggested by the various writers, differ widely. For instance, Ashhurst and the "Reference Handbook of the Medical Sciences," recommend, among other remedies, poultices, while they are condemned by the "American Text-book of Surgery."

Without noticing further the treatment as found in our medical works, we will give our treatment of this case, which we believe may be made applicable to any

case. If it proves to be an instrument in the saving of a life, or an assistance to our brother practitioner in his mission to do good, it will have served its purpose.

After freezing the parts, two incisions were made, crossing each other at right angles, being carried sufficiently deep to include the healthy tissue beyond the limits of the disease. Bleeding was tolerably free, and after sponging the parts well with hot water (previously boiled) a dressing was made by application of dry boracic acid (Wyeth's impalpable powder) over which was placed a thick layer of antiseptic gauze, previously saturated with hot carbolized water. Over this gauze oiled silk was placed, which retained the moisture almost to perfection. The burning at once ceased, the pain disappeared, and the patient was made so comfortable, that in forty-eight hours he was doing his regular choring about house and barn. The dressing was changed once in every twenty-four hours. He was given a ferruginous tonic, and placed upon a light but nutritious diet.

I discharged my patient in eight days from my first visit.

A CASE OF NEPHRECTOMY ON ACCOUNT OF NEPHROLITHIASIS AND PYONEPHROSIS.

By HERMAN MYNTER, M.D.,

PROFESSOR OF SURGERY, NIAGARA UNIVERSITY, BUFFALO, N.Y.

JOHN S——, aged twenty-two, entered the Sisters' Hospital on August 2, 1894, with the following history:

He had complained for the last seventeen years of periodical attacks of pain in the back and left lumbar region. Up to five months ago the attacks occurred about once in six or eight weeks, with free intervals, extended downward in left scrotum and thigh and could only be relieved by hypodermics of morphia. They would suddenly cease and hours afterward he would pass, with great pain, a whitish soft mass, which did not have the appearance of a stone, and then a profuse flow of scalding urine. During the last five months the above symptoms had increased in severity and become continuous. The patient had lost greatly in weight, suffered from profuse night-sweats, loss of appetite, occasionally a dry cough. The parents were healthy, but one brother had died of consumption. At the examination the patient appeared extremely emaciated and cachectic, with protruding cheek-bones and hectic flush. Weight, 101 pounds. There was great tenderness from pressure in left lumbar region, but neither anteriorly nor posteriorly, standing or lying, could any swelling or enlargement of the kidney be discovered. He was also somewhat tender to pressure over the right lumbar region. He passed about one quart of urine in the first twenty-four hours, half of which was pus. The urine had a color like chocolate, specific gravity 1,030, acid reaction, and was loaded with albumin. Microscopically nothing was seen but pus corpuscles.

By cystoscopic examination under cocaine anæsthesia and after preliminary irrigation of the bladder, an excellent view was immediately obtained of the fundus of the bladder. The mucous membrane appeared perfectly normal. The orifice of the right ureter was seen as a small oblique slit, through which a swirl of healthy urine passed every four or five seconds. Turning the cystoscope toward the orifice of the left ureter I saw what appeared to be a deep crater-formed ulcer, about two centimetres in diameter. Nothing appeared for two or three minutes, when suddenly a cohesive, thick, yellowish mass commenced to protrude through the crater, as thick apparently as a little finger. When about two inches of this mass had entered the bladder, it disappeared from view and was followed by a profuse discharge of yellowish pus, which quickly obscured the field. As it was evident from this examination that the patient suffered from a pyonephrosis of the left kidney and that the right kidney was healthy, nephrectomy was advised, although his condition was so miserable that it seemed impossible he could survive such an operation. The operation was performed on August 8th, under chloroform narcosis, the patient having been stimulated for a couple of days with hypodermics of strychnia, nitro-glycerine, whiskey, and rectal alimentation. The pulse was then 130, weak; temperature had ranged between 101° and 103° F. The incision was made along the erectus spinæ muscle ending near the crest of the ileum, combined with an oblique incision along the whole lower border of the twelfth rib. The kidney was almost wholly covered by the ribs, strongly attached to the colon and the surrounding tissue. During the process of enucleation, which was extremely difficult on account of the strong adhesions and its high position, my whole arm almost disappearing up to the elbow in the wound, a large abscess in the kidney itself was ruptured, from which a large amount of ill-smelling pus, estimated at one pint, escaped. The hilus was at last reached, the kidney brought out through the wound, two clamps attached on the hilus in order to finish the operation quickly, and the kidney removed. The ureter was as large as a finger. The wound was disinfected with corrosive sublimate, loosely packed with iodoform gauze and partly sutured. The patient left the table in a state of profound shock, pulseless and with clammy perspiration, but by active stimulation, he revived in a short time. The operation lasted about three quarters of an hour.

The kidney preserved its general contour, but was enormously enlarged, its volume being about six times that of the normal. It measured seven inches in length, four in width, and three in thickness. Its weight was twenty-eight ounces; but as at least one pint of pus escaped, its weight must have been about forty four ounces—two and three quarter pounds. The capsule was adherent and blended with the renal structure. The color in no place was that of a normal kidney, but that of fat and fibrous tissue.

The surface presented numerous large circumscribed swellings which on palpation were soft and fluctuating, and on incision were found to contain a thick, greenish, tenacious pus. On the posterior surface was a large abscess cavity, ruptured during the operation. On section no normal kidney structure appeared. The upper third was a mass of multilocular abscesses which intercommunicated and contained pus of the same character previously described. The middle third was a mass of fat and fibrous tissue; lying in the latter was a large triangular shaped stone, $1\frac{3}{4} \times \frac{3}{4}$ inch, of a greenish-brown color, irregular in shape, and with rough surface. The lower third showed two abscesses, the larger being three-fourths of an inch in diameter. In one of the abscesses in the upper part a rough irregular stone was found. The pelvis was greatly enlarged, full of pus, and contained several cohesive, yellowish masses of necrotic tissue impregnated with pus, like the one which was seen to pass with the cystoscope. Scarcely any traces of kidney tissue could be seen, and its function as a secreting gland had probably long ceased.

August 9th.—Temperature, $102\frac{2}{5}$° F.; pulse, 130. He has passed 19 ounces of urine since the operation, the last of which is perfectly clear and normal. He is extremely weak and is given $\frac{1}{60}$ gr. strychnia and $\frac{1}{100}$ gr. nitro-glycerine every three hours hypodermatically. He has taken one quart of milk during the night.

August 10th.—Temperature, 101° F.; pulse, 120; $28\frac{1}{2}$ ounces of clear normal urine. Patient takes lots of nourishment and rests well.

August 11th.—Temperature, $99\frac{1}{2}$° F.; pulse, 126; 31 ounces of urine. Clamps removed and cavity irrigated and loosely packed with iodoform gauze.

August 12th.—Temperature, 99° F.; pulse, 108; 27 ounces of urine. Patient takes solid food.

August 13th.—Temperature, 100° F.; pulse, 110; 32 ounces of urine.

He gradually improved, passed from 35 to 45 ounces of urine daily; pulse and temperature became normal.

August 23d.—The dressing was found saturated with

fecal matter, a fistula evidently having formed into the colon, but it healed in a couple of weeks.

August 25th.—The patient was sitting up; the large cavity had contracted so that only a small granulating fistula was left. His weight had increased to 105 pounds, he felt perfectly well and was discharged to his home.

September 22d. — Weight 137 pounds, a gain of 36 pounds; patient a picture of perfect robust health, urine normal, fistula closed.

October 1st.—Weight 140 pounds.

October 12th.—Weight 147 pounds, patient has gone to work in a machine shop.

The interest in this case is the ease with which the diagnosis was made by aid of the electrical cystoscope, and particularly the demonstration that the right kidney was healthy, and therefore an operation advisable. Only by operative means in two other ways—an exploratative laparotomy or an explorative suprapubic cystotomy with catheterizing of ureters, could the diagnosis have been cleared up, and there is no comparison between these methods and the simple cystoscopic examination, done without any danger to the exhausted patient. Cystoscopy necessitates, of course, that the bladder shall be able to contain five ounces of clear fluid and that the cystoscope shall be able to enter the bladder; luckily both indications were fulfilled in this case.

A second point of interest was the impossibility of feeling and palpating the enormous kidney before operation. I can only explain this by the strong adhesions of the lower segment of the kidney to the colon and surrounding tissue, by which the kidney was forced to enlarge upward and forward below the diaphragm. A third point of interest was the long time, seventeen years, in which the patient had suffered from nephrolithiasis without a distinct diagnosis having been made, and the rapid and perfect recovery that followed the removal of the diseased organ, the patient in seven weeks gaining 46 pounds in weight. I have during the last three years performed nephrectomy four times. Two operations were done on account of tuberculous kidneys. One of these died on the fourth day of suppression of urine, and the post-mortem examination showed the remaining kidney to be tuberculous. A cystoscopic examination would in this case probably have shown that the operation was contra-indicated. The second case recovered, but died half a year later of general tuberculosis of the urinary organs. The third operation was performed in October, 1892, on account of a large sarcoma of the left kidney in a lady fifty years of age. The patient recovered, and so far, two years after the operation, no relapse has occurred and she is in perfect health.

Longevity among Physicians.—One of the most curious statistical records that has been compiled this century is that by Dr. Salzmann, of Essling, Wurtemburg, on the average duration of life among physicians. He found in going over the ancient records of the kingdom, that in the sixteenth century, the average duration of life among that class was but 36 5 years—in the seventeenth century 45 8—in the eighteenth, 49 8, and at the present time they reach the favorable average of 56.7. It appears from the footnotes to the above that this very great increase in longevity is due to the disappearance of the "black pest," the introduction of vaccination, and the great diminution in the number of typhus epidemics, three classes of diseases which formerly decimated the medical practitioners.—*College and Clinical Record.*

The Gift of a Hospital.—M. Henri Schneider, of Creuzot, France, has built and presented to the town a new hospital, with accommodation for one hundred and fifty patients. The hospital was opened on September 18th, with religious ceremonies conducted by Monsignor Perraud, Bishop of Autun.

VERSION THREE WEEKS BEFORE DELIVERY.

By G. STARKE, M.D.,
NEW YORK.

I BEG to report the following case as of probable interest to the medical profession:

Mrs. J. T. S——, age at present twenty-four; height about five feet four inches; weight about one hundred and twenty five pounds. Four years ago she was delivered of a child at seven months, the baby living but twenty-four hours. Though a breech presentation, delivery at that age of fœtus was easy. Two years ago I delivered her at full term of a boy, also a breech presentation, with forceps, after a rather severe labor, the child being in a state of asphyxiation and only resuscitated after half an hour's work, after the method recommended by Dr. W. E. Forest in the MEDICAL RECORD of April 9, 1892. The boy at this date is hale and hearty.

Mrs. S—— again became pregnant, and having had her last menses December 5, 1893, expected to be confined about September 12, 1894. I saw her on September 8th, and examining her, found another breech presentation, of which fact I informed her, and it had a decided depressing effect upon her. I informed her that, in view of her having had a hard time with the boy, and his life at the time almost despaired of, if she consented I would endeavor to perform version and make an almost certainty of the child being born alive, knowing that she was very anxious for it, particularly if it should be a girl. She consented, and I performed version, by external manipulation alone, inside of ten minutes. Before leaving her, I assured myself by vaginal examination that the head was well placed in the pelvis, and the occiput anterior by external palpation.

On September 14th she sent for me again, fearing that the child had turned again to its former position during sleep, but upon examination found it to occupy the same position I had previously placed it in. She progressed without ill consequences till September 28th, when I was sent for at 8.30 P.M. Arriving at her house about nine o'clock, I was informed that the waters had broken half an hour before, as she was about to go out for a drive. Upon examination found the os dilating, the head presenting in the L. O. A. position. Though good pains did not set in till eleven o'clock, she was delivered of a girl baby at 12.30 A.M. on September 29th, and her progress since then has been uneventful.

The interesting circumstance in this case to me is that version, being intended to be performed only a day or two previous to the expected time of expiration of her pregnancy, was accidentally performed three weeks before delivery, a very unusual procedure. However, in this case with most gratifying result, saving the mother much pain and insuring a shorter labor, and saving me very much anxiety.

The lesson to be drawn from this case is that version can be performed much easier some time before labor sets in, than after the uterine expelling forces have begun to exert themselves, when the uterus usually resents any severe interference or manipulation by grasping the fœtus tighter, often necessitating anæsthetics, besides running grave risks of lacerating the uterine and fœtal tissues, and requiring at least two for the operation. I had a similar case of a transverse presentation some two years ago, where fortunately I was called in a day before the confinement and corrected the presentation, resulting in an easy labor.

I would recommend to all medical men having the advancement of their profession at heart, in all doubtful cases, and when possible, to examine their pregnant patients a week or two before their expected confinement, for the ascertaining and correction of presentations; the same as we are recommended to examine their urine for albumin to prevent complications.

1393 FRANKLIN AVENUE.

Correspondence.

BERIBERI AND BEANS.

To the Editor of the Medical Record.

Sir: In an editorial notice, Medical Record, Novem ber 17, 1894, of "beriberi in New Jersey," you speak of the "ill favored human cargo of a vessel from Navassa, which has entered port at Perth Amboy. There seems to be no doubt that faulty hygiene and lack of suitable food were the factors determining the outbreak. Beans furnished the principal food, it appears, during the two weeks' voyage, and, strange as it may seem, this is just the article of diet which Dr. Simmons recommended in a monograph on the subject in 1880."

As I had the pleasure of assisting the late Dr. Simmons in some of the details of that work, and as the above reference may give a wrong impression, please allow me the space to say that "there are beans and beans," and that in his monograph Dr. Simmons lays stress upon the peculiar kind of bean—a small red variety—that has long found popular favor in the management and treatment of beriberi, once so prevalent in Japan. The large common starchy bean has no value, and I think he so states it, though I have not the paper by me for reference.

In more recent years an unlooked-for confirmation of the value of this bean as a food in cases of beriberi is found in the fact of its large relative amount of albuminoid nitrogen composition. It has been ascertained that the chief element in the production and prevalence of the disease is the lack of the nitrogenous foodstuffs—particularly of the fresh flesh sorts—in the habitual dietaries of the natives. The multiple neuritis is in all probability (as believed by some distinguished investigators in the East Indies and Brazil) the result of the presence of a specific micro-organism, only to be found in low lying, moist countries, among races long deprived of albuminous food. Navassa is notoriously an unwholesome guano and phosphate island in the Caribbean Sea, occupied mainly by contract laborers, often convicts, living under great hardship for long periods. In the past few years the isolated rock has been unpleasantly heard from, with trials for murder under the jurisdiction of the criminal courts of Baltimore. Under the circumstances the occurrence of beriberi can cause no surprise, and scurvy cannot be unknown there.

At the last International Medical Congress at Rome, a paper on beriberi was read by a Japanese naval medical officer—a delegate from the marine department of his government—giving statistics and results of the present management of the disease in their navy. With a rearrangement of the dietary, the introduction of a large increase of nitrogenous food elements, and a corresponding diminution of the carbohydrates, the disease has been gradually eliminated, and for 1893 few, if any, cases are reported. It was formerly very prevalent.

Following a common rule, beriberi requires for its evolution a soil and a specific micro-organism, in this instance the lesion being fundamentally in the white nervetissue of the peripheral nervous system. Want and misery, with deprivation of proper food—albumins of animal origin mainly—will soon produce the disease in countries of its endemic prevalence.

As an example of how beans will vary (coming back to our subject) in relative composition, I append some trustworthy analyses, made by Professor Atwater, of Wesleyan University, at the Agricultural Experiment Station, Storrs, Conn. If such differences occur under equal conditions, what may be looked for with widely varying quality of seeds, soil, and climate, in the relative amounts of legumin, sulphur, phosphorus, and albuminous nitrogen substances upon which the peculiarly nutritive value of some kinds of beans depends? Changes due to parasites, fungi, bad keep, age, etc., are not considered, yet have a share in rendering unfit for consumption foodstuffs, especially the leguminosæ so much given to ships.

	Six Weeks Beans. Per cent.	Soja Beans. Per cent.	Common, as Purchased Per cent.
Water	11.46	8.32	13.70
Protein	19.92	35.24	2.32
Fat	1.81	20 48	2.01
Nitrogenous free extract	60.26	25.86	60.26
Fibre	3.25	4.84	....
Ash	3.30	5.26	3.60
Albuminoid nitrogen	2.78	5.40	....
Non-albuminoid nitrogen	0.41	0.24	....

Very respectfully yours,

C. A. Siegfried, M.D.,
U. S. Navy.

U. S. Steamship Cincinnati, November 26, 1894.

PERMANGANATE OF POTASSIUM IN OPIUM POISONING.

To the Editor of the Medical Record.

Sir: Having been unprofessionally criticised in your journal on October 6th, by Dr. Warfield, in regard to my article on the same subject as this brief reply, and being again made the subject of ridicule from the pen of the original discoverer of permanganate of potassium as an antidote to morphine poisoning, Dr. Moor, please allow me to reply. I would suggest to the two doctors that they read the articles of Dr. Glenn Anderson, of Montgomery, Dr. Joseph M. Rector, and Dr. Harding. Dr. Warfield says that Dr. Moor pointed out plainly to his medical brethren that the administration of potassium permanganate would chemically render inert the amount of morphine remaining in the stomach at the time of administration. If Dr. Warfield has the correct version of the discoverer's ideas of this new antidote, it will only save the use of the stomach-pump in morphine poisoning —nothing more. I will ask Dr. Warfield to read Dr. Moor's original article, and then his reply to my article, and I think he will be led to believe that Dr. Moor even claims the permanganate to be more than a chemical oxidizer in morphine poisoning. In his original article Dr. Moor says that he considers the permanganate to be the antidote, *par excellence*, for morphine poisoning, and further: "I have strong reason to believe that the administration of permanganate will be of service even after absorption has taken place." After my patient was in a fair way to recovery, Dr. Earnest suggested the permanganate upon physiological grounds of its alleged effects. I did not want to use it, as I had no faith in it, but knowing the patient to be in a fair condition, I yielded reluctantly to the administration of the drug. I do not claim that the permanganate did my patient any harm — it merely deprived him for the time being of remedies that would have been of positive benefit. I do not consider permanganate of potassium to be a drug of any value in opium poisoning.

C. Monroe McGuire, M.D.

Walsenburg, Col.

Alcohol and the Bible.—Dr. Harnack, of Halle, has published a brochure to show that the teachings of the Bible are against the doctrines of the prohibitionists. He cites a number of passages from both the Old and the New Testaments in which wine is mentioned as a permissible, if not necessary, article of diet. To "look not upon the wine when it is red in the cup," he opposes "take a little wine for thy stomach's sake."

Dr. M. Rossbach died a short time ago in Munich, at the age of fifty-two years. He was author of the well-known "Lehrbuch der physikalischen Heilmethoden," and joint author with Nothnagel of a treatise on therapeutics.

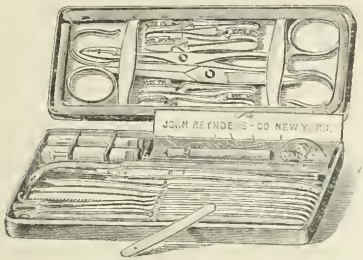
New Instruments.

AN ASEPTIC AND REALLY SURGICAL POCKET-CASE.

By ROBERT H. M. DAWBARN, M.D.,

PROFESSOR OF OPERATIVE SURGERY, NEW YORK POLYCLINIC.

In the *New York Medical Journal* of October 19, 1889, I described, and showed by illustration, a pocket-case for minor surgery, which at that time seemed to me worthy of mention. To-day the accompanying woodcut gives some idea of an improvement upon that case, based



upon further experiment in the matter of compactness and also of lightness. It seems to the writer that this case, as now completed, combines a number of desiderata:

1. It is so shaped as to be able to fit into an upper vest-pocket, and not to spoil the fit of a coat, being quite thin.

2. The instruments are very compactly arranged, there being no waste space. Indeed, the only criticism on the case which occurs to the writer is that a little practice is needed in order to replace instruments speedily after use.

3. The case itself is of aluminum, nickel-plated, as also are the handles of the instruments. Consequently a great gain is made in lightness. Indeed, this case, with about double the number of instruments contained in any other pocket-case, nevertheless is not at all heavy.

It was necessary to nickel the aluminum because of the next point, namely,

4. If either case or instruments become soiled, they may be sterilized in the usual way, by boiling, and to avoid rust we always add an alkali, *e.g.*, some washing-soda. Now, it is known that alkali attacks aluminum, hence the necessity for plating the case and the instrument handles.

Contrast this ease of sterilizing with the condition found in the ordinary leather, velvet lined pocket-case, which is still the favorite with instrument dealers. In course of time the latter becomes grimy with dust, and malodorous from perspiration, and is impossible of cleansing in a surgical sense.

5. The selection of instruments is based upon common-sense and the needs of practical surgery, and no one can claim as much for the ordinary pocket-case. This latter, for instance, rejoices in a single pair of artery-forceps. Indeed, I have seen no other pocket-case with more than one, or at least two, pairs of hæmostatic forceps, whereas every surgeon knows that if one pair be needed, half a dozen are likely to be. This new case contains six, and the needle-holder may, if required, make a seventh.

Again, almost all cases which I have examined still display that abomination, a jointed metallic catheter. This instrument of torture never fits properly when it has been screwed together a few times, and thereafter scrapes the urethra viciously.

The knives are a weak point in most cases and show amateur selection. For instance, there is always the curved, sharp pointed bistoury—a thing which surgeons do not use, because they never stab and cut out. It is not even necessary to do so in opening a boil, in these days of cocaine anæsthesia.

The knives are too numerous, as a rule, and the scalpels have little, baby-blades. By shortening their handles it is easy to make room for blades of adult size, with which a thigh could be amputated if need be.

We may fairly criticise, too, the needles and needle-holder ordinarily found; both being still of the old-fashioned type; whereas surgeons use almost exclusively the Hagedorn needles, and these cannot properly be grasped by the ordinary holder. The advantage of the Hagedorn needles is, that they cut in such a way as to aid hæmostasis when the suture is tied; and also to diminish the size of the scar left by the needle. The cut runs like the buttonholes along the edge of a coat; *i.e.*, at right angles with the wound edge. And this is just the reverse of the direction of the wound made by the old-fashioned needle.

I beg to apologize to all surgeons for these trite remarks upon needles; but inquiry of dealers shows that the great bulk of the profession still buy and use the kind which should be obsolete; apparently not yet knowing these points.

For a good many years, now, the writer has preferred to all others the "patent-eye" or "self-threading" modification of Hagedorn. The Germans used them for a long time before they were much noticed here. They call them "Nähnadeln mit federndem Ohr." If properly made, the needle does not cut the thread at the eye, and it can be threaded in a moment, with bloody or otherwise sticky fingers, and in the dimmest light.

To continue this little critique: We commonly find in pocket-cases some more or less sterile silk, by way of suture and ligature material, lying in one of the dusty pockets aforesaid. Of course suppuration follows its use; otherwise it would disappoint us.

In the aluminum case, instead, will be found two little bottles with rubber corks. Each contains a small glass reel, and one is full of sterile silk, the other of sterile catgut, medium sizes, each in absolute alcohol. Enough surgically pure material is here to supply ligatures and sutures for even a large operation.

The same little aluminum compartment which contains our needles, finds room for a silver *porte caustique;* and also for a few bichloride of mercury tablets, wrapped in rubber tissue; enough for some quarts of antiseptic solution.

In conclusion, the list of contents is appended in full. As to the catheter mentioned, it is a soft rubber Nélaton catheter, of medium size; and besides its obvious function, it acts as an elastic buffer, preventing any rattling of instruments within the case. It may also serve to constrict some small member, as a finger, during operation. It will supply, if sterile, drainage-tubing in emergency. A two-inch section, with the aid of a large safety-pin, makes a very fair tracheotomy tube for infants. It enables one, with ease, to pass twine tied to it, through the nose into the pharynx, and so out of the mouth, thereby permitting instant control of nose-bleed by tamponing both anterior and posterior nares.

Contents of Aluminum Case.

1 Scalpel, full-sized blade.
1 Long, narrow, straight, sharp-pointed bistoury (this may be used as a tenotome).
1 Metacarpal saw.
1 Peaslee needle, curved (eye in point with handle; for passing retention sutures).
1 Grooved director and aneurism-needle combined.
1 Pair dissecting forceps.
1 Pair mouse tooth forceps.
1 Volkmann sharp spoon (an instrument often needed).
1 Pair scissors, with French lock, for ease of cleansing.
1 Needle holder, with French lock; which is also a dressing-forceps and an artery forceps.
1 Silver *porte caustique*.
1 Nélaton catheter.
1 Small package Hg. bichloride tablets, in rubber tissue.
2 Silver probes, one-eyed.

2 Bottles, one containing silk, one catgut, in absolute alcohol.
6 Hæmostatic clamps.
Assorted sizes of Hagedorn's "self-threading" needles.

The pocket-case thus described is made by Messrs. Reynders & Co., of this city; and is sold at about the cost of other pocket-cases.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 1, 1894.

	Cases.	Deaths.
Tuberculosis	100	110
Typhoid fever	26	9
Scarlet fever	90	8
Cerebro-spinal meningitis	2	2
Measles	47	2
Diphtheria	202	59
Small-pox	13	1

The Physical Strain Involved in High Speeds.—The exaction that modern railroad speed makes on the physical stamina of railroad men is demonstrated in the fact that seven engineers are required to take the Chicago flyer out and seven back, says the Boston *Transcript*. The running time between New York and Chicago is twenty-four hours, and the average speed is forty-eight miles an hour. Each engineer and engine runs three hours. Machine and man return with a slow train to their starting-point to relieve the strain on both. Then the engineer is given forty hours' rest before he goes on the flyer again. This rest is absolute, no work of any kind being required of the engineer. Though the average speed is forty eight miles an hour, the locomotive must at some points be driven at sixty or more. The physical strain on the men in the cab at those bursts of speed is something terrible. The engineer has fifty things to look out for, and is being shaken and swayed all the time. The fireman is constantly feeding the insatiate furnace. On the run of the Empire State express three tons of coal are shovelled from the tender into the furnace between New York and Albany. It is not wonderful that the engineers of this train are given alternate days for rest and recuperation. Fast travel not only wears out rails and machines, but human creatures' lives. —*Scientific American.*

Origin of the Term Anæsthetic.—Mr. Edgar Willett, in a communication to the *British Medical Journal*, records a conversation he had with Oliver Wendell Holmes when the latter was in England in 1886. The discussion had turned on the subject of anæsthetics, when he said: "Do you know the origin of the term?" On receiving a negative answer he replied, "Then I will tell you. I believe it was I who invented it, and this is how it occurred. Many years ago, when ether and chloroform were only just coming into use, Morton, the dentist at Boston, who was largely responsible for the introduction of ether, came to me and asked me if I could suggest for him a word which could be used for both drugs, and also a word which would describe the effect produced by their inhalation. After trying two or three words, æsthetic occurred to me as meaning sensitive, and in consequence anæsthetic as being insensitive easily followed, with anæsthesia for the condition produced. That," he concluded, "was, I believe, the origin of the term."

The Middle Tennessee Medical Association, a recently organized society, held its first meeting in Nashville on November 20 and 21, 1894. A number of interesting papers were read and discussed, and the meeting was regarded as a success.

Contagiousness of Phthisis.—It has been decided in Toronto that phthisis is a contagious disease, and accordingly the board of education has decided to forbid children suffering from it to attend the public schools.

Count Leo Tolstoi is, as might have been expected from a consideration of his other eccentricities, a pronounced anti-vaccinationist. He holds that "the obligation of parents to let their children be subjected to operations deemed necessary by doctors seems to me as great an outrage as the obligation of parents to subject their children to school teaching imposed upon them by the government."

Individual Communion Cups. — The Homœopathic Medical Society of the County of Philadelphia, at a recent monthly meeting recommended the abolition, by all churches, of the common communion cup, or chalice, and the substitution of individual cups.

Against Christian Science.—The Humane Association, at the closing session of its annual meeting, held in Evansville, Ind., on October 11th, adopted a resolution condemning, in strong terms, the practice of Christian Scientists, and urging all societies to investigate any suspicious deaths, and prosecute, if they are found to result from the ministrations of this doctrine.

Trusses.—Dr. A. Landerer, of Stuttgart, recommends the use of rubber pads filled with glycerine for trusses. He finds them durable as well as comfortable, and says that they never cause atrophy of the tissues against which they press.

The Czar's Death has been attributed by some imaginative newspaper correspondents to the effect of poison secretly administered by Nihilist members of his household. This report is characterized by Dr. Leyden as pure fiction. The post-mortem examination, as detailed elsewhere, established the correctness of the diagnosis of chronic nephritis, with commencing atrophy of the kidney, secondary enlargement of the heart, and inflammation of the left lung. The stomach was intact.

ON THE NEW USE OF SOME OLDER SCIENCES.

BEING A DISCOURSE ON DEGENERATION AND ITS STIGMATA.[1]

BY CHARLES L. DANA, A.M., M.D.,

NEW YORK.

GENTLEMEN AND LADIES: As I survey the medical activities of the present time they seem to be working in three distinct streams of fruitful and progressive effort. The first, and just now greatest, takes in all that may be meant by bacteriology or the science of minute organisms. Through this we are learning the secrets of disease and health; through it we shall some day, I hope, reach a germ-free millennium, or at least learn to live unscathed among our little enemies teeming in the air and dust.

Next, one finds that while medical men are abandoning faith in old-time Homeric drugs and drugging, they are working with an intenser energy than ever to perfect the technical details of their art. In every branch exactness of observation, precision in examination, and resourcefulness and ingenuity of treatment are increasing, until the reproach that medicine is not a science is slowly losing its force.

Finally, I see a new and extraordinary energy put forth in the study of the physical characters of man, and the significance of the lines along which each individual is built. We are trying to read in man's general conformation the story of his character, his weakness, his capacity, his power of resistance to disease and temptation—in fine, his moral and intellectual endowments. It is because this movement, though it has reached great proportions in Europe, has made little impression here that I propose to make one phase of it the subject of my remarks to-night.

It is a doctrine as old as Hippocrates that different people have a special tendency to different diseases, and that they react in different ways to the influences about them; that one will have catarrhs, another gout, another rheumatism, and another consumption; that one is lethargic, another nervous, and another melancholic. It is not of these kinds of investigation that I shall speak; though this new science does in a certain measure what the quasi-sciences of physiognomy and of phrenology, of diathesis and temperament, once claimed to do. It does not seek to accomplish its object, however, by feeling the bumps on the head, or noting the lines on the palm, or studying the hand-writing, or by mystic rites performed over a lock of hair. It is a science quite different from so-called phrenology, or physiognomy, or chiromancy—arts which are merely incongruous collections of fatuous guesswork. This coming science has no name that yet specifically indicates its work. It is approached on the one hand by anthropologists, and on the other by students of nervous diseases, of insanity, and of crime, and it receives accessions from the learned savants of the universities and the modest instructors in the gymnasia.

It is a study of the human body in its largest significance, a measurement of the capacity and fruitfulness of the soil. By and by all the harmful microbes of the earth will be subdued, and we will hear no more of them except as curiosities in germs; but the human soil, on which they used to grow, will remain, with all its ever-increasing complexity, and physicians will then have only the functions of interpreting its values and patching up its injuries or inherited defects.

A sort of dim foreshadowing of this science is found in the history of physiognomy and its allied arts. I use the word and touch upon the subject with some hesitation. Five hundred years ago Petrus de Abano, of Italy, discoursed upon it and was subsequently burned for heresy, *secundum artem*, in the flames at Padua. Not longer ago than the times of George II. all persons "fayning to have knowledge of Phissiognomie or like Fantastical Ymaginacions" were deemed rogues and vagabonds, and liable to be publicly whipped or sent to the house of correction. The attempt to measure a man by his looks, however, has always been made, and its professional votaries have crystallized their knowledge into many a scientific treatise of admirable length and erudition. In those days there were onychiologists, who read character from the nails; podoscopists, who studied the signs in the feet; metaposcopists, who read the face, and many other subdivisions of the general art of fooling people by examining certain fractions of their body. The ancients, however, did not build their science up securely; they could not resist the desire to mingle prophecy with their imperfect divination, and as time passed and knowledge grew, both prophecy and the various arts of physiognomy declined.

A little over a hundred years ago a devout clergyman of Switzerland, Louis Lavater, gave the last impulse to this line of work in a most learned, pious, and industriously written treatise on physiognomy, which he dedicated to the promotion of religion and right thinking. Lavater called attention to the striking way in which physiognomy sometimes indicates the character and intelligence of the individual. Perhaps he overdid the thing a little. His pictures of bad men were so frightful that the reader's vanity was almost compelled to feel that he must be good, while his virtuous faces were so insipid as to excite self respecting men to a distinct desire for vice.

The soul and intelligence, said Lavater, show themselves in the head and brow, and their centre is the eye; the moral life is indicated in the face, and its expression centred in the nose and cheeks; the animal and physical life are centred in the stomach. They showed their predominance also in the mouth and chin.

One day Lavater made the mistake of thinking that an executed assassin was an eminent philosopher and preacher, Herder. Worse mistakes have been made, but still such things impaired the dignity and security of his already decadent system. Lavater's teachings were too simple in theory for a science and too complicated in practice for an art. His illustrations remain, and his head of Satan in particular represents a character which no one can see without desiring to resemble it. His physiognomy died in the arms of a more successful form of philosophy.

It was only a few years later that an Austrian physician, Dr. Gall, began his lectures on what is still known as phrenology. The story of how he noticed the bulging eyes of his school fellows who surpassed him in their memory, and of how he found big bumps over the ears of murderers and over the temples of thieves is probably familiar to many. It was at least part of the learning of my school-days. Dr. Gall was an industrious enthusiast,

[1] Delivered at the Anniversary Meeting of the New York Academy of Medicine, November 28, 1894.

and there is little in the phrenology of to day which is not due to his labors, though he had able helpers and successors in Spurzheim and Combe. Practical phrenology now is really but a shrewd empiricism based on physiognomy, and not upon the classical bumps at all.

Taking a standard phrenological bust as sold by the professors of the art, I have drawn over the various faculties, as indicated by Gall, lines by which I could map out the functions of the different parts of the brain, so far as they have been absolutely determined by modern investigations. These show some curious juxtapositions. Thus the bumps of murder or destructiveness, and secretiveness which lie just above the ears, correspond with the centre for hearing; the bump of thieving, which is a little in front of the ear, lies over the centre for the movements of the mouth; while self-esteem and reverence correspond with the more measured activities of the legs; I find also that parental love is identical on the bust with the sense of sight, and hope with the motions of the shoulders and arms. Perhaps some philosopher of the future will reconcile these differences and construct upon them an esoteric metaphysics; but at present it seems to me that physiology has quite extinguished the science of bumps. While the actual contributions of Dr. Gall to science were small, his work called attention to the importance of studying the conformation of the head and the function of the brain, and gave an impetus to more serious and fruitful studies.

It is since Dr. Gall's time that the word "degenerate" has become one of common usage in French literature, running through works on heredity, social economy, art, morality, crime, insanity, and disease in all its forms. We find French literature full of articles upon degeneracy and civilization, degeneracy and crime, degeneracy and disease. There is in France a whole school of the Decadents, as they more euphemistically are called. The term has been adopted by the Germans, and runs through the work of Lombroso and his followers in Italy. In England and this country its use and significance seem to me to be much less appreciated. Yet since the first applications of the new science have been toward helping us recognize those who belong to the class known as degenerate and unstable, I shall devote a little time to explaining what is meant by the word.

The term has an unpleasant sound, and nobody likes to hear dry expositions of depressing phenomena. The New Yorker of to day will hardly tolerate a tragedy; he wants his drama farcical, his art sensuous, and his novels with a pleasant hymeneal ending. I cannot believe it possible for me to make a discourse on degeneracy at once lucid and attractive. But if one will pass the tip of the tongue over the roof of the mouth, five or six out of every one hundred adults will feel a curious ridge along the middle of the hard palate. This is called the *torus palatinus*, and whoever has it possesses one very interesting mark of degeneracy. The finding of this will, I am sure, give a certain percentage of people a personal interest in the subject, and will make them listen with some quietude in order to learn if it has any painful significance.

I do not need at this day to refute that shibboleth of the Reign of Terror that all men are born equal. We all know very well that babies start in life with very unlike endowments. For the purposes of my explanations, however, I shall only say that some are born like and some are born unlike their parents. Those who have more or less fully the mental and physical characters of their family are considered technically normal, while those unlike it are degenerate. The degenerate are those who differ from the average standard as set up by the family from which they spring; they are variations from the healthfulness of mediocrity; they are the peculiar people. Here, for example, is an illustration familiar to all. An honest, healthy, and respectable couple have a number of children; most of them take after their parents more or less closely and grow up honest, healthy, sturdy, perhaps mediocre or somewhat more than mediocre men and women. But one of the children is different: he is wilful, perverse, impulsive, deceitful; perhaps, however, talented in music or art, in business or literature. He is looked up to as the genius or the doubtful character of the family, and all the friends wonder where he got his endowments. He is one of the degenerate. If his talent overrides his moral imperfections he makes, perhaps, a success of life, and he is called technically simply an unstable, or popularly an erratic man. If his talents and bad tendencies are pretty evenly balanced he is called a degenerate of the superior type, while if he discloses decided mental weakness or develops an epilepsy, or hysteria, or some curious form of hypochrondriasis, he is called an inferior degenerate.

From this last class are fed also the insane and many criminals. The weak-minded, imbecile, and the idiot stand at the lowest level of the degenerate class. The common characteristic of all is that they are variations from the family average, they have mental faculties and physical powers not evenly balanced, and if they marry they may accentuate the degeneracy, while eventually their family becomes sterile and runs out. This tendency to sterility is the final and uniform criterion. The histories of prominent families of Europe, aristocratic and royal, are often cited as illustrations of this phenomenon. But it is not confined to them, and we see it in the country as often as in the cities.

There is, however, a brighter side to this picture. The human race possesses a conservative force which constantly tends to bring individuals back to the average and healthy type. Giants do not breed giants, or dwarfs dwarfs; neither do idiots breed idiots, despite the reiterations of controversial journalism, nor do criminals breed criminals. These classes have no children, or their children are better than the parents. Men and women of genius, and even those of extraordinary talent, follow the same rule. Their children tend to drop to the level. There is a centripetal force that brings the generations back to the type of the average man. No amount of acquired aptitude or special skill is transmitted to the children, though some of that with which one is naturally endowed may be passed on. The degenerate class in all its grades is a very large one, embracing five to ten per cent. of adults; few successful men can be said to be free from the taint. And since perfect stability of the organism is only found in the average, or some would say commonplace man, it may be said that degeneracy is a condition not altogether undesirable. Such a view is quite justifiable. I am flying in the face of the old adage, that the best possession in life is *mens sana in corpore sano;* but I do not think that perfect health and perfect sanity are things that any individual should desire. It is good for society as a whole, but not so for the individual, or, I might parenthetically and professionally add, for the doctor.

I have often noticed that families with a streak of insanity, or inebriety, in their membership number the brilliant and successful men. Only the insanity, like the boil, should affect the other man. No man of genius had ever perfect physical proportions or perfectly stable organizations. On the other hand, the portraits of beautiful women are not the portraits of women who have had great intellectual attainments, and the beauty of women has only affected the world's history indirectly through lower channels. Perfect beauty means mediocrity, and man's desire for the one is the force which brings back the degenerate to the other.[1] There is a scientific justification for the fun which one of our daily papers so often pokes at pulchritude. I do not mean that one must be ugly in order to be brilliant, but only that in women and men of talent or wickedness there is

[1] The well-known artist, Mr. A. B. Frost, is quoted by Robert Bridges (The Bookbuyer,) as saying, referring to artists' models: "I might mention that there is a singular peculiarity about the women. All the handsome ones are stupid and can't put an idea into a pose, and all the bright ones who can and will pose and help you work are decidedly plain both as to face and figure."

some deviation from the standard type which the modern sanitarian would call the normal.

But here I must make some important modifications in my text. I have spoken as though there were but two classes of people; 1, the normal, which includes the great majority; 2, the degenerate. All writers have so far chosen to make only these distinctions and have established the signs by which to divide all humanity into the sheep and the goats.

But in this, as it seems to me, one important element is left out, or not sufficiently considered. While most people may be what the modern æsthete or green carnation critics call "middle-class," the remnant are not all below the average, as their name "degenerate" would imply. Assuming at least that the human race is slowly progressing, it must be that the average man and woman is also becoming of a slightly higher type; and this in turn must be because many of the variations from the healthy average are distinctly above it. Some of the people who have the peculiarities of instability and tendency to die out, do nevertheless give birth to a more vigorous stock than they themselves possess. In other words, unless the world is growing worse there must be a class of greater than average vigor, who may be called the progressives or "regenerates." There are, however, as yet no anatomical marks known which distinguish these as a type.

I hope I have made measurably clear the idea of degeneracy as it has been developed and taught by latter-day writers. It forms a class of which the members are as far apart morally and intellectually as the possibilities of human nature allow. Yet it has common characters in the reproductive weakness, in the defects of physique, and in the instability of their mental faculties. They are all wanderers from the normal lines. Furthermore, and this is the point to which I have all along been, very slowly I fear, tending, they have about them certain marks or *stigmata* which indicate their divergence, and are badges of their servitude or of their freedom. The study of these marks forms the application of modernized physiognomy and anthropometry to the determination of the degenerate classes. This is the new use of the older sciences.

In France, Moreau, Magnan, Féré, and others have followed up the work of Morel, who may be called the father of the study of degeneracy. But undoubtedly the greatest impulse has been given to these studies by Professor Lombroso and his pupils. This eminent scientist believes that criminals are unlike their own race, but resemble each other and are a family among themselves, with a family likeness and common bodily peculiarities. This conclusion is one to which I cannot at all agree, and which I feel sure is not yet subscribed to by men of science. The exact position in which Lombroso's work stands, I shall refer to later. Meanwhile one cannot overestimate the value of the impulse which he has given to investigations of the human body. If there is ever to be a complete and exact science by which we can in a measure infer character from figure it will be very largely due to the work of the great Italian criminologist.

I propose now, however, to go into some of the details of the curious discoveries that have been made by investigators, not in Italy alone, but in all parts of the world. I do it with the hope that my descriptions will not lead to any unpleasant habits of self examination or to surprises that act disagreeably upon one's vanity. I shall take up the points somewhat at random, for I have not time to present the subject in any systematic and complete manner.

Of all the various systems of which the body is composed, the bones have been thought to be allied most completely with the development of the nervous system. Sir William Gull once suggested that the Socratic advice *γνωθὶ σεουτον* should be interpreted in these days "examine your urine;" but the modern physiognomist would rather say, "examine your bones."

A perfect bony system is a rather good index of vitality at least, and its variations and anomalies make up a large part of the stigmata of degeneracy. The presence of excessively long arms, for example, is a phenomenon greedily seized upon by the Italian school as indicating a return to man's ape-like state, before he fell from grace and his arborial gambols in primeval forests.[1] But long legs and a small chest are also found to be evidence of degeneracy; and whatever may be said of the marks written on the bones, none of them prove that their anomalies are signs of a return to savagery. Degeneracy is not a form of atavism.

Naturally the conformation of the head and face has been studied with much earnestness and much practical success. The skull of man is never quite symmetrical, but it tends to become so; on the other hand, the brain tends to become asymmetrical, *i.e.*, the left side to be a little larger than the right. When things go a little wrong in the human make-up, the skull shows it quickly by getting out of shape. The size does not count very much, for we know that men of genius, like Gambetta, have had skulls that would barely be large enough for a boy. But odd shapes do signify. In olden times the physiognomists thought that men of evil character had a sugar-loaf (oxycephalic) skull, while Gall found his murderer's bump over the ears. And modern criminologists lay much stress on the size of the jaws.

There are, at least, thirty ways in which the head varies from the normal type. Many of these are most trivial, and it is only on the principle that a dozen small things make an object of respectable size that one is justified in giving attention to the facts that are collected. Ordinarily we look in a man's face to see whether it is in general attractive, intelligent, interesting, beautiful, or the reverse. But the anthropologist looks more closely and hunts for his stigmata. One-third of all thoroughly bad men, for example, according to Dr. Penta, have a plagiocephalic or twisted-shaped skull.[2] A still larger proportion,[3] forty-five per cent., have projecting jaws, or prognathism, wide jaws (twenty-nine per cent.), and wide orbits (thirty per cent.)

The nose in the criminal is often rectangular, short, large, and upturned; the face shows early wrinkles and a peculiar pallor. The criminal jaw weighs 94 gm. (3 ounces), the normal jaw but 80 gm. (2½ ounces) (Manouvries). The cheek-bones are prominent, the orbits are large, the frontal sinuses and brows protrude, and the teeth are defective and badly placed. The shape of the palate stands in close relation to that of the skull, and the neat and workman like way in which nature joins the parts in the middle shows that she has done well elsewhere. When the palate has a ridge along its centre, *torus palatinus*,[4] or is high and narrow, or uneven and badly shaped, we count it among the signs of degeneracy, though it weighs lightly in the scale. Criminals have three or more of these various anomalies.

The size of the head, as already stated, counts perhaps less than anything else, unless the deformity be greatly exaggerated. The good and the bad, the sane and the insane, have heads of about the same size, and even prehistoric skulls do not show much inferiority. Civilization began and completed its work with almost precisely the same amount of brain tissue.

The anomalies above described have a rather forbidding and perhaps alarming sound, and it is pleasant to know that individually they are not very significant. A homely face can be quite free from the stigmata of sin, while one of a fascinating and even beautiful type may have much that suggests degeneracy.

[1] When the arms hang straight down by the side, the tip of the middle finger is 14 ctm., or about six inches from the knee-cap. In negroes it is only five to eight ctm., or two to three inches (Krause).

[2] Arch. de Psych., vol. xv., p. 327.

[3] Ibid.

[4] Among 71 patients in the general wards at Bellevue Hospital I found a distinct *torus* in 4, and in 2 of these cases the patients had nervous disease. In 57 patients examined in the alcoholic pavilion, I found the *torus* in 11 cases, or twenty per cent. The *torus* is more marked in inebriates than in the insane, though palates otherwise deformed are more frequent in the latter class.

There are, as artists and anatomists know, certain definite proportions between the circumferences of the neck, shoulders, chest, waist, and hips. These proportions differ for infants, men, and for women.[1] Among the unstable there are often found misfits in these proportions, so that a man, for example, has approximately a child's or woman's proportions. This condition is known as feminism or infantilism, and many striking illustrations of it have been shown by Dr. Charles Féré, of Paris. I have, I am sure, seen it in some classical statues, and I believe it will be found that the Greeks had a certain unholy admiration for some of these beautiful but perverted types of the human figure.

We every-day people have rather agreed to ignore the ears, yet it is remarkable to what uses they lend themselves at the hand of science. Laycock thought that the circulation in the ear was an accurate indication of that in the brain, and that its development coincided with that of the brain and skull. The ear to him was, to the brain, as accurate an indicator as the tongue is to the stomach. Mr. Ellis speaks of an observant schoolmistress who could tell when her pupils were tired by the state of the circulation in their ears. Professor Grandino, of Turin, however, may be said to have done the ear the most illustrious service. He has examined these organs in twenty-five thousand healthy men and women, besides eight hundred insane and four hundred and sixty-seven criminals. I have before me the typical ear as it should be, or at least as the Professor depicts it from the results of his laborious studies. I must confess that after having mastered its admirable symmetries I have gained a new experience in æsthetics. For now it gives me a distinct delight when I come across a perfect aural organ, such as one experiences in seeing a beautiful picture or listening to the harmonies of an up-to-date sonata.

It is surprising how many shapes the ear may take when one comes to look at it seriously in the light of a newly growing science which is thirsty for morphological data. There are at least seven distinct ways in which the ear can be wrong; each corresponding perhaps to a deadly sin, for each is more prominent in the sinner than in the saint. I am not going to enumerate these points, for I cannot do it except in the most technical language, and besides, I do not like to give people who are kind enough to listen to my discourse any opportunity to form a poor opinion of themselves. The long lobes and a peculiar wrinkle in the cavity of the ear are the things which have most significance.

One of the most curious things discovered by the patience of the neurologist has been the prehensile foot (*pied prêhensile*). Drs. Ottolenghi and Carrara examined the toes of one hundred and sixty-two normal people, thirty-one epileptics, fifty-six idiots, and three hundred and fourteen criminals.[2] Among normal people the distance between the first and second toe at the base rarely exceeds 3 mm. ($\frac{1}{8}$ inch) in men, while in the abnormal classes such excess is three times as frequent. The idiot classes seem to be especially marked with this stigma, so that it would be inferred that the activity of the intelligence is indicated in a measure by the distance between the toes. This would seem absurd, were it not that the peculiarity suggests a return to the prehensile toe of the ape, and is therefore classed as a mark of atavism.

I said some time ago that chiromancy had not been taken up seriously by scientists. The lines and furrows which have been studied as a parlor game, and about which prophetic and pseudo scientific works have been written, is mainly but guesswork. Yet the lines so delicately arranged on the finger-tips are beginning to assume some significance. Mr. Galton, in his work on finger-marks, established the fact that they never change in the same individual, and that they may be to a certain extent classified. His investigations were confined to normal people. Alix did the same for the finger-tips of apes, and now Forgeot, of Lyons, says that in young thieves of Boulogne are traces of the same arrangements seen in apes, and Féré finds them among sixteen per cent. of epileptics.[1]

Much has been written about the hand; artists have depicted its perfections, physiognomists have interpreted its shape and expression, cheirologists and the gypsy queens have tried to prophecy from its markings. But a study of its peculiarities by the inductive method takes one into entirely new fields, and shows that to interpret the significance of the hand one must start on quite new lines. There is something perhaps in the fact that the artistic hand has somewhat tapering fingers, but beyond this one deals with uncertainties. And I recollect an idiot youth whose extremities had the contour of a genius or a Trilby.

If one examines the hands of a large number of persons with a nervous endowment, he will find curious defects in the length and relative proportions of the fingers. The length of the finger is determined by that of the middle one. If the index and medius are closed upon the palm, the ring and little finger being left extended, the middle finger will reach close to the place where the so-called life-line runs down, between the ball of the thumb and that of the little finger. It will touch the palm just below the highest part of the ball of the thumb.[2] The middle finger is taken as the standard of length by which to gauge that of the others. In a normal hand the forefinger reaches just to the root of the nail of the middle finger, the ring finger is longer and should reach nearly to the middle of the nail of the medius, while the little finger should reach to the last joint of the third finger. Now in inebriates, epileptics, neurotics, and the degenerate generally, these proportions are often not observed. The most common defect is shortness, especially of the third and little fingers, though sometimes a disproportionate length occurs. Sometimes these fingers are unnaturally slender or the little finger is slightly bent. The most common abnormality of the thumb is excessive shortness, with a defective mobility. These peculiarities well accentuated form what we may call the "decadent hand"—the hand that writes our sensuous novels, the Hauptmann drama, paints symbolic pictures, and exploits pure æstheticism. Such hands may be well-formed to the ordinary eye, and may be attached to slender and graceful limbs. But this kind of beautiful hand and arm is found quite as often among the children of alcoholics and among those highly cultivated families which have become degenerated by vices and vicious crossing.

The hair adds a little to our knowledge of the individual, but not very much. Light hair and blue eyes seem to be dangerous endowments in the Italian race, but this is not the case with the Anglo Saxon. It may be a comfort to know that hair grows plentifully on the heads of criminals, and that prematurely bald men are rarely bad, through any hereditary defect at least. The degenerate has often a thick head of hair and a thin beard, while in modern society the normal man seems to be equipped in just the opposite way. That twist of the hair known as the crown of the head, should be in the middle line, or very close to it, and no one is entitled to more than one crown. When it is found shifted off well to one side, or is doubled, the twist becomes a stigma. Art and fashion permit one to tip the hat slightly to the side, but nature orders that we wear our crown in no jaunty or frolicsome mode. It is often thought that an abundance of hair signified a vigorous vitality, but this is not strictly the case. The excessive

[1] The average circumferences in men and women are given by Krause as follows, in centimetres:

	Men.	Women.
Circumference of neck	34	32
" at level of iliac region	70	73
" level of hip bone joints	81	84
" breadth between trochanters	34	35
" shoulder breadth	39.1	35.2
" hip breadth	30.5	31.4

[2] Féré: La Famille neuropathique, p. 281.

development of hair on the body, particularly in women, is regarded as one of the minor stigmata of degeneration.

My remarks would be both incomplete and misunderstood if I left it to be inferred that degeneracy, in its various forms, is determined by bodily marks alone. There are two other classes of stigmata, the physiological and the mental. Under the former, we include peculiar defects in the function and practical working of the body; under the other we include certain mental characteristics. The degenerate are apt to have an unstable circulation and a deficient vitality that responds abnormally to stimulants of various kinds. Mentally a peculiar characteristic is a tendency to morbid fears, introspection, idiosyncracies in taste, and impulsive acts. These and many other of the stigmata occur in the normal, however, and I do not propose to enter a branch of the subject which is much less definitely worked out and less susceptible of demonstration.

I have now described to you the gradual development of a science of human measurement out of the cruder sciences of physiognomy, temperament, and phrenology.

The metaposcopist of the Greek school viewed the body and detected in it signs of some dominant quality. The man was quick and irascible like the dog, or slow and sensuous like the pig, brave and forceful like the lion, everyone resembling in feature or character some lower animal. The mediæval artist added to this the science of divination and prophecy. In the times of Lavater the physiognomist tried to interpret from the attitude, the complexion, and features, the various complex elements of the individual's disposition.

The phrenologist of the Gall school went still further, and described all the intellectual and moral faculties, mapping out for the man the total sum of his capacities, his aptitudes, and his prospects in life.

The modern student of the human frame is much more modest. He asserts only that he can by the presence of certain stigmata say whether the individual is of stable and normal organization, or if he belongs to that class which I have described as the degenerate. Nor does he pretend to do this in all, but only in those whose defects are well-defined and reasonably numerous. Perhaps every one has some stigma of degeneration; but at least five out of a hundred adults have many and striking ones. The degree of their degeneracy may be in a measure decided, but cannot be determined by anatomical marks alone. And it is on this point that I must differ from the Italian criminologists, who claim that there is a criminal, an insane, a neuropathic type.

In conclusion, let me say that the final work of modernized physiognomy will not be to fix upon human beings any stigma which marks them as necessarily useless, defective, or dangerous. We have not discovered a type of criminal man, or of the insane man, or epileptic or neurotic man. All these have common marks which show simply that they belong to the same somewhat handicapped family. Their presence in an individual will show that he must be especially careful in educating and using his natural power. The discovery of degeneracy throws an additional responsibility upon him, for there are few so bad but that with a proper environment they can get along successfully in life.

There may be some born criminals, but they are very few; most are simply persons of degenerate type who fail to husband properly the endowments they possess. We do not excuse the cripple who attempts to become a sprinter, nor should we excuse the morally defective who indulges in debasing habits and low temptations.

All modern studies in the lines I am exploiting seem to show that man must be more than ever careful of his education, his training, and his surroundings, and of using all possible moral and spiritual agencies to strengthen his defects and make more stable his powers. The future of the degenerate depends enormously upon these factors, and his responsibility lies in his following that line of life which is right for him. By this means one can render many defects harmless, and make the unstable almost as firm in judgment and healthful in body as the happy possessors of perfectly balanced organizations.

If I have succeeded in showing that this is to be the end and teaching of modernized physiognomy, and shall have aroused your interest in its progress, my object will be accomplished to-night.

THE PRESENT STATUS OF THE SPECIFIC TREATMENT OF DIPHTHERIA.

By PROFESSOR EDWIN KLEBS, M.D.,

ASHEVILLE, N. C.

FORMERLY OF THE UNIVERSITY OF ZURICH.

Upon my recent arrival in this country I found the greatest interest manifested, both in professional circles and by the laity, on the subject of diphtheria, and the greatest expectations seemed to prevail on all sides from Behring's diphtheria antitoxin as a practically unfailing remedy for the rapid cure of that disease.

The reliable information which has reached the profession in this country from Germany being comparatively meagre, and coming, as I did, directly from there, and having through previous and more recent labors been intimately connected and interested in the subject, I was naturally interrogated on all sides as to my views, and especially so by Dr. Shrady, the editor of this journal, upon whose request I am pleased to state them herewith for publication.

The use of pathogenic bacteria for the production of curative remedies may be in two directions, and for two purposes, first, by using their own secretion products against them and for their destruction (the possibility of which is apparent in the dying out of artificial cultures long before the nutrient material is exhausted), and secondly, by using these organisms for the production of immunity by their direct introduction into the blood of the animal.

In the first place, we will have to produce the curative remedy from the culture fluids; in the second, from the fluids of animals in whom artificial immunity has been produced. The question arises, "Which is the surest and easiest method?" The degree of immunity differs materially in the various diseases due to specific disease-germs; it is, for instance, very great and long lasting in variola, very small and of short duration in diphtheria, and entirely wanting in pneumonia.

The second method adopted by Behring, to use the serum of animals in which immunity has been produced, can therefore only be followed for the cure of diseases which secure at least a moderate degree of immunity to persons having recovered from them, and if we accept the results of experiments upon guinea-pigs as applying also to man, diphtheria belongs to this class.

In this connection the clinical experience must not be overlooked, that man may acquire diphtheria again, after a short period from the time at which all evidence of the previous disease had entirely disappeared. I have lately been able to report several such cases,[1] while the presence, for some time, of virulent diphtheria bacilli, especially in the nose, after recovery from the disease, and without the production of membranes, or of general symptoms, speaks, nevertheless, for the production of at least temporary immunity in man also. However this may be, Behring certainly is entitled to credit for having shown that a great degree of immunity from diphtheria can be obtained in animals by the injections of increasing large quantities of virulent diphtheria cultures into their blood.

According to the results obtained in Europe, the serum from such animals has certainly a high degree of curative property, since by its subcutaneous injections all fresh and light cases have been uniformly cured, and the best series of reports of all cases (severe and light, in-

[1] Wiener Med. Wochenschrift, Nos. 31–33, 1894.

cluding tracheotomy cases) have reached as high as eighty-eight per cent. of recoveries.

Some observers, as for instance, Hahn, of the Friedrichshain Hospital in Berlin, have expressed themselves more doubtful as to their experience, and it is probable that the variability in degree of individual cases caused the difference in the results obtained. However, upon these less favorable reports the injected quantities were increased to 100 c.c. (a little over three fluid ounces), especially by Ehrlich, and apparently with good results.

To come to an understanding, two questions will have to be answered: 1st. Are there no dangers connected with the use of Behring's serum? 2d. Cannot the same results be obtained in an easier and safer way?

As to the first question, the exponents of the serum treatment accept it as a settled fact that no harm can come from its use; and so far as their experiments upon animals show, they are entitled to this belief. But that it is also true as to man can by no means be accepted as proven, if we will only remember that the very small quantities of organic matter which we inoculate in vaccinating against small-pox have undoubtedly been the means of transmission of human diseases, especially syphilis and tuberculosis. Without, in the remotest sense, affiliating with the opponents to vaccination, who, on account of occasional harm, would throw away the valuable and life-saving discovery of Jenner, I recognize nevertheless the danger which experience shows to exist, and believe that by abandoning human vaccine matter for animal lymph the profession took an important step for the prevention of incidental infection. But even bovine vaccine matter is not absolutely safe, since we have no guarantee of the absolutely perfect health of the animal. For instance, calves are frequently found to suffer from tuberculosis, without recognizable symptoms, and nothing short of the killing of the calves and painstaking autopsies, as I inaugurated in Austria, before the vaccine matter derived from them is used, can be considered as having met all the precautions necessary, and to which persons, especially under compulsory vaccination, would seem to be entitled. If, however, such precautions become a duty in vaccination, where only the minutest quantity of organic matter is inoculated, how much more is it necessary to look to the absolutely perfect health of animals from which we derive serum for the treatment of disease, and of which it is proposed to inject 100 c.c. for the cure of diphtheria?

It is, indeed, well known that in the horse, which is especially made use of for obtaining the serum, there may exist latent diseases of infectious character, for instance a chronic form of glanders may be confined for a long time to the cavities of the head and nose, without occasioning any discharge whatever, and with but little or no glandular swelling, but which, nevertheless, may be a source for fatal infection. Only the most careful post-mortem examinations can guard us against the occasional use of apparently healthy but nevertheless diseased animals, and the killing and examination of these animals is necessary before their serum previously obtained is used for therapeutic purposes. Nothing has as yet been said or published on this aspect of the serum treatment, but it should not be ignored because of the value of the animals and the long time necessary before they have been brought to a state of sufficient immunity; and since it is only a question of money the State should step in and take the matter under its supervision and control.

The exponents and followers of the serum treatment will naturally reply that so far no harm has followed its application. It is, however, not at all shown that this danger has been sufficiently appreciated. Of the severer cases twenty to thirty per cent. have terminated fatally after applying the treatment, and who can maintain that all the fatal cases were really due to the disease?

I willingly admit that the dangers spoken of may be diminished to a small degree by the painstaking selection of animals, but under all circumstances the obtaining of serum for therapeutic purposes will ever be a very costly method.

This leads me to the second question. Can we obtain a bacterial curative substance for diphtheria in an easier manner, which is safer and cheaper while equally effective? I have for a long time followed the thought that pathogenic bacteria, the same as all other living organisms, secrete substances which are poisonous to themselves, of which the retention of excrementitious substances from the kidney and liver of man is a familiar instance. In the case of pathogenic bacteria this is also manifest from the fact that artificial cultures die out long before they have exhausted the nutrient substances in their culture media. This principle governed me in the use of tuberculocidin and antiphthisin for the cure of tuberculosis, and also of antidiphtherine, which latter I have proposed for the cure of diphtheria. That this principle is correct becomes further evident from a number of quantitative experiments made by me with tubercle bacilli.

In the beginning of July of this year I prepared three litre cultures, containing 500 c.c. each, of old and new culture fluids (of sterilized glycerine, pepton, and meat extract), and on July 14th I inoculated each with equal quantities of tubercle bacilli from the same source. The results on August 22d were as follows:

No. 1 contained only old culture fluids; in this culture the tubercle bacilli had grown but little, did not cover the surface, and their weight, after having been dried at 28° to 30° C., was only 0.046 gm.

No. 2 contained 300 c.c. old, and 200 c.c new culture fluid; the tubercle bacilli had grown better, covered the surface more, but only in a very thin layer, without attachment to the side of the flask; their weight, determined in the same manner, was 0.443 gm.

No. 3 contained 200 c.c. old, and 300 c.c. new culture fluid; the culture approached more to a normal one, covered the entire surface, and in a few points attached itself to the side of the flask; the weight of tubercle bacilli, determined in the same manner, was 2.586 gm.

The latter is about half, or slightly over, the weight of the tubercle bacilli from a normal culture of equal size and kind.

These experiments show that considerable quantities of toxines must be formed before the growth of the pathogenic germs is entirely prevented; only upon entirely ripe cultures is their growth impossible. But these experiments show further that the growths in my experiments have by no means reached the weight which would correspond with the new culture fluid which was added to the old.

If we take round figures, 500 c.c. of new culture should furnish in a certain time 5 gm. dried tubercle bacilli; 300 c.c. 3 gm. and 200 cc. 2 gm. The experiment shows, however, that the weight fell short in all. In No. 1, of exclusively old culture fluid, only the one hundredth part was obtained; in No. 2, instead of 3 gm. I obtained only 0.45 gm.; in No. 3, instead of 3 gm. only 2.5, showing that the presence of toxines in the old culture fluids exert a damaging influence upon growing tubercle bacilli.

Quite similar have been experiments with cultures of other pathogenic germs, and we can accept as a law that the diminished growth and the dying out of bacteria depend upon accumulation of their secretions. The latter substances, which belong partly to the albuminoid group, are partially toxic, and I distinguish therefore soz-albumin and toxalbumin, which must be separated from each other.

The soz-albumin from tubercle bacilli cultures is represented in antiphthisin, and of diphtheria bacilli cultures in antidiphtherine. The cost of production of the latter depends entirely upon the facilities for large or smaller quantities, and it will be my endeavor to produce it so cheaply that it will be within the reach of the poorest family in the land, as soon as I shall have demonstrated its clinical value. To this end I expect the arrival of a

large shipment from my laboratory in Strassburg about the first of the year, and it is my purpose to then furnish the remedy free of all cost for the purpose of making comparative trials of its value with that of the serum of Behring. For present comparison I have at my disposal a series of fifty-one cases treated by various physicians in Germany with antidiphtherine. Of these fifty-one cases seven, or 13 7 per cent., died, and forty-four, or 86.27 per cent., recovered. They include both light and severe cases and such where tracheotomy was required.

A similar series of cases under serum treatment, reported by Ehrlich, shows 13 3 per cent. of mortality and 86.7 per cent. of recoveries. The small difference may depend upon the greater number of tracheotomies in my cases. As to the results in the latter alone, I have five deaths in eighteen cases, or a mortality of 27.7 per cent., which is as favorable as under the serum treatment.

I have thus far applied the antidiphtherine only locally, believing that the process is a local one in the beginning; my investigations have shown me that the diphtheria bacillus is chiefly found in the superficial layers of diphtheritic membranes, and, as the latter become older, in the advancing edges of its formation the bacillus may be demonstrated, when none will be found in the central portions. The application of antidiphtherine has been free from all unfavorable effects whatever, and upon its early, thorough, local use depend its prompt and curative effects. Upon a suitable cotton-wrapped probe the remedy is applied upon the diphtheritic patch, the latter having first been cleansed with dry cotton—gently pressing and rubbing the soaked cotton upon the diphtheritic and suspected patches, and leaving it in contact as long as the patient can comfortably hold it. We repeat this two or three times, and then swab the entire pharynx and fauces; great gentleness, and at the same time thoroughness, are essential, especially with very young children. In the latter we may, however, touch the greater part of the fauces and pharynx with the cotton, at one time holding the latter in a forceps with which we may also pass upward behind the velum and naso-pharynx if we suspect trouble there. If none of the patches have been omitted, the temperature falls in the course of three to five hours, and a sense of well-being returns. If the fever does not subside the application must be repeated, and new patches be looked for. In their absence the application must be made in the nose and naso-pharynx also, where patches may be hidden from recognition.

A new rise of temperature indicates a new development either upon the old or a new focus, and the applications must thus be repeated more or less frequently according to the course the cases pursue. Under the most favorable course two or three applications should be made daily until all evidence of disease in the throat has disappeared. The membrane soon loosens and is cast off, leaving a smooth, shining surface, covered with epithelium, a very important result, as thus streptococcus infection is prevented.

The remedy may also be used subcutaneously or per rectum, especially in severe and older cases. Beginning with $\frac{1}{10}$ c.c., and increasing by $\frac{1}{10}$ c.c. every hour, we reach 1 c.c. in nine hours, after which the same quantity is repeated two or three times a day, or still increased, if necessary. Animals bear the subcutaneous use without any unfavorable effect. For the present in the human subject I recommend that the action of the heart be carefully observed during the subcutaneous use of this preparation.

A New Medical Fraud.—An ingenious swindler is going about the city, collecting money from poor people under the pretence that he is an agent of the Board of Health. He gives it out that a new law compels the payment of $2 a year to the Board, of which he is the collector, in return for which the physicians of the Board will attend the family free of charge.

THE "OYSTER EPIDEMIC" OF TYPHOID FEVER AT WESLEYAN UNIVERSITY.

By H. W. CONN, PH.D.,

PROFESSOR OF BIOLOGY, WESLEYAN UNIVERSITY, MIDDLETOWN, CONN.

WHILE it has been for some time suspected that raw oysters may be a possible means of the distribution of germ diseases, there have been no cases where the theory has been positively demonstrated. The recent outbreak of typhoid at Wesleyan University is, in this respect, therefore, so unique as to be of especial interest, and for this reason the results of the investigation as to the cause of this outbreak are given below in some detail.

The history of the epidemic was as follows: About October 20th there began to appear among the students a number of cases of mild fever, which were for several days not regarded as serious. After about a week, however, one or two of them developed into typical typhoid fever, and several others were suspected of being of the same nature. For a week and a half following October 20th, new cases appeared somewhat rapidly, and by November 1st there had appeared among the members of the college about twenty-three cases of fever of more or less prominent typhoid character. After November 1st the number of new cases diminished, although two appeared on November 2d, one on November 5th, and one as late as November 9th. Subsequent to that period no new cases have developed. There have been among the students about twenty six cases of fever which have been, with more or less reason, regarded as typhoid Of these twenty three have been pronounced typhoid by the physicians in charge, while the others are of such a slight nature and have so few typhoid symptoms, as to make it at least doubtful whether they were really typhoid fever. Of the cases of undoubted typhoid, thirteen have been very serious, and the others not very serious. Four deaths have occurred, and at the time of writing there are one or two other patients in a critical condition. It will be noticed from these facts that the outbreak of typhoid fever in college began about October 20th, and the last case appeared about November 9th.

As soon as the serious nature of the disease was recognized, an investigation as to its cause was begun. Of course, at that time it was not known that the disease would be limited to the dates above mentioned, and it was regarded as possible that there was in college a constant source of infection. The students that were sick were found to room in all of the college buildings, and also in several houses in town. Moreover, it was seen that they did not board at the same boarding-place, and there appeared at first, therefore, to be no connection between them except the college campus. The first object of suspicion was the water from two wells at the back of the college buildings, which was used occasionally by the students of the college for drinking purposes. On this suspicion the use of the water was immediately stopped, and an examination of the wells was made. Chemical examination showed in one of the wells an exceptionally large amount of albuminoid ammonia. The examination was made immediately after a heavy rain following a long drought, which might possibly have accounted for this. A bacteriological examination was set on foot according to the method of Professor Vaughn. Bouillon cultures from the water of each well were made and cultivated for two days in a culture oven. Then 20 c.c. of the culture was inoculated into the abdominal cavity of white rats. The white rats, however, were entirely unaffected by the treatment, indicating plainly that pathogenic germs of a typhoid nature could not have been present. Moreover, a little inquiry soon showed that the wells could not have been the cause of the trouble. In the first place several of the students who were sick had certainly not drank from either of the wells. Secondly, the wells were used almost as much by certain young people from the town as by the students themselves, and there was no corresponding outbreak of typhoid in the city. In fact, Middletown, at

the time, proved exceptionally free from all kinds of fevers. These facts taken together, made it necessary to exclude the wells from the possible sources of infection.

It was noticed at the outset that the ladies of the college, about fifty in number, were exempted from the disease. This, of course, indicated that the cause of the infection could not have been in any unsanitary condition connected with the public college buildings in general, but must have been some source of infection to which the young men were exposed, and not the young ladies. After carefully looking over the facts it was further found, that all of the cases of sickness, with three exceptions, occurred in three of the college fraternities. The men did not all room in the fraternity buildings, though most of them did board at the fraternity club houses. This localizing of the disease to three fraternities proved the first usable point of departure in the investigation.

In the college there are seven fraternities, and most of the college students board at the fraternity clubs. In the three fraternities afflicted there were about one hundred students, and among the one hundred students, as above stated, about twenty-five cases of typhoid developed. This is seen at once to be an extremely large proportion. It is usually supposed that some ten to fifteen per cent. of those exposed to typhoid take the disease, and here was a percentage at least twice that proportion. This large percentage indicated at once that there must have been some extremely virulent source of infection to which probably every member of the fraternities was subjected. In no other way could the large percentage of cases among the students be accounted for.

In the attempt to locate the source of the trouble in connection with the three fraternities, however, every source of possible contagion was investigated. The plumbing was examined, and though found to be defective in at least one case, in the other houses it was in first-class condition. It was hardly possible to accuse the plumbing, however, inasmuch as the three clubs afflicted were situated at a distance of half a mile from each other and were connected with different sewers. The probability that these three houses should have been defective in their plumbing at the same time was very remote, and their connection with different sewers, together with the absence of typhoid in the city, made it impossible to accuse the plumbing. The possibility of transference of the disease from house to house was also considered, an attempt being made to find some early case which could possibly have been a source of infection to the other houses. But this proved futile. There were no early cases, for almost at once, upon October 20th, two or three cases developed simultaneously, and, of course, this made it impossible to explain the epidemic by personal contagion. It was found, moreover, that the students who were taken with the disease in many cases had no connection whatsoever with the other fraternity houses, either through their room mates or otherwise. Another source of possible infection was suggested in a lot of new football suits which had recently been purchased, and which had been thought to have given rise to one or two cases of blood-poisoning. Inquiry, however, soon showed that most of the students who were sick had nothing to do with the football suits, and they were of necessity ruled out.

Naturally, one of the first objects of suspicion, after the disease had been located among the members of the three fraternities, was the table of the clubs. An examination was immediately made into the sources of supply of these three fraternities. All of them used the city water, which, of course, made it impossible to accuse the water as a source of the typhoid, there being no corresponding typhoid fever in town. The milk-supply of the three fraternities was also ruled out by several facts. The three fraternities were supplied by two different milkmen, and each of these milkmen supplied one or more of the other fraternities in college, as well as a large number of customers in town. Moreover, upon inquiry it was learned that these milkmen had not exchanged milk with each other, and that they lived at a distance of several miles from each other outside of the city. No cases of typhoid fever could be located in or near either of the milk-farms, as having occurred within the last six months. It was, therefore, impossible to accuse the milk. In the same way all the other articles of food used by the fraternities were investigated, without success. The three fraternities did not have the same grocer, nor the same butcher, nor the same butter supply, nor did they obtain fruits from the same sources; and whenever, in regard to any article of food, it was found that there was a point of likeness between the three fraternities, it was found at once that the other fraternities in college shared with them in having the same source of supply. After carefully inquiring into every article of diet used on the ordinary table, it was found necessary to exclude the table as a source of infection. The attempt was then made to find some special, unusual article of food that had been used during the fall by the three fraternities, but it was impossible to do so.

When the dates of the outbreak above given are considered, it will be seen that they have themselves almost conclusively pointed to one single source of infection that had occurred in these three fraternities at a date something like two weeks earlier than October 20th. The period of incubation of typhoid fever is known to be from about eight days to about twenty eight days, and all of the cases came in such close connection with each other as to indicate almost beyond question that they were due to one single source of infection, that occurred within two weeks prior to October 20th. On October 12th all of the fraternities in college held their annual initiation, followed by an initiation supper, and suspicion was soon thrown upon these suppers. The date of the suppers was exactly such as would be needed to explain the outbreak, and as soon as it appeared that new cases diminished after November 1st, these suppers became the most probable source of infection. When the initiation suppers were taken into consideration, one of the three exceptions above noticed disappeared, because one of the men who did not belong to the college fraternities had attended one of the three initiation suppers. An examination of the bills of fare at the suppers in question was therefore instituted. It was found that nearly every article of food must be excluded, on the same grounds as the articles of food at their ordinary table. Their milk, their water, their ice, their ice-cream, their fruits, their celery, and in fact, nearly all other articles of diet, they either did not obtain from the same source, or obtained them from a source which supplied every other one of the seven college fraternities as well as the people in town. There was found, indeed, to be but four points of union between the three fraternities. One was the celery used in the salad, a second a small amount of fruit, a third some ham, and the fourth the oysters which were eaten. The celery, the ham, and fruit, however, were from sources which supplied other clubs and a large part of the townspeople, and could, therefore, not have been the cause of the special infection confined to these three fraternities.

As soon, however, as it was found that the three fraternities each ate raw oysters from the same oyster dealer, the problems began, one after the other, to be solved. It was found that none of the other four fraternities ate these raw oysters. Two of them ate no oysters, a third ate oysters which, however, had been cooked, and the fourth obtained oysters from an entirely different source. Nor could it be learned that the lot of oysters had been used raw to any extent among the people in town, most people cooking their oysters. Another one of the abovementioned exceptions was also explained at once, because the student, upon being questioned, stated that about the time of the initiation suppers he had eaten of the raw oysters in the store of the oyster dealer. The oysters in question were served at each fraternity on the half shell, at the beginning of the supper, and it was, therefore, almost certain that nearly every person who attended the banquet ate of them. Correspondence and questioning, however,

were immediately instituted, which resulted in tracing in this way a connection between every student who was suffering from typhoid and these oysters, with one doubtful exception of a student who has not yet been personally questioned. It was learned also that there were in attendance upon these three suppers, in addition to the students in the college, a considerable number of alumni from out of town, and five students from Yale College. Letters were immediately written, therefore, to all of these persons to learn if they had eaten of the raw oysters, and whether they had suffered from any febrile disturbances. It must be remembered that the alumni were, as a rule, considerably older than the students, and it was, therefore, to be expected that the alumni would be more likely to be exempt from the disease than the students themselves. From twenty responses received from the alumni it was found, however, that there were two cases of genuine typhoid fever, which had developed simultaneously with those in the college, and that there were three other cases of sickness which had not been regarded as serious. These might or might not have had some connection with the banquet in question, though it is quite doubtful. Of the five students in Yale College, two were taken with typhoid symptoms at just four weeks after the banquet. Both of them developed into severe cases of typhoid fever. In regard to these two cases at Yale, it should, however, be noted that they appeared quite late, indeed four weeks after the supper had been held; and although four weeks is not too long a period of incubation to be possible, still it is unusual. They developed, however, at exactly the period that the last case in Wesleyan made its appearance. It is also a fact that there were two other cases of typhoid fever in Yale College that certainly had no connection with these banquets or these oysters, and it is therefore not certain that these two cases are to be attributed to these banquets. It is, however, a remarkable coincidence that of four cases of typhoid at Yale two should have been those who attended the banquet at Middletown and ate of the oysters in question, and that these two should have developed within the four weeks following the banquet. It is therefore at least probable that these cases were due to the same cause.

It will be seen that, as soon as the oysters were accused of the trouble two of the three cases above mentioned of typhoid occurring outside the fraternities, were at once explained. The fourth case remained isolated. This case was a member of the faculty, who had not attended either of the banquets. He was taken with a slight fever, and inasmuch as it appeared at about the same time with the students, it was regarded as identical with the other cases. It proved, however, a very slight fever, lasting only a few days, and it is therefore at least doubtful whether it was typhoid. Whether this person ate of the raw oysters cannot be positively determined. It is a fact that raw oysters were eaten at the table where he boarded at about the time of the banquet, but as yet no positive connection between the person and these oysters has been made out. Whether, therefore, this case is to be regarded as an isolated case of fever having no connection with the others and not strictly typhoid fever, or whether it is a fact that it is also explained by some connection with the infected oysters, has not been determined.

Inquiry was made at once as to the source of the oysters, and it was learned that while they had grown in the deep water of Long Island Sound, they had been deposited in the mouth of a fresh-water creek for a day or more to freshen. This freshening, as is well known, consists of the absorption by the oysters of fresh water which causes them to swell up and become plump. These oysters had thus been "fattened" before being sent to Middletown. Further inquiry showed that, within about three hundred feet of the place where they had been deposited, was the outlet of a private sewer coming from a house wherein were two cases of typhoid fever. The persons in question were a lady and her daughter. They were taken sick at such a period as to call in a physician for the first time October 11th, which, of course, means that the disease had been in its period of incubation for probably considerably over a week earlier. The oysters were sent to Middletown on October 10th, and therefore they were deposited at this place in exactly the time to receive contamination during the early days of these two cases of typhoid. Of those two cases one proved extremely severe, and the lady died on October 21st. In the other case, the fever, after running about five weeks, disappeared and convalescence set in. It is, of course, very easy to understand that the typhoid germs could have found entrance into the oysters from this source of contamination. Now, it has been known for some time, having been shown by Foster and Freytag, that the typhoid germs will live for a long time in sea-water, or indeed, in a concentrated salt solution. Specimens of the oysters from the creek, however, were put into the hands of Dr. Foote, of Yale College, who soon showed that if the typhoid germs were forced in between the two valves of the shell they would remain alive in the oyster for a time sufficient to enable the oyster to be carried to Middletown and to be used at the initiation banquets. Whether or not they will grow and multiply in oysters, has not yet been positively determined.

Shortly after the oysters had been placed under suspicion, it was learned that there were at Amherst College several cases of typhoid fever. Correspondence was instituted, which resulted in showing that at Amherst there had been held an initiation supper on the night of October 12th. Most of the cases of typhoid at Amherst occurred among the members of one fraternity, who, as at Wesleyan, neither roomed nor boarded together. They, however, had attended the initiation supper on October 12th, had eaten of raw oysters at the supper, and inquiry showed that these raw oysters also came from the same place as the Wesleyan oysters, and had been fattened in the mouth of the same creek. As at Wesleyan, certain wells were first placed under suspicion, but examination showed them to be good. While, of course, this did not conclusively demonstrate that the cases at Amherst were due to the same source of infection as that at Wesleyan, it rendered it at least probable.

The facts above related, it will be seen, point with conclusive force to the oysters as the cause of the typhoid outbreak. The dates of the outbreak, October 20th to November 8th, plainly point to one source of infection about October 12th. The fact that two cases of genuine typhoid developed at the same time among the alumni, and that two others appeared also among Yale students, none of whom have had connection with the three fraternities later than the initiation supper, or before that time, plainly demonstrates the initiation supper on October 12th as the time of the infection. At these initiation suppers only one article of food or drink was used which was not used by the other fraternities in college and by the people in town in general. That one article of food, the raw oysters (not eaten raw by people in town in general), was learned to come from a place where it was certainly subjected to a probable contamination of typhoid fever from two severe cases of the disease. The use of raw oysters from the same locality elsewhere, has been found, at least in one case, to have been followed by a similar outbreak as occurred in Wesleyan. These facts taken together, leave no possible doubt that the Wesleyan typhoid fever was caused by the oysters in question.

It must not, however, be inferred that because the lot of oysters supplied at these initiation suppers was infected, therefore, that all the oysters from the same locality would be thus infected. The public press has certainly exaggerated the condition of affairs. The oysters from the same locality were widely used in Connecticut, and doubtless in many cases have been eaten uncooked. There has been, it is true, quite a little typhoid fever in Connecticut during the past month, but it has not been possible thus far to trace very much of it to the

eating of raw oysters. The probability is that the oysters fattening in the locality in question would not, as a rule, be contaminated, but that it would only be an exceptional condition that would produce the result. It would be necessary that they should be lying in this place at just the period when the typhoid germs were swept by the currents or eddies from the sewer over the oyster-bed; and such a condition, even though there might be continued cases of typhoid in the course of the sewer, would doubtless not by any means be a constant one. Oysters, as a rule, are said to open their shells on flood-tide rather than ebb-tide, and this would, of course, make it more difficult for them to be contaminated by sewage from sewers above them on the creek. While this would by no means make the chance of contamination impossible, it would certainly render it less. It is not to be supposed, therefore, that the oysters deposited in the creek for fattening would all, or indeed many of them, become contaminated by the typhoid material, but that only exceptional conditions would produce the result. Where a private sewer containing typhoid excreta opens in the vicinity of such an oyster-bed, the danger must certainly be considerable. Where the typhoid material is mixed in the city sewers with the large amount of sewage, and is subsequently diffused through a considerable body of salt water when the sewer empties into the sea, the danger of oyster contamination must be considerably less. But there must be danger to public health from oysters fattened in any fresh water in the vicinity of sewage.

Doubtless many cases of mysterious typhoid have been due to such a cause. To trace these cases is a matter of extreme difficulty. The peculiar conditions which have occurred here have been such, however, as to bring the matter into clear light, and to throw with certainty blame of typhoid distribution upon a source which has for some time been suspected, but not demonstrated. That the practice of fattening oysters in the mouth of rivers and in the vicinity of sewers is dangerous to the public health, is beyond question shown by the combination of conditions which have made it possible to trace the Wesleyan typhoid outbreak to the eating of a lot of infected raw oysters.[1]

AN IMPROVED METHOD OF THE RADICAL OPERATION FOR CARCINOMA OF THE BREAST.[1]

By WILLY MEYER, M.D.,

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

SINCE Heidenhain has shown that in a great number of cases of cancer of the breast the pectoralis major muscle is also involved by the disease, and that, if left in place, the growth is more liable to recur,[2] it has become, I believe, the duty of the surgeon always to remove this muscle with the breast and the axillary contents. Only, if carried out according to this plan, the operation should be called radical.

According to well-known methods the surgeon generally first removes the breast with the axillary contents. If he believes in doing in every instance as radical work as feasible in fighting this treacherous disease, he will then cut out the pectoralis major muscle from its origin to its insertion.[3] It means no serious addition to the operative procedure, but rather still more radical work, also to extirpate the pectoralis minor muscle at the same time. It enables the operator to remove the loose connective tissue and fat under this muscle, which is often diseased.

Within the last three years I have operated, according to this plan, on six female patients, and found by increasing experience, with reference to the technique:

1. That the extirpation of the pectoral muscles, carried out in this way, means an addition of about fifteen to twenty minutes to the operation, including ligatures.

2. That it saves blood and time to first cut off the insertion of the muscles on the humerus and coracoid process, and then to reflect the muscles downward. The arteriæ perforantes being on the stretch, can then be well seen and caught with the forceps close to the intercostal muscles, before being divided. If we pursue the reverse method, viz., cut off the origin of the muscle on ribs and sternum first, and then turn up the same toward the humerus, these arteries often tear near the intercostal muscles and the ribs. It is then difficult to catch and ligate the bleeding points.[1]

The parasitic theory of the etiology of cancer is yet unproved. On the other hand, inoculation of small pieces of cancerous tissue into the peritoneal cavities of animals has been successful. A cancer of the same type developed in such a spot. Clinical observations also make it highly probable that small particles of cancer-tissue, if entering hitherto healthy tissue, can there produce the same growth. Kraske gives a *résumé* of the special literature on this subject, and relates two very interesting cases in this respect.[2] He found in two cases of ulcerating cancer of the rectum, where the tumor could just be reached with the finger, low down immediately above the sphincter muscle, secondary small cancerous nodules of the type which was represented by the main growth. In both patients a healthy strip of mucous membrane, of at least 10 ctm. length, was interposed between the original and, as he explains it, the secondary tumors. He believes that the latter originated from the proliferation of the living epithelial cells which had severed their connection with the primary carcinoma, and had then been implanted in the lower portion of the rectal mucous membrane. Small tears in the latter, made by the examining finger or instruments, the hyperæmia and catarrhal condition of the lower end of the rectum always present in these cases, will favor the development of the inoculated particles.

With reference to the breast, the unavoidable handling of the tumor by the operator's hands and the assistants' hooks has been considered harmful, and called upon to explain the distressingly low percentage of cures after the operation. It has been assumed that during these manipulations cancer-cells or, if we accept to-day the theory of the parasitic origin, the parasites themselves, might be pressed into the lymphatics and thus disseminate the disease through the body.[3] It has therefore been proposed to attack the axillary cavity first, clean out its contents before severing their connection with the breast, and then to remove the breast and axillary contents together.[4] This procedure may be of some importance. Yet there are multiple other lymphatic vessels, which are

[1] Read before the Section on Surgery of the New York Academy of Medicine, November 12, 1894.

[2] Lothar Heidenhain: Ueber die Ursachen der localen Krebsrecidive nach Amputation Mammæ. Verhandlungen der deutschen Gesellschaft für Chirurgie, Berlin, 1889, and von Langenbeck's Archiv für klin. Chir., 1889, vol. xxxix., p. 97.

[3] Heidenhain believes that it might be best to remove the strip of periosteum of clavicle and sternum, to which the muscle is attached, with the latter. Before making this addition to the operation, I, personally, should rather wait and see whether future observations prove that by leaving in place the respective pieces of periosteum a regional recurrence is favored.

[1] The arteriæ perforantes are branches of the intercostal arteries. They are of tolerably large size. After having traversed the intercostal muscles, which they supply with blood, they enter and feed (besides the serratus anticus major muscle and a portion of the abdominal muscles) the pectoralis major muscle and the mammary gland. Heidenhain emphasizes the fact that these arteries and their ramifications are accompanied by cancerous lymphatics above the fascia of the pectoralis major muscle. He therefore advises to divide the vessels "within" the latter. It is, in my opinion, a still better plan to divide them "underneath" the muscle, just above the intercostal muscles.

[3] A. G. Gerster, on the Surgical Dissemination of Cancer, New York Medical Journal, February 28, 1885.—It has been my personal misfortune to have had among the patients on whom I removed a cancer of the breast, quite a number in whom there was no regional recurrence of the disease, but who died within one year and a half after the operation, helpless, almost paralyzed, and with great pains, from metastatic growths in the spinal column.

[4] Gerster: Loc. cit.

not touched by the knife in such an operation, and which can carry away infectious material in different directions, thus, for instance, to the opposite side, to the supra-clavicular region, etc. (It is, of course, understood, that in cases of long standing these regions may have become

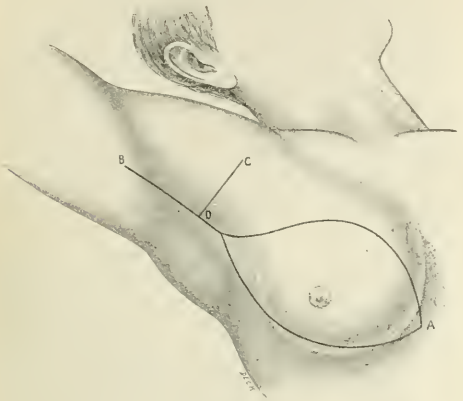

Fig. 1.

infected before an operation for the removal of the cancer of the breast is undertaken.) As Dr. Gerster wrote me the other day, the result, as far as recurrence is concerned, has not been improved by this procedure. This fact is a matter of course, since we know that the fascia of the pectoralis major muscle and this muscle itself, as well as the loose fatty tissue below the same and below the pectoralis minor muscle, so often are the seat of cancer. And this, not very rarely, in cases where the tumor is yet comparatively small and the breast freely movable over the underlying tissues.

The most harm is surely done during the manipulations with the knife, the hooks, and the hands "within the operating field itself," as long as we work "within" and not "outside of" the diseased area. During the operation lymphatic vessels between breast and fascia, those of the pectoralis major muscle, between and below the pectoral muscles, in the axillary, sub- and infra-clavicular fat, all more or less filled with epithelial cells, are compressed, cut, and torn. Their contents enter the fresh wound. Direct local infection of hitherto healthy tissue by cancer is liable to take place. I believe that especially the primary tearing off or preparing the breast tumor with the knife from the subjacent fascia of the pectoralis major muscle, or from the superficial layer of its fibres, if the tumor be adherent to the fascia—as it has been the general custom of operators up to date—may at times directly infect the large fresh wound with microscopical elements of cancerous tissue. It has been shown that just the fascia of the pectoralis major muscle and the superficial layer of fibres of the latter, often contain a very large number of microscopical cancerous deposits.

By first excising the breast with the axillary glands and then extirpating the muscles, the latter procedure forming the second part of the operation, we also increase the loss of blood. Many vessels are cut—and have to be tied—twice.

In view of these considerations I have thought that in order to avoid local or remote infection, also to save loss of blood, and still to be as complete in the work as possible, that the following might be an improvement: *Not* to excise the breast tumor in connection with the axillary contents first, and *then* to remove the pectoral muscles and clean out the sub- and infra-clavicular space; but "*to extirpate the breast, the contents of the axillary and of the sub- and infra-clavicular region, and the pectoral muscles, in one mass.*" In other words, I thought I would try and let the knife never enter the infected area (cancer), but work "everywhere" around the latter in healthy tissue, of course as far as this may be feasible in such cases.

For this purpose the operator must first come down to landmarks, when reflecting back the flaps of skin, before attacking the seat of the cancer proper. These landmarks, as I mapped them out, would be: *a*. Above: cephalic vein and clavicle. *b*. Outward: The tendon of the pectoralis major muscle on the humerus. *c*. Below: the border of the latissimus dorsi muscle. *d*. Inward: The sternal extremity of the clavicle and the sternum itself.

My plan of operation was the following:

1. Skin incision as usual, embracing a liberal piece of skin around the nipple, which incision is at once run up into the axillary cavity, about an inch and a half to two inches farther than in the ordinary operation. This in order more easily to reach the tendon of the pectoralis major muscle on the humerus. (See Fig. 1, A, B.)

2. Additional skin incision from the clavicle at the junction of its middle and outer thirds downward, meeting the first wound at right angles. (Fig. 1, C, D.)

3. Reflection backward of the three skin flaps with as thin a layer of the underlying fat as possible, leaving just enough so as not to endanger a future necrosis of the flaps,[1] exposing: *a*. The insertion of the pectoralis major muscle on the clavicle and sternum. *b*. The insertion of the same muscle on the humerus, the cephalic vein in Mohrenheim's sub-clavicular space (guide!). *c*. The border of the latissimus dorsi muscle. (See Fig. 2.)[2]

4. Division of the pectoralis major muscle in its tendon close to the humerus (the raised arm of the patient must be somewhat lowered for this purpose), and preparation of the same downward (Fig. 2) to its insertion on the clavicle. Here it is cut off at once down to the sternal extremity of the bone, in order to thoroughly expose the contents of the axillary cavity and the infra- and sub-clavicular region. During this time an assistant exerts some traction on the breast, to put the tissues on the stretch.

5. Preparation and excision of the sub clavicular, infra-clavicular, and axillary fat, glands and lymphatics, with the knife, beginning over the bundle of nerves and vessels high up in the cavity, and continuing this procedure from the lower border of the sub-clavian and axillary vein downward. As soon as freed, these contents, having been divided on the outer side from the fat in the

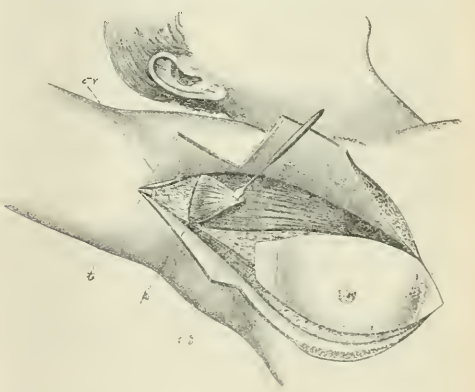

Fig. 2.—*b*, Pectoralis major muscle; *t*, tendon pectoralis major muscle; *c*, *v*, cephalic vein; *l*, *d*, latissimus dorsi muscle.

upper part of the sulcus bicipitalis of the arm, are raised and cut out from the outer side inward. This means, beginning from the border of the latissimus dorsi

[1] Further experience must show how much fat must be left attached to the skin. It means, no doubt, a better prognosis, with reference to recurrence, to say: "the less the better," or, "none whatever."

[2] This plate has been drawn by the artist without his having witnessed the operation. He was obliged to work guided only by my explanations.

muscle. This excision is continued, including the fat on the sub-scapularis and teres major muscles, until the chest-wall, viz., ribs, intercostal, and part of the serratus anticus major muscles, are plainly before us, and until the "lower" surface of the pectoral muscles is reached. Fat with glands and lymphatics are nowhere cut into, but remain in one piece and attached to the outer lower border of the pectoral muscles in their normal anatomical relation.

6. Division of the tendon of the pectoralis minor muscle on the coracoid process.

7. Gentle elevation of the breast and muscles by an assistant's hands in order to put the blood-vessels which enter and leave the pectoralis major muscle on the stretch. As mentioned above, they are clamped before they are divided.

8. Amputation of the pectoralis major muscle at its insertion on the sternal extremity of the clavicle, and of both muscles at their insertion on the ribs and sternum with the knife close to these bones. This insertion forms the pedicle of the whole mass. If cut off alongside the sternum after having been separated from the ribs, the extirpation of the cancer is finished.

9. Suturing of the wound as far as possible; plate-sutures for the sake of better coaptation of the skin-flaps, drainage of the axillary cavity as usual.

10. Dressing; the large defect is always to be covered with rubber tissue in order to favor rapid healing under the moist blood-clot; good compression.

Grafting of the resulting granulating wound, which will follow the removal of a liberal piece of skin, may be done in about eight or ten days without narcosis, ethyl-chloride being used for anæsthetizing the area of the arm or thigh, from which the grafts are taken. The granulating surface need not be scraped for this purpose.[1]

On September 19, 1894, I had my first opportunity to operate according to this plan.

Mrs. F. O——, aged thirty-seven. Slowly increasing tumor of the left breast since eighteen months. It never ached, and thus made the patient neglect to consult a doctor. Examination on September 15th showed a tumor of goose-egg's size in the centre of the breast. Nipple not retracted. Axillary glands hard and infiltrated. September 19th operation as just described, with the exception of omitting the additional incision from the clavicle downward. One upper flap only and one lower one were thus formed. This was a mistake. It somewhat impeded the easy reach of the attachment of the muscle on the clavicle. I should advise always to make this incision, especially in fat patients. I had done so, in fact, in my former cases, in which I first cut away breast and axillary contents, and then the muscles. The operation was not difficult. Only when preparing from the edge of the latissimus dorsi muscle inward and upward, in order to reach the chest-wall and the pectoral muscles (from below), I found it somewhat inconvenient in comparison with the former method of operating, to have the great mass of tissue above. Clever assistants will here be of great help. Temperature never rose above 100° F. First dressing changed on the sixth day; primary union throughout; drainage-tube removed; patient out of bed. To-day arm freely movable. The specimen which I hand around will show nicely, how radically the operation has been done. The whole mass is in one piece. The microscope substantiated the diagnosis of cancer.

As seen in this, as well as in my former cases, where I extirpated the pectoralis major muscle entirely, the loss of the latter never interfered with the motion of the arm. On the contrary, the patients were able to sooner move the arm in all directions than I have seen if the muscles be not or only partially removed. The strong inner (clavicular) portion of the deltoid is fully able to adduct the arm. Some patients complained of a tight sensation over the chest, they "felt their ribs exposed." This annoyance was soon, however, overcome. In order to avoid stiffness in the shoulder-joint, the patients should be ordered to begin with active and passive motions after the first change of dressing, viz., between the eighth till tenth day after the operation.

I am, of course, fully aware that also this most radical method of operation will not prevent recurrence of the growth "in loco," nor metastases in remote parts, especially not, if the patients be subjected to the operation in an advanced stage of the disease. Yet I venture to consider it a step in trying still further to reduce the chances of probably infecting the fresh wound and the entire system with cancer by our work "during" the operation; also to do as complete work as possible.

In this view I thought it permissible to communicate this method to the Surgical Section, having so far had only one personal practical experience.

Mr. President and Gentlemen, the idea of removing the carcinoma of the breast in this way was conceived by me last winter. By a peculiar coincidence not one case of carcinoma of the breast came under my care since then until September, even not during a four-months' service at the German Hospital. This paper was written in the latter part of September. It was announced to the Secretary of the Surgical Section at about October 20th. Before doing so, I had very carefully perused the newest literature, especially the elaborate articles on the subject by Dennis, Weir, and Bull, in order to ascertain whether others had removed a cancer of the breast in the way just described. I did not find this procedure mentioned. Now, ten days ago, on November 2d, the November issue of the *Annals of Surgery* has come into my hands. In this issue Dr. William S. Halsted, of the Johns Hopkins Hospital, has published a brilliant article upon the results of operations for the cure of cancer of the breast, performed by him at the Johns Hopkins Hospital from June, 1889, to January, 1894, in which he recommends practically the same way of operating just proposed by me, viz., the removal of the breast, fat, and glands of the axillary cavity and infra-clavicular region "in one mass." He thinks it advisable to explore and clean out also the supra-clavicular region in almost every operable case.[1] He has operated in this way on most of the fifty patients whose histories are recorded. As will be seen by comparison, our methods differ in some respects. I shall mention those which seem to me to be of some importance.

Halsted surrounds the base of the breast with an incision, and reflects a triangular flap of skin downward and outward.

I first reflect back three flaps of skin, two upper ones and one lower one, so far, until I reach the landmarks mentioned above, namely: the tendon of the pectoralis major muscle, the cephalic vein, the clavicle and sternum, the border of the latissimus dorsi muscle.

Halsted's third step of the operation reads: "The costal insertions of the pectoralis major muscle are severed, and the splitting of the muscle, usually between its clavicular and costal portions, is begun, and continued to a point about opposite the scalenus tubercle on the clavicle." The sixth step reads: "The splitting of the muscle is continued out to the humerus, and the part of the muscle to be removed is now cut through close to its humeral attachments;" and the eighth to tenth: "The lower outer border of the minor muscle having been passed and clearly exposed, this muscle is divided at right angles to its fibres, and at a point a little below its middle." "The tissue, more or less rich in lymphatics and often cancerous, over the minor muscle near its cor-

[1] Julius Schnitzler u. Karl Ewald: Zur Technik der Hauttransplantation nach Thiersch, Centralblatt für Chirurgie, 1894, No. 7, page 148. According to my experience, immediate grafting on the very uneven basis of the fresh defect is not advisable.

[1] This is, no doubt, a very wise addition. I shall certainly add this point to my plan of operating laid down above, in every case coming under my care. By lengthening the additional incision as proposed by me (Fig. 1, C, D,) upward above the clavicle, this operation can be easily and rapidly done. Of course, we shall clean out the supra-clavicular space thoroughly, by removing the fat with glands and lymphatics also "in one piece."

acoid insertion, is divided as far out as possible, and then reflected inward in order to liberate or to prepare for the reflection upward of this part of the minor muscle." "The upper, outer portion of the minor muscle is drawn upward with a broad, sharp retractor. This liberates the retractor which until now has been holding back the clavicular portion of the pectoralis major muscle."

In the manner as I have planned and performed the operation, the belly of the pectoralis major muscle, as well as that of the minor, is not touched at all. To repeat briefly what has been said above: I first cut off the humeral attachment of the pectoralis major muscle, prepare its upper border free from the cephalic vein, and detach it with the knife close to the clavicle. Then the muscle is turned downward and inward, until the tendon of the pectoralis minor muscle can be cut off from the coracoid process. Later—that means after the tissue over the bundle of vessels and nerves high up in the axilla, and after the axillary, sub- and infra-clavicular fat, glands, and lymphatics have been carefully prepared in the well-known manner, "but *left in their original anatomical relation to the breast and to the muscles*" [1]—both muscles are raised and cut away from above downward and inward.

Further: Halsted turns the mass over to the outer side and cuts it off on the base of the skin-flap, which had been primarily formed and reflected outward. This I believe will be more convenient for the operator.

As my procedure follows the direction of the fibres of the pectoral muscles from above downward, the mass must be turned upward and inward first, when preparing from the axilla, and then inward. A clever assistant will be easily able to hold it out of the way. When the pedicle, the sterno-costal insertion of the pectoralis major muscle, is reached, a few strokes with a sharp knife complete the operation.

Further experience must show whether Halsted's or my plan of operating deserves preference.

I personally should prefer the operation as proposed above and carried out by me. It seems to me to be more anatomical than that of Halsted. It also is, I trust, still more radical, since in every instance the entire pectoralis major muscle (and the minor) will be removed. I think, this is absolutely necessary, in order to do radical work. Heidenhain specially states, that he considers a muscle, which has been invaded by cancer, suspicious from its origin to its insertion. "Not a fibre of the muscle should be left behind." On this ground I should also prefer to abstain from all splitting of the pectoralis major muscle between its different portions. By *not* working within the belly of the muscle whatsoever, we shall, no doubt, be best guarded against infection of the fresh wound with cancer, and against regional recurrence.

The nucleus of the operation, however, is the following rule: "Lift *all* the tissue, that may be diseased, and often will be found on microscopical examination to be diseased *throughout*, out of its bed *in one piece*."

That this kind of radical operation will be "the" operation for the extirpation of carcinoma of the breast, there can be no doubt. It is proved by Halsted's unprecedented percentage of cures. He so far records cure in ninety-four per cent. of his cases, including the cases operated up to February, 1894, a number which has never been reached by a surgeon before.

I venture to hope that, by absolutely and continuously working everywhere around the seat of disease, by never trespassing on the belly of the muscles, and always removing the latter completely, this extremely gratifying result might be also secured by others.

Thus will then, at last, it is to be hoped, also this terrible foe of suffering mankind, this dread especially of the female sex, become oftener silenced and made more submissive to the surgeon's knife, provided the operation is done early, before remote parts of the system have become infected.

[1] The lower outer border of the minor muscle is thus not clearly exposed, but remains attached to the axillary fat.

A RÉSUMÉ OF THE SUBJECT OF BILIARY CALCULI.[1]

By THOMAS S. SOUTHWORTH, M.D.,

ASSISTANT TO THE CHAIR OF MEDICINE, VANDERBILT CLINIC; INSTRUCTOR IN DISEASES OF CHILDREN, NEW YORK POLYCLINIC; PATHOLOGIST TO THE NURSERY AND CHILD'S HOSPITAL.

To approach intelligently the question of the formation of biliary calculi it is necessary to have a clear conception of the physiology of the liver and of the biliary secretion in and from which they are formed. It is not essential for this purpose that we should deal here with the anatomy and minute histology of the liver, but we may proceed at once to a brief review of our knowledge of the bile itself. For, although from the size of the liver, and consequently its apparent importance, its function was studied as early as that of any of the other abdominal viscera, it was not until the full development of the sciences of organic chemistry and experimental physiology that satisfactorily definite information could be obtained concerning the secretions and functions of this organ.

Bile is formed continuously, but the rate at which it is produced is subject to great variations. The flow diminishes during abstinence, increases immediately after meals for about an hour, decreases somewhat thereafter, and again flows freely during the third and fifth hours of digestion. Much difficulty has been experienced in arriving at an approximate estimate of the quantity secreted in the course of twenty-four hours. There can be but little accuracy in reasoning by analogy from the secretion in the lower animals, and the operative fistulæ in man upon which observations have been made have in most cases existed under pathological conditions which would greatly interfere with the results obtained. Moreover, as the presence of the bile in the intestines influences the quantity and quality of the bile excreted by the liver the results obtained by the observation of biliary fistulæ must differ very much from those which would be produced were the bile pouring normally into the intestine to be partially reabsorbed by the portal system and returned to the liver. Thus we only know definitely that where reabsorption from the intestine cannot take place, the quantity of bile in man is from a pint to a pint and a half per day.[2] Under normal conditions we presume it to be somewhat larger.

Comparisons made between the pressure in the veins of the portal system and that in the bile-ducts have shown that the biliary pressure is two and one-half times as great as that of the blood supplied to the hepatic cell, proving conclusively that the process is not one of filtration but of definite secretion. As it flows from the intrahepatic ducts the human bile is a non-viscid fluid of a golden red color, sweet-bitter taste, feebly alkaline reaction, and a specific gravity of about 1.010. The viscidity which we usually associate with it is acquired from admixture with a substance secreted by the mucous membrane of the gall-ducts and gall-bladder. This is known as the mucoid nucleo-albumin of the bile, and increases in amount in proportion to the length of time the bile remains in the gall-bladder. The bile contains as the direct secretory product of the hepatic cell the so-called bile acids, glykocholic and taurocholic acids, the former preponderating, and the biliary coloring matter bilirubin, which is readily oxidized to biliverdin, or by intestinal action changed to other derivatives. In addition to these specific products of the liver it also excretes through the bile cholesterin, neutral fats, soaps, lecithin, traces of a diastatic ferment, mineral matter, and gases, of which the chief is CO_2. While, if we disregard the very slight traces of a diastatic ferment, we know that the bile has no power to decompose starches, proteids, or fats, we are still convinced that in addition to its excretory functions it undoubtedly plays a by no means unimportant part in

[1] Read before the Section on General Medicine, New York Academy of Medicine, November 20, 1894.

[2] Arthur Gamgee: Text-book of the Physiological Chemistry of the Animal Body, vol. ii., p. 276.

the intestinal economy by neutralizing the acidity of the chyme, and thus preparing the way for pancreatic activity, as well as its direct or indirect saponifying, antiseptic, and laxative effects.

Gall-stones, as shown by autopsy records, are of much more frequent occurrence than we would suppose were we to judge only from clinical evidence. Schröder found at the autopsies in the Strassburg Hospital gall-stones in 4.4 per cent. of the men and 20.6 per cent. of the women. They are rare under thirty years of age, more frequent from thirty to sixty, and after the latter age occur very often. Women, and especially those who have borne children, furnish by far the largest number of cases. The large majority of biliary calculi are formed and found in the gall-bladder; certain forms, however, may rarely be found in the larger ducts, or even in the intra hepatic ducts. Stones which are found in the cystic or common ducts have, however, almost invariably come from the gall-bladder. Their specific gravity is very low, so low that when dried they may even float upon water until the air which they contain has been expelled. The calculi are rarely single, but usually multiple (5 to 30), and have been found in a single case to the number of seven thousand eight hundred and two. In size they vary from fine sand to masses 15 ctm. in length. The average size is that of a hazel nut. They are composed chiefly of cholestrin, bilirubin calcium, and calcium carbonate, singly or in combination with each other. The color and consistence depends upon the composition. White or light-colored stones are entirely or largely composed of cholesterin; brown, green, and black tints are given by bilirubin-calcium, biliverdin, and other derivatives of the biliary coloring matters. Calcium carbonate is often found in a green external layer. All calculi from the same gall-bladder have usually the same composition, structure, and color. Their shape is affected by the space in which they lie. The facets upon their surface depend upon their numbers and are almost invariably due to mutual pressure while soft, and not to attrition.

When stones are sawn in two they present, as a rule, 1, a central nucleus; 2, a middle zone of multiple concentric lamellæ; 3, a laminated external layer or shell. These three divisions are very often of diverse color and composition. The nucleus is of the greater interest; it is more commonly formed of a combination of biliary pigment and calcium, called bilirubin-calcium, or of mucus and epithelial cells. These latter by desiccation may leave a hollow centre. Very rarely foreign bodies, such as needles or intestinal worms, have been found as the nucleus of the concretions.

The most common and most numerous variety of cal culi, "the habitual tenants of the gall-bladder," are the mixed cholesterin calculi, yellow or whitish-brown in color, occurring in groups of varying numbers, often 70 to 100 together, from the size of a pin's-head to that of a small cherry, faceted by mutual pressure, frequently lamellated on section, and often soft and friable before exposure to the air. Other much rarer varieties of cholesterin stones are the white crystalline and the stratified cholesterin calculi. The former are usually single, often of considerable size, of pure white transparent crystalline structure, and are usually found in a recess of the gall-bladder or in the common or cystic ducts, encircled by the wall, which is frequently even adherent to the stone. The stratified variety, although containing sixty per cent. of cholesterin, are usually darker from an admixture of biliary coloring matters, and more frequently multiple and faceted than the former. On section they appear to be formed of concentric lamellæ of varying color, throughout which crystallization, beginning at the centre, has advanced to variable distances.

Less frequent as a class than the cholesterin stones are those formed of the compound of bilirubin and calcium. These may rarely be pure, in which case they are small, dark concretions. Usually, however, they are mixed with some cholesterin or calcium carbonate, in which case they are still dark, occur singly or at the extreme by twos or threes, are found in the gall-bladder or ducts, and are made up of broad, structureless lamellæ which may be arranged about a crystalline cholesterin nucleus. Other occasional forms are described, including those made up of calcium carbonate.

When we approach the question of the formation of gall stones we have to deal with a delicate problem. It has long been recognized that increasing age enhances the liability to biliary lithiasis, as well as anything which tends to retard the movement of the bile in its passage. Now two of the main factors in keeping up a movement of the bile are exercise and deep respiratory action. Both of these are usually lessened as age advances, and to these may be added sedentary habits, and, in women, diminution of diaphragmatic respiration by the wearing of corsets and during the existence of pregnancy.

Neither heredity, nationality, diet, nor diathesis seem in any way to influence the incidence of cholelithiasis, for the amount of cholesterin and calcium salts in the bile bears no relation to the general tissue change or to the food of the patient, but they are constant in their amounts as proven by elaborate experimentation. We know that while bilirubin is abundant in the bile, cholesterin is excreted in comparatively small quantities, yet we have just seen that the cholesterin stones are by far the largest and most numerous, while bilirubin-calcium enters into the composition of calculi in smaller amounts and less frequently. We must therefore look for some local causative factor which shall explain the precipitation of the elements of the calculi from the biliary secretion. Naunyn[1] believes this agent to be the bacterium coli commune, which penetrates from the intestine along the ducts to the gall-bladder. When there is no stasis in the biliary system, and the gall-bladder is frequently emptied no harm results, but if the flow of bile be retarded the continued presence of the bacterium sets up a catarrhal condition of the mucous membrane, during which calcium salts are excreted by it in excess. These combine with the bilirubin to form bilirubin-calcium, and the albumin from the mucous membrane of the gall-bladder aids in its precipitation. On the other hand, the cholesterin, of which by far the larger number of stones is composed, has been conclusively shown to be the product of the epithelium of the ducts and the gall-bladder, and to bear practically no relation to the small amount excreted by the liver. This has been proven by the fact that the percentage of cholesterin increases in the bile in proportion to the time it remains in the gall-bladder, and also that pure cholesterin stones will increase in size in the gall-bladder when there exists complete occlusion of the cystic duct, whereas, for the growth of bilirubin stones fresh supplies of bile must at least reach the gall-bladder at intervals. Naunyn found that in the gall-bladder of persons dying with gall-stones the epithelial cells contained or were extruding myeline masses of a glassy, structureless character, which under the action of acetic acid became clumps of cholesterin crystals. These myeline masses are then rudimentary or embryonal calculi, ready to crystallize upon any opportune object, usually about little masses of bilirubin-calcium or clumps of epithelial cells and mucus. If now there be free exit for the bile through the cystic duct, these microscopic masses may be swept out by the flow of bile into the intestine, but if the flow be tardy, or there be obstruction, their further growth, by the addition of subsequent lamellæ is readily understood.

The radiating crystalline character which is noticed throughout the whole or a part of many of the pure or mixed cholesterin calculi requires a word of explanation. This is a subsequent change which takes place later and more slowly than the growth of the stone by the accretion of structureless cholesterin. The process begins in the centre, either in an original cholesterin nucleus, or more often in myeline material which has penetrated by infiltration and filled a hollow at the cen-

[1] Klinik der Cholelithiasis. Leipsic, 1892.

tre left by the drying or escape of soft or semi-fluid substances which formed the original nucleus. From this centre crystallization extends outward in radiating striæ through the different lamellæ, aided perhaps by fresh cholesterin, which penetrates from the outer zone along minute canals called infiltration canals. It is even possible that, during this process, in many cases, bilirubin-calcium may be dissolved and displaced.

It is hardly necessary for me to consume your time in reciting the classic symptoms of biliary colic—sudden pain, chill, fever, sweating, vomiting, and often, later, swelling and tenderness of the liver, distention of the gall-bladder, discoloration of the urine, icteric hue of the skin, and clay-colored stools. Of far greater interest to us, as pertaining to diagnosis, are the more unusual variations. It is very difficult to understand in all cases why stones which have lain quiet in the gall-bladder for a long period should suddenly be forced into the cystic duct. Where errors in diet, over exertion, falls or jars, child-birth or menstruation have immediately preceded, it is easier to form an hypothesis and believe that unusual peristaltic action is excited in the walls of the gall-bladder, either indirectly by reflex nervous influences, or directly from extension outward along the muscular fibres of the bile-ducts of unwonted peristalsis in the intestine. Prodromal symptoms in the way of sensitiveness in the epigastrium, chilliness or slight icterus, sometimes exist for a day or two before the attack of colic; but it is much commoner for this to begin suddenly. Murchison[1] states that the attacks occur shortly after the ingestion of food; Naunyn, however, contends that they are more likely to take place some hours after eating, when the chyme begins to pass into the duodeneum and thus explains the frequent occurrence of a first attack about midnight. The pain of biliary colic is usually severe and hard to bear, of a rending, boring character, and radiating upward. In other instances, however, it may only amount to a slight burning sensation, or even be entirely absent. Fever may either be absent or play a very important *rôle*. It is frequently preceded by a chill, and is generally of short duration, but may continue for days if the other conditions persist. Vomiting is usually severe and prostrating. Occasionally it brings to light some of the stones which have caused the attack. The muscular contractions or cramps in the abdomen, legs, arms, or hands are of reflex origin. With these symptoms only the attack may terminate, after a short time, by the falling back of the stone into the gall-bladder, or by its passage from the common duct into the intestine; but if its progress is slow after it has reached the common duct other symptoms are added. The bile, which is secreted continuously, cannot escape by its usual outlet but distends the gall-bladder, which may be felt in one-third to one-half of the cases under the right rectus or to the outer side of that muscle. The gall-bladder filled, the intra-hepatic ducts become distended, with resulting tenderness and enlargement of the liver, and finally the bile is forced into the lymphatics and passes through the thoracic duct into the blood. Here it first shows itself in discoloration of the urine, but when it passes into the blood more rapidly than it can be excreted by the kidneys it begins to be deposited in the tissues, revealing itself first in the conjunctivæ and later in varying intensity in the skin. The bile being thus diverted from the intestine the stools become pale or clay-colored and the movements constipated.

As is the case in many another affection, of which the text-book description is clear and classical, in actual experience there are many variations in the occurrence, intensity, and sequence of the cardinal symptoms. As Charcot[2] has pointed out, the chill may precede the pain, or the chill and fever may not be proportionate to the intensity of the pain. In other persons there may be pain and chill without fever, or fever without chill, or fever without pain. Many of the attacks, estimated at fifty per cent., pass off without jaundice, or this may develop, with its attendant train, as early as twelve hours after the inception of the attack. The duration of the pain may be half an hour or half a day, or it may persist continuously or recur intermittently for several days.

Without going exhaustively into the question of differential diagnosis it may be mentioned that where icterus is absent the case must be distinguished from cardialgia, lead colic, renal colic, fecal impaction, peritonitis, appendicitis, and intussusception. Death, though rarely, may occur during the course of an attack, from suicide, collapse, syncope from pre-existing cardiac lesions, or rupture of the ducts or gall-bladder, with consequent infectious peritonitis. In the latter instance prompt laparotomy has saved life.

If, as Naunyn claims, in old age every tenth man and every fourth woman has gall stones, how shall we reconcile this fact with the infrequency of biliary colic in general, and among the aged in particular. Sénac believes that hepatic colic originates only between the twenty fifth and thirty-fifth years, and that after sixty stones are frequently passed without reaction or pain. It is quite possible that calculi in the gall-bladder may be not only latent but entirely harmless; in fact, unless their mere mechanical presence cause ulceration or infectious conditions they give no signs of their presence until they enter the ducts. Arrayed on the one hand as factors opposing the progress of the stone are the small size and peculiar conformation of the ducts, the elasticity of the walls, and the reflex spasm of the muscular fibres from irritation, as well as the size, consistence, and form of the stone itself. On the other hand, assisting its progress we have the slight pressure of the bile and the much more important peristaltic contractions of the muscular coat of the gall-bladder and ducts. The cystic duct has a diameter of but 3 mm., while that of the common duct is 6 mm. Here we perhaps have an explanation of the partial alleviation of the pain which often takes place in the course of an attack, probably as the stone passes from the smaller cystic to the larger common duct.

While after death the gall-ducts offer much resistance to attempted dilatation, it is evident from post-mortem findings in those who had suffered from repeated passage of gall-stones that the ducts can not only be dilated but remain so permanently. The opening of the common duct into the duodenum is the least distensible portion, as shown by the greater frequency with which stones are arrested at this point than at any other. Histology has contributed the important fact that in youth muscular fibres are abundant in the walls of the ducts, but that in old age they are much atrophied or have disappeared entirely.

We are now in a position to understand some of the possibilities why the passage of stones in different cases and at different ages may be accompanied by such varying reaction. If, as we may readily concede, the pain of biliary colic is due to the stretching of the ducts and the reflex spasm of their walls, we can see that the passage of a small calculus through an already dilated duct may be accompanied by little or no pain, while it is easy to conceive, with Naunyn and others, that the atrophy of the muscular fibres in old persons either prevents the violent peristalsis in the gall-bladder which forces the stones into the duct, or renders impossible the reflex spasm of the duct, which is probably the chief source of the pain, so that gall-stones which are much more frequent at this age may remain indefinitely in the gall bladder or be passed without the knowledge of the patient. A very few persons escape with but one attack of biliary colic in a lifetime. Most frequently, however, the attacks are repeated at longer or shorter intervals. The successive attacks in the same individual may be marked by great differences in the intensity of the suffering, or one may be of short duration, the next extend with exacerbations and remissions over several days.

One stone or many may pass during a single attack. One instance is recorded where two hundred and forty-

[1] Clinical Lectures on Diseases of the Liver.
[2] Leçons sur les Maladies du Foie. Paris, 1887.

four calculi were recovered from the stools in five days. Smaller numbers are much more frequently found. Much difference of opinion has existed as to the size of stones which can be passed through the ducts. The majority of those so passed are not larger than peas; it is probable, however, that calculi as large as the kernel of a hazel-nut can also pass. The chief hindrance, as we have already seen, is usually encountered where the common duct enters the duodenum. Here a rupture of the tissues with the formation of a duodenal fistula may allow even a large stone to escape. Recorded instances of the passage per anum of very large stones are probably the result of direct ulceration from the gall-bladder into the intestine.

Directions are usually issued that the stools shall be examined for calculi after an attack of colic, but the concretions are not always found, often because of careless methods or lack of persistency. The surest method is to pass the softened stool under the action of running water through a piece of muslin or a hair-sieve. This treatment should be extended to all stools for eight days, for although in most cases the stones appear in the fæces after twenty-four to forty-eight hours, cases are recorded where they have been retained until the eighth day. Apropos of this question, one fact which is not generally appreciated is worthy of especial consideration. Experimentation by causing gall stones of varying composition to be swallowed by healthy men, and search instituted therefor in the stools, has shown that only firm or hard stones, or those having a hard cholesterin shell, reappear in the dejections. Soft stones and those of pure or mixed bilirubin-calcium suffer disintegration in the intestine. Naunyn, in his extensive researches, has found but one such stone in the stools, and that showed signs of erosion. It is therefore evident that however valuable may be the positive evidence of stones passed per rectum, the failure to find the same cannot be considered as proving that the preceding attack of pain did not result from the passage of a calculus.

Besides the acute attacks above described, accompanying the expulsion of calculi through the biliary passages, there is a further extensive group of affections of the liver and biliary tract dependent upon the continued presence of calculi. These are grouped under the comprehensive term "irregular cholelithiasis." An attack of acute biliary colic may end in three ways: 1, By the falling back of the stone into the gall-bladder; 2, by its expulsion into the intestine; 3, by its impaction in the biliary passages. Stones thus impacted usually give rise, for a time at least, to repeated attacks of colic, and it is evident that the occurrence of jaundice and associated symptoms will depend upon whether the site of the impaction be in the cystic or common duct. Gall stones are often found post mortem in these ducts. The majority are large stones, larger than cherries, ofttimes they are the size of a walnut or even greater. Such stones may have been formed *in situ*, but in the majority of cases they are doubtless stones which have become impacted and grown by accretion. They may allow the bile to pass them into the intestine, in which case they may exist for years without harm and without symptoms. They may furnish the necessary factors for the development of various infectious and ulcerative conditions, or again they may intermittently or permanently interfere with the exit of the bile. In the latter event chronic icterus results.

When chronic icterus is established, and this may happen as readily from a stone which has lain for years in the duct as from a freshly impacted calculus, the patient may succumb as early as the tenth day, or he may live for weeks, or months, or even years. It is not the obstruction alone which causes death, but the complications to which it gives rise. Everything depends upon whether the obstruction is partial or complete. If the occlusion of the duct is absolute, so that no bile can pass, the ducts behind the obstruction become dilated, the gall bladder is distended, jaundice increases, gastric and intestinal digestion become disturbed, and the patient succumbs from hemorrhage or from emaciation and marasmus. Where chronic icterus exists, with but intermittent or partial obstruction, the degree of icterus is variable, the liver remains of normal size, or is but slightly enlarged, and there is no distention of the gall-bladder. Itching of the skin is usually a distressing symptom, and hemorrhages from the mucous membranes may take place, but the intestine continuously or intermittently receives some bile, as shown by the color of the fæces, and the nutrition of the patient does not suffer as rapidly as in the previous case.

Among the common baleful results of cholelithiasis, more especially with obstruction of the common duct, is the production of cholangitis, or an inflammation of the biliary radicles. Here again we find the bacterium coli commune as a specific cause of the infection of the bile. Cholangitis is not always purulent, even when it produces fatal results. Where the process has been distinctly suppurative, cultures have shown an admixture of staphylococci and streptococci. Still greater importance attaches to the fact that cholangitis leads to cholecystitis and hepatic abscess. Infectious cholecystitis is excited by the presence of the bacterium coli commune where calculi are retained in the gall-bladder, especially when the cystic duct is blocked by a stone. The contents of the gall-bladder are at first the retained bile and the infected secretion of the mucous membrane. The biliary constituents are, however, promptly reabsorbed and the gall-bladder then is filled with a sero-purulent fluid, containing usually but a small number of pus-cells. The more abundant the pus the more applicable to this condition is the term "empyema of the gall-bladder." This should be clearly distinguished from a condition known as "hydrops of the gall bladder" which arises when the cystic duct is blocked without previous infection of the contents. The bladder then contains after a time a semi-transparent strongly mucilaginous fluid, which is sterile and without any traces of pus.

Hepatic abscess above referred to may result from suppurative cholangitis, by extension from an empyema of the gall-bladder, or from the pressure of a stone in the common duct upon the portal vein causing thrombosis and pylephlebitis. Carcinomatous involvement of the biliary tract is of such frequent occurrence with cholelithiasis as to suggest strongly its dependence upon that condition. Its possible existence should always be kept in mind in cases of chronic jaundice occurring in old people.

What, then, is the fate of the stones which remain in the gall-bladder? In many instances doubtless they remain unrecognized and innocuous, for they are revealed by the necropsy when no symptoms occurred during life which could be referred to their existence. But in other cases their presence is more or less pernicious. Hypertrophy of the muscular fibres of the gall-bladder occurs, with slow contraction of the viscus about the mass as a whole, or else it becomes sacculated with enclosure of one or more calculi in the recesses. Sooner or later a desquamative catarrh of the mucous membrane is set up, with thinning or ulceration of the mucosa from pressure. Ulcerations may heal with the production of cicatrices, or perforation of the walls may take place with consequent peritonitis or the formation of an encapsulated abscess beneath the liver; or again, where adhesions have previously been formed to the other viscera or to the abdominal wall, fistulæ may be formed opening externally, or into the stomach, duodenum, ileum, or colon. Through these latter fistulæ the stones incarcerated in the gall-bladder may escape into the gastro-intestinal tract and be passed per anum, provided their smallest diameter does not exeed 3 c.m., otherwise they may be arrested at the ileo-cæcal valve. Larger stones or masses of small stones have often caused intestinal obstruction and called for surgical interference.

The treatment of biliary lithiasis naturally resolves itself into four divisions: 1. Treatment of the acute attack. 2. Treatment directed to resulting conditions.

3. Prophylaxis against repetition of the attacks. 4. Surgical indications in acute and chronic cholelithiasis.

During the acute attack the indications are clearly to relieve the pain, relax the spasm, facilitate the expulsion of the stone, and prevent subsequent complications. The pain of biliary colic is usually so intense that the patient demands that our first efforts be directed to its relief. This is most promptly and efficiently accomplished by the subcutaneous injection of morphine in full dose (gr. ¼) repeated at intervals according to indications. Morphine, however, may aggravate rather than allay the vomiting, and also tends to decrease the biliary secretion. It is therefore best combined with atropine, which does not influence the secretion of bile, but does restore the disturbed tone of the muscular fibres, assisting in the subsequent expulsion of the stone by normal peristalsis in the ducts. Where the attacks are prolonged opium and extract of belladonna by the mouth are better borne than morphine, and in very long or intermittent cases other analgesics—antipyrine, chloral, amylo-valerianic ether, or sodium salicylate may be wisely substituted. Relaxation of the spasmodic contraction will be favored by prolonged hot baths (95° to 100° F.), and chloroform by inhalation may be temporarily required. Vomiting is best allayed by repeated large draughts of sodium bicarbonate and hot water (℥ j.–℥ ij. to Oj.). This is at first rejected but afterward retained. Later gastric irritation may call for the usual sedatives—bismuth, dilute hydrocyanic acid, and carbonated waters. The pain and spasm somewhat relieved, our next interest is to hasten the passage of the calculus through the duct. For this purpose such cholagogues as are known to favor the secretion of more abundant and more fluid bile must be called into requisition. Salicylate of soda, besides its analgesic power, stands here in the front rank, with ox-gall, glycerine, and calomel. Ferrand's[1] experiments not only show that glycerine in massive doses (℥ v.–℥ j.) is taken up by the lymphatics of the stomach and carried to the liver, where it produces a free secretion of fluid bile, but its ingestion has also produced prompt alleviation of the pain and apparent passage of the stone. Calomel, like other metals, is arrested by the liver, where it passes into the portal system, and produces a direct stimulation of the hepatic cells. Ether and chloroform act reflexly by their action on the stomach. Aloes, euonymin, and podophyllin, and the benzoates of sodium and lithium are also much vaunted in this connection. Durand's mixture — ether, 3 parts, turpentine, 2 parts — once much in vogue in doses of ℥ ss.–℥ j. in bouillon, but badly borne by the stomach, has now been relegated to the treatment of more chronic cases. Olive oil, recommended by Chauffard in doses of ℥ vj.–℥ viij., and given in two portions, with an interval of a quarter of an hour, with the patient lying upon his right side, is both safe and inoffensive, and often well tolerated by the stomach. Willemin has seen it followed by almost instantaneous relief of the pain, which occurred so quickly as to be probably the result of reflex action. The more prolonged the attack, the greater the danger of secondary complications. When congestion is marked and inflammatory conditions in the liver threaten, moist heat applied over the liver by poultices or fomentations relieve pain by lessening congestion, and reduce the liability to inflammatory reaction. If the process be more advanced and there be signs of cholecystitis or hepatitis, more active antiphlogistic remedies may be indicated—eight to ten leeches, mustard or vesicants, or cold in the form of ice-bags may be cautiously employed.

Infectious cholangitis and hepatic fever call for antiseptics which will be excreted in the bile. Calomel is best given in three to eight grain doses every two to three days. The benzoates, and especially benzo-naphthol, have been strongly endorsed. Salol and salicylate of soda are particularly useful when there is fever. In considering certain of the above indications for treatment it is impossible to sharply distinguish between cases of short and long duration, if we would avoid useless repetitions, and much that has been said is applicable to cases where the stone remains impacted in the duct. In the intervals between the attacks, to remove the impacted stone or to prevent the occurrence of fresh crises, glycerine, ℥ j. to ℥ iv. per day, may be given in slightly alkaline water, or olive oil may be administered in ℥ ij. portions at bedtime. A method taught in one of our largest clinics, and practised with considerable success, is the administration of the oil, once daily, in milk, one tablespoonful the first day, and an additional tablespoonful each day until upon the sixth day six are taken. Whatever the method of giving the oil may be, it should cease on the sixth or eighth day, and not be resumed until the same number of days have elapsed.

Prophylaxis is of course only applicable to those who have previously suffered from the passage of calculi. It is therefore to be considered after, rather than before, the treatment of the acute attack. It should be directed toward securing a free secretion of bile by the use of cholagogue remedies, and toward favoring satisfactory evacuation of the bile from the gall-bladder. To this latter end active exercise, massage, and hydrotherapy are useful in themselves, and also because they favor deep respiratory efforts. Our knowledge of the influence of diet upon the incidence of cholelithiasis is so slight that we can only caution against over eating and the excessive use of rich food-stuffs, alcohol, or condiments. Daily evacuation of the bowels should be secured, and the clothing should be such as to allow unimpeded play of the abdominal and respiratory muscles. No case of chronic biliary lithiasis need be considered hopeless, or, if the symptoms be not urgent, condemned to surgical procedures, before testing the result of a course at Vichy or Carlsbad, or some other of the hot sodium, or sodium and magnesium springs, for the results under such treatment are often surprisingly prompt and successful.

Surgical interference may be required both in acute and chronic cases. In the former, where rupture of the ducts or gall-bladder has taken place during the paroxysm, with escape of bile and threatened peritonitis. In chronic cases, to relieve an incarcerated calculus in the duct, or to remove masses of calculi from the gall-bladder when these conditions have caused ulceration, infectious cholangitis, cholecystitis, or empyema of the gall-bladder, especially where there is danger to the patient from the continued temperature, emaciation, or threatened general infection. Jaundice, and its accompanying hemorrhagic tendency enhances, many fold, the dangers of operative interference, but does not in itself constitute a counter-indication.

19 West Forty-sixth Street.

Football Casualties and Fatalities.—B. Foote, a student at the Fairfield Seminary, near Little Falls, N. Y., became violently insane a week ago because of injuries received in a football game in which he played centre rush. He rushed around the dormitory all Sunday night in his football suit, and was only secured by a ruse at daybreak. He was then taken to the Utica Insane Asylum, where he is now confined. Daniel McTiernan, fourteen years of age, who played at Worcester on Saturday, December 8th, in a school game, was fallen on in a rush, and was so injured that he died during the night. At Shreve, O., on December 8th, Walter Blackburn, nineteen years of age, received injuries in a football game which caused his death. While "interfering" with another player, Blackburn was thrown heavily to the ground and five or six of the players fell on him. When he was extricated he was paralyzed from the neck down, and a surgical examination disclosed the fact that the spinal column had been fractured.

"**Teratalogia**" is the name of a new quarterly journal devoted to "ante-natal pathology." It is edited by Dr. J. W. Ballantyne, of London.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 15, 1894.

THE REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THE report of Surgeon-General Tryon for the year just past contains one item of more general interest than such documents usually do, namely, the treatment of pneumonia. During the year there were thirty-three cases of acute pneumonia admitted to the hospital in this city, and of that number thirty-one recovered. This unusually low mortality-rate is naturally regarded as a result of the method of treatment adopted. This method consisted in the hypodermic injection of one-thirtieth to one-twenty-fifth grain of sulphate of strychnine every three or four hours, together with a very free use of alcoholic stimulants. The health of the Navy in general was excellent. The remarkable immunity of the officers and men on board the ships in the harbor of Rio de Janeiro, during the yellow-fever epidemic there a year ago, is referred to with a pardonable show of satisfaction. There was but one case of yellow fever on an American man-of-war out of a total complement of 1,762, and this case might have been prevented had the sanitary regulations been obeyed. During this time of practically complete immunity on American war-ships, there was disease on board the vessels of every other nation in the harbor, while many merchant vessels lost nearly their entire crews. A circular has been issued calling for reports relating to the sanitary measures employed in the prevention of yellow fever on board war-vessels, and it is hoped that such reliable information will be obtained from the answers to this letter, that the medical department will be able to formulate sanitary rules and regulations on the subject that will be of value as a guide to vessels of the Navy when obliged in future to serve in an infected port. When such general sanitary rules, embracing special precautionary measures against the introduction of yellow fever and cholera or board vessels of war have been formulated, they will be submitted to the authorities with the request that they be made department regulations.

Concerning the Naval Museum of Hygiene, the report states that the exhibits have now all been transferred to the building, formerly the Naval Observatory in Washington, which was recently set apart by the Secretary of the Navy for this purpose. "The interest that has been manifested by the service and by professional and scientific bodies, in the growth and development of a museum identified with the practical study and advancement of sanitary science, is shown by the steady increase in the number of exhibits. By the removal of the museum to commodious and permanent quarters, the object of its organization can now be satisfactorily fulfilled, and opportunities offered for accomplishing good work in the future. One hundred and ten new exhibits were added to the collection during the past year, including the complete and interesting model of the system of disinfection practised at the quarantine station at New Orleans. This model was exhibited at the Columbian Exposition at Chicago, and presented to the Museum by the Louisiana State Board of Health. Thirty specimens of animal parasites, contributed by the Department of Agriculture, have also been received, remounted, and labelled."

The necessity of organizing a hospital corps is insisted upon, for the services which such a corps, well drilled and equipped, could render would be invaluable to the Navy. Such a corps exists in the Army, and its usefulness has been demonstrated time and again. Other navies are introducing it, and much time and thought are there being given to its perfection, and the Surgeon-General therefore urges that some legislative action relating to this subject be taken by Congress at an early date.

Dr. Tryon refers again to the strange oversight in relation to the sick quarters in the new ships. "On board of ten vessels no quarters are designated for the treatment of the sick and wounded; in the case of the Minneapolis the omission was probably due to an oversight, as this vessel was designed on similar lines to her sister ship the Columbia. Subsequent to the examination of the plans of our uncompleted warships, the drawings of the armored cruiser Brooklyn and the battleship Iowa were submitted to the Bureau and, in consultation with the President of the Board of Inspection and Survey, and the Bureau of Construction and Repair, suitable sick quarters were located." In view of the omissions in the past, it is very reasonably suggested that, hereafter, the medical department be consulted as to the location of sick-bays on ships which may hereafter be constructed.

THE MICROBES OF THE EYE.

THE researches of bacteriologists have shown that the conjunctival sac is a famous feeding-ground for microbes of all kinds. A very complete and learned review of the question by Dr. A. Cuénod (*Gazette des Hôpitaux*), shows the present status of the subject and indicates that, in time, all inflammatory conditions of the conjunctiva will be distinguished nosologically by their specific microbes rather than by the vascular reactions. Thus, he shows that the acute catarrhal inflammations are due sometimes to the bacillus of Weeks and, more rarely, to a pneumococcus or streptococcus organism. The purulent conjunctivitis of genital origin is usually due to the gonococcus. Croupous conjunctivitis may be due to the bacillus of Loeffler, but is oftener a mixed infection.

In chronic inflammatory conditions there have been found the trachoma coccus (Koch, Poncet, Michel), the gonococcus, and a microsporon described by Noisewski. In xerosis, the bacillus of pseudo-diphtheria is present. The bacilli of tuberculosis and of lupus also may develop in the conjunctiva.

According to Cuénod, in the healthy conjunctival sac one never finds the microbes characteristic of the three principal forms of acute conjunctival inflammation (blen-

orrhagic, diphtheritic, and contagious catarrhal). Only exceptionally does one meet with staphylococci, streptococci, and pneumococci. The conjunctiva is, therefore, reasonably aseptic in healthy eyes. The constant flow of lachrymal fluid across its surface is believed to have some antiseptic influence.

TYPHOID FEVER AND SOCIETY.

Typhoid fever, like death, is no respecter of persons. A lay journal laments the fact that this very democratic disease has attacked several members of "society" during the past fall, and has thereby interfered sadly with many high social functions. Dr. Samuel Wilks, in a recent address, asserts that typhoid fever seems to need no specially adapted soil, but seizes upon the vigorous and healthy as quickly as upon the weak. This is the general experience, though as age increases some immunity is experienced. Most intelligent persons nowadays know that typhoid is communicated through what we eat—and especially through what we drink. In the houses of the intelligent and of the wealthy, and in many well-conducted hotels, sterile waters are largely provided. Yet the disease continues to affect the rich and poor. This only shows that the watchfulness is not complete enough; it is easy to forget when the enemy is a subtle and invisible one, and one that lurks in dark and unexpected places, as do the germs of enteric fever.

FRIGO-THERAPEUTICS.

French medical science seems unhappy without some sensation. Perhaps the very latest is that which goes under the name of "frigo-therapeutics." Accounts of it have been telegraphed to our daily papers. Professor Pictet, we are told, recently explained the new method before the Academy of Medicine. He began the development of his new treatment "by experimenting on dogs, and found that when they were plunged into a bath at low temperature and were kept there for some time, they became ravenously hungry. Being himself a sufferer from stomach disease, he had forgotten what it was to have an appetite. So he descended into the refrigerating tank at a temperature many degrees below zero. He wrapped a thick pelisse and other warm clothes about him, but after four minutes he began to feel hungry. At the end of eight minutes he climbed out of the tank with a painfully keen appetite. Many such experiments were made. All meals taken after a short stay in the refrigerator agreed with him. He found that his dyspepsia was cured after the tenth descent."

This account has a very up-to date flavor about it. The idea of curing dyspepsia by making the patient sit in a cold tank is certainly original, but it will, we fear, apply only in carefully selected cases, and the freedom from dyspepsia may be accompanied with colds, coughs, and rheumatism.

And who knows but that sitting in a hot tank might not be still more effective. Dr. Ashmead describes, in the *University Medical Magazine*, the hot-tank treatment of the Japanese, which there seems to be very popular. He says that "In Bungo, Japan, near a town of a thousand homes and five thousand inhabitants, on the coast of Kiushiu, at the foot of an old volcano, there is a warm-spring watering-place much frequented by poor people. They crowd there between the barley harvest and the June rice planting. Eighty-two springs belong to the place. A peculiar way of taking this treatment is the sand-bath, and this is the manner of it: Some of the springs, all of them hot, are so near the beach that they are covered by the full tide. When the waters recede, basins are dug in the sand heated by these, and frequenting patients bury themselves in these holes up to the neck. Those who use the sand-baths usually remain for several hours in them, umbrellas being held over their heads to protect them against the sun."

It is going to take a good deal of skill to determine whether the cold tank or the hot sand is the better way to cure chronic invalidism. In attempting to make a choice between the two it may be safest to follow the habitual rule when supping with the Sheolistic gentleman who blows hot and cold in the same breath, and use a long spoon.

News of the Week.

Spurious Antitoxin. — It is reported that there is a spurious antitoxin in the market. The Health Department has very properly and promptly determined to institute proceedings against such as can be proven to be offenders.

Appointments of Deputy Coroners.—Dr. Emil W. Hoeber, Coroner-elect, has appointed Dr. John B. Huber Deputy-coroner, with the very commendable view of utilizing autopsical material for pathological study. The choice was made after consultation with several leading physicians. Dr. W. O'Meagher, also Coroner-elect, has appointed, with the same ends in view, Professor James E. Kelly, M.D., well known as a skilful surgeon, a thorough anatomist, and an accomplished pathologist.

Errata in Dr. Cleaves's Article.—On page 718, first column, eighteen lines from the bottom: "There was a rise in the temperature of from 1 to 8 degrees," should read, "of from .1 to .8 degree."

The Death of Dr. Stuart Douglas.—At the seventieth stated meeting of the Society of Alumni of Bellevue Hospital, held at the Hotel Brunswick, Wednesday, December 5, 1894, the following resolution was adopted:

Whereas, In the death of Dr. Stuart Douglas, the Society of Alumni of Bellevue Hospital has lost one of its most esteemed members and friends, whose ability had already brought distinction and gave promise of a brilliant future; therefore, be it

Resolved, That this Society extend to the members of his family their most heartfelt sympathy. And be it further resolved, that this resolution be spread upon the minutes of the Society, and a copy sent to his family and the medical press of New York and Virginia. Matthew D. Field, William E. Studdeford, John M. Brooke, *Committee on Resolutions.*

Examinations for the Public Services.—An esteemed correspondent writes that an item appearing in a recent issue concerning the proportion of successful candidates for the medical staff of the Army and Navy, might convey a wrong impression as to the difficulties of the ex-

aminations. The item was gleaned from the reports of the Surgeon-general of the two services, and of course did not make mention of the previous training of the candidates. Our correspondent states that a large majority of those who succeeded in passing the examinations had studied under teachers who make a specialty of preparing candidates for such examinations; while most of those who failed had made no such special study. The examinations are rigid but fair, and no young graduate who studies faithfully under competent instructors need despair of success.

Edward Henry Van Winkle, M.D., died of paralysis of the heart, at 25 West Ninth Street, last week, aged seventy-nine. Dr. Van Winkle was born in the town of Aquackanorick, N. J. He was graduated from the College of Physicians and Surgeons, and began to practise in 1838. Three years ago he retired.

Opening of a New Hospital for Incurables.—Seton Hospital, at Spuyten Duyvil, was formally opened on December 4th. Twenty years ago Sister Irene, Mother Superior of the New York Foundling Asylum in Sixty-eighth Street, began to raise funds for a hospital for those afflicted with incurable diseases. She is an old woman now, and was unable to attend the opening of the institution, but she had the satisfaction of knowing that her purpose had been accomplished.

The hospital overlooks the Hudson, and is surrounded by spacious grounds. It is named for Mother Seton, the founder of the order of the Sisters of Charity in the United States. The building is of brick, four stories high, 250 feet front, and 200 feet deep. To the east and west there are two wings, each 90 feet deep. The building was begun about three years ago and cost $330,000. All expenses have been met and the hospital opens entirely free from debt. It will be in charge of Sister Mary Dolores, and a board of managers yet to be appointed. The chief of the medical staff will be Dr. J. West Roosevelt.

Tablet to the Memory of Dr. Wells.—A tablet of bronze erected to the memory of Dr. Horace Wells, of Hartford, Conn., was unveiled on December 11th, without ceremony, owing to the inclemency of the weather. It commemorates the fiftieth anniversary of the discovery by Dr. Horace Wells of nitrous oxide gas as an anæsthetic. On December 11, 1844, the late Dr. John M. Riggs, at Dr. Wells's request, administered nitrous oxide gas to him and extracted a tooth without pain. The tablet bears a medallion portrait of Dr. Wells and the inscription:

"To the memory of Horace Wells, the dentist, who upon this spot, December 11, 1844, submitted to a surgical operation, discovered, demonstrated, and proclaimed the blessings of anæsthesia."

Two hundred and fifty dentists in this country contributed to the fund for the tablet. The Connecticut State Dental Society gave a banquet in honor of the event.

A Popular Subscription to Supply the Poor with Diphtheria Antitoxin has been started by the New York *Herald*, which paper subscribes $1,000.

The Elmira Reformatory.—The commission appointed by Governor Flower to investigate the Reformatory has made a majority report in which it is said, as a conclusion: The Elmira Reformatory is not a perfect institution in all respects, as this report indicates. There is room for improvement in some matters that could not properly be covered in this report. As it is organized and conducted, however, it is a model reformatory. Its results have been extraordinary as regards its success in the reformation of criminals. It probably stands pre-eminent among the reformatories of the world. These results are due to the unselfish devotion of the managers, and the extraordinary qualities of Mr. Brockway as an organizer and executive officer, added to his intimate knowledge of the criminal character. The managers are fully justified in the confidence they have reposed in their General Superintendent. Whatever defects we have noticed, as brought out by this investigation, have in no way involved hardship or injustice to any inmate, as far as has been shown by the evidence, except in the single case of Aaron. This case is one among more than 6,000 convicts who have been received at the institution since its establishment. A very few changes, not difficult to effect, and involving but little additional cost, would render this an ideal institution of the kind.

1. The number of inmates should never exceed the number of cells, and the number of cells should not be increased. Doubling up has evident evils to which it is unnecessary to refer. Intelligent and efficient treatment of inmates requires a close study of individual characteristics. We believe that the work of the Reformatory could be better done with a population of 600 than with 1,200.

2. The Reformatory physician should have an assistant, who should reside in the Reformatory, and the medical care and supervision of inmates should be conducted on the lines indicated in the body of this report.

3. Should the administration of corporal punishment be restored, no blows should be given except on the buttocks, except in self-defence or in instances of violent resistance. Very respectfully submitted.

AUSTIN FLINT, ISRAEL T. DEYO,
Commissioners.

A minority report by Judge Learned thinks that punishment was inflicted too often, and criticises the laws regarding the institution. Governor Flower dismisses the charges. On the whole, the general management of the institution has been amply justified.

Progress of Serum Therapy.—A Sero-therapeutic Institute for the east of France is in process of formation. At Amsterdam serum is being prepared by Professor Forster. Various journals, both political and medical, are collecting subscriptions, and considerable sums have already been obtained. In Spain the preparation of serum has been begun in the Municipal Laboratory of Barcelona, under the direction of Dr. Jaime Ferrán. Two horses are being immunized by Drs. Robert amd Llorente. Dr. F. Spät writes to the *Münchener medicinische Wochenschrift* to point out that the germ of "sero-therapy" is to be found in a passage of Pliny which has been overlooked by Sprengel, Haeser, and other historians of medicine. It is well known that Mithridates, the famous King of Pontus (B.C. 124–64) was believed to have made himself proof against poisons, apparently by a system of graduated dosage till tolerance was established. As the

result of his experiments on himself, he is said to have hit upon a kind of universal antidote which was famous in the ancient world under the name of *mithridaticum*. One ingredient in this antidote seems to have been the blood of the Pontic duck, which the King added because that fowl lived on poison (*sanguinem anatum Ponticorum antidotis miscere quoniam venenum viverent.* Pliny, Natural History, Lib. xxv., S. iii., Ed. Harduin, p. 210). In the *Riforma Medica* of October 30th, Dr. Ricardo Agostini calls attention to some experiments on the preventive and curative inoculation of the diphtheria poison, made some thirty five years ago by Dr. Giuseppe Babola, of Santa Margherita di Montagnana. In 1859 that practitioner referred, in the *Gazzetta Medica Italiana*, to two such experiments which might serve as the basis of future researches. He states that he inoculated two healthy girls with membrane taken from the throat of a sister who was seriously ill with the disease, the result being a very mild attack in each case. Some years later he returns to the subject in the same journal, (March 7, 1863). In the same periodical for February 13, 1864, he reported a further series of experiments, for which he claimed fairly successful results, especially as regards the prophylactic effect of the inoculation. His method was to make two or three punctures on the arm with the point of a lancet that had been dipped in diphtheria products removed from a patient's throat with forceps. Babola compares his method with vaccination and the inoculation of syphilis, and attempts to explain its mode of action.

The Index Medicus is to be discontinued.

A Medical Passe-Partout.—The head of the Berlin police has decided on issuing to practitioners in that city what may be translated as a "crowd threader," on the presentation of which all constables will be bound to assist the possessor in making his way through crowds. The privilege is to be applicable to foot doctors only; the carriage-keeping section of the fraternity must make their way by their own unaided efforts, or rather by those of their coachmen.

The Profits of an Amateur Sport.—The expenses of one football team (Yale) for one year (1892) were $15,284.62 and the gross receipts $31,300.71, leaving the net receipts $16,016.09. The net receipts last year were for the same team, $22,914. In 1892 the team paid for drugs, surgical supplies, medical services, and rubbers, $857.89.

St. Francis Hospital, New York.—Dr. John Dorning has been appointed Visiting Physician to the St. Francis Hospital.

Exportation of Live Cattle to Germany.—The German Ambassador at Washington has notified the Secretary of State that, in consequence of the introduction of Texas fever into Germany by means of two shipments from New York, the importation of fresh beef and cattle from the United States to Germany will soon be prohibited. No such disease is reported among recent shipments, however, and it is believed that that is only an excuse, and that the real reason is to retaliate against this country on account of the discrimination against German beet-sugar in the new tariff law.

Obituary.

JOHN MILLS BROWNE, M.D.,

EX-SURGEON-GENERAL UNITED STATES NAVY.

John Mills Browne, Ex-Surgeon General, United States Navy, born in Hinsdale, N. H., May 10, 1831. Graduated at the Medical Department of Harvard University in March, 1852. Appointed from New Hampshire, March 25, 1853; entered the service as Assistant-Surgeon and performed first duty on board the storeship Warren, Lieutenant Commanding Fabius Stanly, at Saucelito, opposite San Francisco; in September, 1854, the Warren, Lieutenant Commanding D. McDougall, proceeded to Mare Island and became the temporary residence of Commander D. G. Farragut, the inaugurator and first commander of the Navy Yard; Medical Officer of the Navy Yard until May 10, 1855; then duty on board Coast-survey steamer Active, Lieutenant Commanding, James Alden; attached to Active until November, 1857; Active employed in surveying the coast and harbors of California, Oregon, and Washington Territories in the winter of 1855–56, with the steamer Massachusetts and the sloop Decatur; Passed Assistant Surgeon, May 12, 1858; brig, Dolphin, Lieutenant Commanding, John N. Maffit, June 1, 1858, Home Squadron off Cape Verde, Cuba, Dolphin captured the brig Echo with over three hundred slaves destined for the Cuban market; Echo sent to Charleston, S. C., subsequently the surviving negroes were taken to Liberia in the frigate Nisagra; October 1, 1858, steamer Atlanta, Commander D. B. Ridgly, Paraguay expedition; December 25, 1858, Hospital Norfolk, Surgeon Ninian Pinkney; May 9, 1859, sloop Constellation, Flag Officer William Inman, Fleet Surgeon Thomas D. Smith, Flag Ship of African Squadron; visited Madeira, Cape de Verde Islands, St. Helena, Liberia, St. Paul de Loanda and other ports and islands along the west coast of Africa; September 25, 1860, at night off Congo River, Constellation captured the bark Cora with seven hundred and five slaves, which was sent to Liberia; commissioned as Surgeon June 19, 1861; December 23, 1861, steam sloop Kearsarge, Commander Charles W. Pickering, special duty coast of Europe; visited Cadiz, Algesiras, Gibraltar, Tangier, Ferrol, Brest, Cherbourg, Boulogne sur-Mer, Calais, Ostend, Flushing, London, Margate, Ramsgate, Deal, Dover, Folkstone, Hastings, Queenstown, Azores, Madeira, Teneriffe; off Cherbourg, June 19, 1864, Kearsarge, commander John A. Winslow, after an engagement of one hour and two minutes, destroyed the rebel steamer Alabama; Kearsarge left Europe in August, 1864, for the Azores, and from thence proceeded to Fernando de Noroha and Las Rocas, off Brazil, in search of the rebel steamer Florida, returned to Barbadoes, thence to St. Thomas, and arrived at Boston November 9, 1864; December 23, 1864, temporary duty Navy Yard, New York; April 29, 1865, Navy Yard, Mare Island; special duty to superintend the erection of the Naval Hospital at Mare Island; duty in charge of the hospital at Mare Island, 1870–71; Fleet Surgeon, Pacific Fleet, 1871–72. Commissioned as Medical Inspector, December 1, 1871; Navy Yard and Naval Hospital, Mare Island, 1873–74; Fleet Surgeon, North Pacific Station, 1874–76; Naval Hospital, Mare Island, 1876–80. Commissioned as Medical Director, October 6, 1878; President of Medical Examining Board, Washington, D. C., 1880–82; Member of Board of Visitors, Naval Academy, Annapolis, Md., 1881; Naval Representative at the International Medical Congress, London, Eng., 1881; duty in charge of Museum of Hygiene, 1882–85; duty on Board of Naval Regulations, 1882; Member of National Board of Health, 1883; Naval Representative at International Medical Congress, Copenhagen, 1884; Member of Retiring Board, 1885–88. Chief of Bureau of Medicine and Surgery, with title of Surgeon General of the Navy, from April 2, 1888, until date of retirement, May 10, 1893.

Reviews and Notices of Books.

THE MEDICAL RECORD VISITING LIST, OR PHYSICIANS' DIARY FOR 1895. 16mo. New York: William Wood & Co.

THE present edition of this very popular Visiting List has been revised to increase the amount of matter calculated to be useful in emergencies. The most important change is in the list of remedies and their maximum doses in both apothecaries' and decimal systems, and the indication of such as are official in the United States of America. The items of essential information which really meet the pressing emergencies of the bedside are so well arranged for ready reference, under appropriate headings, as to occupy but a small amount of space, leaving ample room for the simple and effective record of daily visits, weekly charges, ledger posting, and memoranda. It still retains its convenient pocket size, with suitable flap-cover and pencil-carrier.

THERAPEUTICS: ITS PRINCIPLES AND PRACTICE. By H. C. WOOD, M.D., LL.D., Professor of Materia Medica and Therapeutics, and Clinical Professor of Diseases of the Nervous System, in the University of Pennsylvania. Philadelphia: J. B. Lippincott Company. 1894.

THIS is the ninth edition of Professor Wood's well-known treatise on therapeutics, "a work on medical agencies, drugs, and poisons, with especial reference to the relations between physiology and clinical medicine." There is little that can be said of a standard work, such as this has become, whose popularity is attested by the call for a new edition every two or three years. The present edition has been adapted to the new Pharmacopœia of the United States, all of the new remedies therein admitted, as well as a number of unofficinal drugs, being carefully and adequately discussed. To the few who do not know the work, we can recommend it as one that shares, with Ringer's Therapeutics and a few other classical treatises, the honor of being an indispensable requisite to the therapeutic division of every medical library.

SYLLABUS OF LECTURES ON HUMAN EMBRYOLOGY: An Introduction to the Study of Obstetrics and Gynecology. For Medical Students and Practitioners. With a Glossary of Embryological Terms. By WALTER PORTER MANTON, M.D., Professor of Clinical Gynecology and Lecturer on Obstetrics in the Detroit College of Medicine. 12mo, pp. 126. Philadelphia: The F. A. Davis Co.

THOUGH being, in accordance with its title, only a synoptical outline of the facts of embryology, this little book will be found convenient and useful for the general student. The essentials of the subject are set forth clearly, a useful chapter gives hints as to practical methods of study, and a satisfactory glossary is appended. Interleaved blanks add to the convenience of the book for laboratory use.

MATERIA MEDICA, PHARMACY, PHARMACOLOGY, AND THERAPEUTICS. By W. HALE WHITE, M.D., F.R.C.P. Edited by REYNOLD W. WILCOX, M.A., M.D., LL.D. Second American Edition, thoroughly revised. Philadelphia: P. Blakiston, Son & Co. 1895.

THIS book is presented to the profession entirely remodelled according to the last edition of the Pharmacopœia. It has been especially prepared to adapt itself to the wants of American medical men. It is concise, and still gives clearly all the points anyone cares to know on the newest drugs, their doses, method of application, in short, just what each physician ought to know.

Especially interesting we note the chapters pertaining to prescription writing, doses of drugs, incompatibles, etc.

Besides the carefully written chapters on action of drugs on various organs, we note: 1, Pharmacopœial inorganic materia medica; 2, pharmacopœial organic vegetable materia medica; 3, pharmacopœial animal materia medica. Remedies officinal in B. P.

A great many new drugs have been added to this new edition, *e.g.*, Borium strontium preparations, hydrogen dioxide, etc. We also note additions of various organic drugs, strophanthus, rhamnus, purshiano-aspidosperma, and many others.

The authors are to be congratulated on the rapid appearance of this second edition, and this book well deserves a place in the library of every practitioner.

A PRACTICAL SYSTEM OF STUDYING THE GERMAN LANGUAGE, FOR PHYSICIANS AND MEDICAL STUDENTS. For Self-instruction. By ALBERT PICK, M.D. Newtonville, Mass.: Pick & Tanner. 1893–94.

WE have previously noticed the first six parts of this very practical work for self-instruction in medical German, and need only add that the complete work fully justifies the opinion then expressed, that the method offers to the diligent student a less difficult means than most other self-instructors of acquiring the amount of German necessary for reading books or journal articles written in that language. There is no easy road to German, but this work appears to open up a shorter path than any we have yet seen to the acquirement of that smattering of the language which is all that most of us have the time or the ambition to gain. The separate parts are convenient for carrying in the pocket and studying in the carriage, the street-car, or during long vigils of the night.

A PRACTICAL TREATISE ON NERVOUS EXHAUSTION (NEURASTHENIA). Its Symptoms, Nature, Sequences, Treatment. By GEORGE M. BEARD, A.M., M.D. Edited, with notes and additions, by A. D. ROCKWELL, A.M., M.D. Third edition, enlarged. New York: E. B. Treat. 1894.

THIS well-known treatise, for many years a classic, appears on later reading as interesting and original as when first published. Accepted throughout the thoughtful world as conclusive, the ideas that it embodies are still too little a part of general medical knowledge. The physician who is endeavoring to practise medicine without them is earnestly advised to secure the new edition of this book, and increase his power of usefulness by familiarity with the symptoms and treatment of a very common and distressing disorder. The original text is made still more valuable by Dr. A. D. Rockwell's careful notes and additions, which bring the work well up to date, and offer many practical suggestions.

WHEN ALL THE WOODS ARE GREEN. A Novel. By S. WEIR MITCHELL, M.D., LL.D., Harvard. New York: The Century Co. 1894.

NOT long since a French journal published an elaborate article on medical novelists, the writer of which, with the strange national egotism of most of his race, had seemed to think it needless to mention, if indeed he had ever heard of, any but Frenchmen. He discovered two whose art consisted in weaving into a romance some of the cases of sexual psychopathy collected by v. Krafft-Ebing and others. It is a pity the writer had not seen this delightful story of the Canadian forest, with its incidents of salmon-fishing and love making, for it would have shown him that medical novelists need not treat of medical subjects, but can excel in the field of pure literature without calling in forbidden topics to give their tales a spice. We believe that Dr. Mitchell's fame will rest upon his work as a physician rather than on what he has done in the field of poetry and romance, yet that he well deserves the high rank which he already holds as a poet and novelist no one can gainsay. He has the talent, at least, of giving us living men and women in his tales, and he holds the interest of the reader to the end.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twentieth Annual Meeting, held at Hot Springs, Ark., November 20, 21, 22, and 23, 1894.

FIRST DAY, TUESDAY, NOVEMBER 20TH.

THE Association was called to order by the Chairman of the Committee of Arrangements, Dr. Thomas E. Holland, of Hot Springs. Prayer was offered by Rev. Joseph A. Dickson. An address of welcome on behalf of the State was delivered by Governor George W. Fishback. Hon. W. H. Martin, of Hot Springs, followed with an address of welcome on behalf of the citizens.

The Uses of Medical Societies.—DR. X. C. SCOTT, of Cleveland, O., delivered the presidential address. All medical associations, he said, should be carried on for the purpose of elevating the profession and producing a beneficial influence upon its members, and also that they may meet face to face and thus learn to know each other personally and better. They should elevate personal character, afford protection to professional interests, and advance personal attainments. To be successful the financial affairs of the Association should be conducted with the same careful and rigid supervision that pertains to any private business. He thought the idea of reading all papers before the general body would afford larger audiences, create better and more interesting discussions, and consequently result in greater good to the majority of the members. Since the last meeting some of the States have passed excellent laws governing the practice of medicine, surgery, and midwifery, but he was sorry to note that other States failed in the passage of similar laws.

Some Observations on the Rights and Duties of Medical Witnesses.—HON. W. S. KERR, of Mansfield, O., read a paper with this title. The weight of expert medical evidence depends upon two qualities—first, the skill, learning, and experience of the witness, and, second, his honesty. The latter quality can be and should be alike in all. The former, in the nature of things, must vary and differ in degrees almost infinite in number. The evidence of an expert should be compensated for, commensurate with its value. In criminal cases the amount should be fixed by the court, in civil by agreement between the expert and the party calling him. The medical expert should never have his opinions for sale.

Bone and Joint Tuberculosis, the Future Field of Litigation against Railways.—This paper was read by DR. EMORY LANPHEAR, of St. Louis, Mo. The author submitted the following conclusions: 1. Most chronic joint affections are tuberculous; "scrofula" has no existence, being but an attenuated tuberculosis. 2. The family history is unimportant, as tuberculosis is always acquired, never inherited. The presence of tuberculosis in the family simply gives a better opportunity for infection. 3. Infection may occur very early in life, but the germs may lie dormant for many years in the lymph-glands, and local tuberculosis develop only after an accident. 4. An injury to a bone or joint must be slight in order to cause tuberculosis. If severe, the resultant inflammation is not favorable to the proliferation of the bacilli. 5. An injury alone can never produce tuberculosis. The bacillus must always be present in the system, or introduced into a wound at the site of injury. 6. *Per contra*, bone or joint tuberculosis would never develop without a slight local injury. 7. If after a railroad accident, falls, wrenches, or other accidents may have possibly occurred, the local trouble may be due to them as well as to the railway injury. There must be a direct sequence to attribute the disease to the local injury.

Enlargement of the Heart without Valvular Disease.—DR. ROBERT H. BABCOCK, of Chicago, read a paper on this subject. The author said that idiopathic enlargement of the heart, as Fraentzel designates it, affecting primarily the left ventricle, is due primarily to prolonged high arterial tension, and this increase of arterial tension may be secondary to a cirrhosis of the kidneys, chronic arterio-sclerosis, congenital narrowing of the arterial system, and some obscure condition probably dependent upon defective assimilation and elimination, which is not fully understood, connected probably with the circulation of toxines in the blood. Prolonged high arterial tension he considered the chief factor concerned in the production of this form of enlargement of the heart. The enlargement may involve either the right or the left side of the heart, or both. Prolonged high arterial tension, when independent of organic disease of the kidneys or blood-vessels, seems to be due to what the Germans call *luxus consumption*. It is observed in individuals who belong to the better class, who are more or less sedentary in occupation, who are hearty feeders, and oftentimes great diners-out. The treatment was divided into, first, the treatment of the stage of loss of compensation, in which the heart is at first broken down in its resistance. Rest is the important factor, along with cardiac stimulants and the administration of remedies calculated to decrease the high arterial tension. Digitalis, strophanthus, and their congeners are not suitable to the cases in the stage of loss of compensation, since the effect of digitalis, and to a less degree strophanthus, is to increase the resistance within the arterial system, and thereby increase the strain, already too much for the impaired right ventricle. It is preferable to administer an arterial stimulant rather than one of the so called cardiac tonics. Under the effect of rest and cardiac stimulants improvement in the condition is generally manifested speedily.

The author then referred to the Schott method of treating these cases, which consists of baths and gymnastic exercises.

Malaria a Water-borne Disease, was the title of a paper read by Dr. W. H. DALY, of Pittsburg. The author said, in summing up the evidence in a given case of so-called malaria, it is important to remember that the water-vehicles of malaria may include contaminated land water, taken into the stomach on the stalks of celery or on the leaves of lettuce, or it may find its vehicle in the rinsing of milk cans with malaria water, or in the adulteration of milk with contaminated water containing the Laveran germ; the cistern water stored under the earth may be easily contaminated by the earth water containing the germ, if the cistern itself is cracked or otherwise inefficient. The author defined his position on this question by quoting from an article published in the MEDICAL RECORD of September 15, 1894.

The Influence of Early Treatment on the Late Manifestations of Syphilis.—DR. A. RAVOGLI, of Cincinnati, said that syphilis must be seriously treated. Mercury is the true antitoxin for this disease. It is necessary in instituting treatment, to take under consideration the general condition of the patient, his habits, his general health, his surroundings, etc., which have great influence in the toleration of the medicine. The author believes that early, well-directed treatment of syphilis will prevent tertiary symptoms. Mercury can be administered either by the stomach, by subcutaneous injections, by inunctions, or by baths. The selection of the method should rest on the good judgment of the physician.

SECOND DAY, WEDNESDAY, NOVEMBER 21ST.

Intestinal Indigestion. — DR. A. P. BUCHMAN, of Fort Wayne, Ind., read a paper on this subject. He said that intestinal putrefaction is, in its incipient stages, not due to a pathological condition of the tube below the stomach and duodenum, but is dependent solely upon errors of gastric and pyloric digestive processes. Excess of food ingested will universally induce such putrefactive processes, which in infancy and childhood are exhibited in the bowel diseases of early life, and can

with reasonable certainty be differentiated from deflections by other causes, by the odor and appearance of the dejecta. The toxic elements generated in this process, sooner or later, render glandular and cell environments of the intestinal tube unhealthful. The air patients breathe, the water they drink, and the food they eat, are charged with a miasm which absolutely forbids a healthy reaction, hence most complicated and decidedly serious pathological conditions arise. Another chief source of intestinal indigestion arises from the inability of the tube below the pylorus to successfully cope with the relatively enormous quantities of carbohydrates and hydrocarbons that are daily and continually ingested. The second and third stages of intestinal indigestion were then dwelt upon. Colon baths properly medicated are very useful in the general treatment and care of patients suffering with intestinal indigestion.

Abortion of Typhoid Fever.—Dr. J. E. Woodbridge, of Youngstown, O., read a paper in which he gave his experience during the past year in support of his theory.

The Importance of Urinalysis in Diagnosis.—Dr. A. B. Walker, of Canton, O., held that no opinion of a case of any importance should be given without there having been made a careful examination of the urine. He believed many a case of Bright's disease might be prevented, if, when the first symptoms of the disease manifest themselves, a careful examination of the urine were made, and the proper treatment and diet prescribed. An interesting case was cited in point.

Physicians' Prescriptions.—Dr. Starling Loving, of Columbus, O., read a paper with this title, in which he alluded to the difficulties which young practitioners encounter when they essay their first prescription. He said we seldom read of mishaps from defectively written prescriptions in England, Germany, or France, where prescription writing is more extensively and systematically taught. Sufficient attention is not always given in this country to compatibilities, chemical and therapeutic, to solubilities, the influences of light, temperature, air, and of other circumstances affecting the condition of drugs and chemicals. Many failures in treatment and many accidents, some serious in character, result from carelessness or want of accuracy in the directions given to nurses and patients for the administration of medicines after they have been brought ready for use.

Poisons.—Dr. William F. Barclay, of Pittsburg, followed with a paper on toxics. Toxics enter the circulation, and their action on the normal cells produces toxines, and the multiplication of these products brings on pathological conditions. Nothing is more easily demonstrated than that the emunctories throw off toxics. We observe at once, upon the entrance of a toxic into the circulation, that all the functions of the body are impaired to a greater or less degree, and the vital forces are at once disturbed or arrested. Primarily the circulation, and secondarily the nervous system, are impaired, and shock is superinduced. In the stage of shock nature seems intent upon relieving herself of all effete matter by the discharge of the contents of each viscus of the body. All such efforts should be assisted by artificial means.

Quinine in the Treatment of Chorea.—Drs. Frank R. Fry, and M. A. Bliss, of St. Louis, briefly reviewed Professor H. C. Wood's theory that chorea is due to disturbances in the spinal inhibitory apparatus, and the suggestion derived from it, that inasmuch as quinine had been found physiologically to stimulate spinal inhibition in animals, the drug be given to patients affected with chorea. The writers recited a number of their own cases from clinic and private practice, in the treatment of which they have been using quinine, and their results confirm those of Dr. Wood and others. They called attention to the fact that they have not used as large doses as others, yet had very satisfactory results. They suggest that this drug has a decided value in the treatment of certain infectious diseases, in which class, according to the opinion of some authorities, chorea belongs.

Reflex Irritation as a Cause of Disease.—Dr. Edwin Walker, of Evansville, Ind., said that no error in modern times has had such a tenacious hold on the professional mind as that of reflex irritation as a cause of nervous disease. The speaker said that he had never seen a case of epilepsy, insanity, catalepsy, hysteria, or grave neurasthenia, nor any organic disease of the nervous system cured, or even permanently benefited, by any operation on the genital tract, done either by himself or anyone else.

Third Day, Thursday, November 22d.

The Mental Symptoms of Cerebral Syphilis.—Dr. Frank P. Norbury, of Jacksonville, Ill., read a paper with this title, of which the following were the conclusions: 1. Somnambulism and allied states, lapses of intelligent conceptions with associated loss of memory, are mental symptoms of cerebral syphilis. 2. Sudden somnolence with ocular spasm or paralysis points to syphilis; when preceded with headache and monoplegia, is almost pathognomonic. Headache, quasi-periodical, as defined by Gray, with marked insomnia, suddenly ceasing and followed by psychical disturbance is due to syphilis. 3. Melancholia or mania, when following periodical headaches, insomnia, and somnolence (*a*) with ocular spasm or other form of monoplegia or heterogeneous paralysis, is due to syphilis. (*b*) Pseudo-paranoia. By this he means cases presenting all symptoms of paranoia, systematized delusions depending on hallucinations of sight, hearing, taste, or smell, with slight impairment of general mental functions, is due to syphilis, as we know that syphilis causes isolated local losses of power, and it is noteworthy when the special senses are involved that mental derangement usually results. (*c*) Pseudo-paresis, characterized by fibrillary tremor of tongue, indistinct speech (partial or complete aphasia), uncertain and trembling gait, with delusions of grandeur and occasional outbursts of maniacal excitement, pupillary involvement, all characteristic symptoms of paresis, but which yield readily to antisyphilitic treatment, we can say it was due to syphilis. 4. Class four have had epileptiform and apoplectiform attacks. We find cases in which treatment was undertaken too late. The symptoms are those of terminal dementia, only occurring in patients of previous sound mental condition and with no special hereditary history.

The Surgical Treatment of Injuries of the Head.—Dr. Charles B. Parker, of Cleveland, O., contributed a paper on this subject, of which the following were the conclusions: 1. In a case of doubt as to the character of a head injury, explore by incision, if necessary. 2. In the case of wounds, especially the smaller and punctured, enlarge them for exploration and cleansing. 3. In all cases of fracture, depressed or fissured, operate, elevating the depression and exploring the fissure for a depression of the inner table, which so often occurs. 4. Leave principal fragments of bone after elevation, if surgically clean, even if entirely detached from the dura mater and pericranium, thus averting cerebral hernia, vertigo, and other cerebral disturbances. 5. All these operative measures should be conducted under the most rigid aseptic and antiseptic measures.

Traumatic Lesions of Cranium and Brain.—Dr. George N. Lowe, of Randall, Kan., reported four interesting cases. The first case was one of depressed comminuted fracture of the right parietal bone at the junction of the temporal bone, caused by the kick of a horse. There was also a contused lacerated wound of all the soft tissues along the entire ramus of the left inferior maxillary. In this case the author trephined and elevated the depressed comminuted bone fragments. Recovery.

Castration for Hypertrophied Prostate.—Dr. B. Merrill Ricketts, of Cincinnati, reported a case of castration for hypertrophied prostate. The arteries were twisted, the wound closed, and integument coapted with a continuous silkworm-gut suture. The patient rallied

well from the chloroform and suffered no inconvenience or pain thereafter. The wound was examined on the fourth day and primary union was found to have taken place. The patient left the hospital at the end of the sixth day. On the second day after the operation he said that he could urinate with greater ease, and that the pain was slight; that he could sleep four hours at a time during the night, whereas formerly he had been getting up once every hour.

Tumor Albus of the Knee-joint.—This paper was read by Dr. William E. Wirt, of Cleveland, O. The author classified the treatment under the two headings of constitutional and local measures, and the local under the subdivisions of conservative and operative treatment. The author first considered constitutional treatment, and then the local treatment, which he divided into the conservative and operative. The conservative measures to be carried out in the treatment of this affection are counter-irritation and local applications, fixation, protection, rest, and correction of deformity. These were considered under their respective heads.

Resection of the Knee for Separation of the Lower Epiphysis of the Femur.—Dr. A. H. Meisenbach, of St. Louis, said separation of the epiphysis is a condition that may occur either on account of trauma or disease. There seems to be a difference of opinion by writers as to the frequency of its occurrence, especially as the result of trauma. Traumatic separation of the lower end of the femur occurs in about from one-fifth to one-third of all the reported cases, and in the majority of instances previous to the sixteenth year, seldom later. The forces that are necessary to produce this separation are various. Thus during childbirth traction may produce it. Volkmann states that he has produced it when the hip is diseased, when making rotation in seeking for crepitation, or extension in the application of plaster-of-Paris dressings.

Other forces are indirect external violence, usually of a twisting character, or lateral, or at right angles to the axis of the limb. The readiness with which the dislocation of the separated diaphysis into the popliteal space occurs can be explained: 1, on account of the anatomical structures of the surrounding parts; 2, the force and position of the patient, the popliteal space being in the direction of least resistance, while on the anterior aspect we have the quadriceps tendon, the patella, and the ligamentum patellæ. The occurrence of pathological separation of the epiphyses is regarded by the latest writers on surgical pathology and diseases of the bones, as a not infrequent accident in diseases of the bones and joints. It is noted in osteomyelitis of the long bones.

Hydrocele —Dr. W. C. Weber, of Cleveland, O., read a paper on this subject. He first dwelt upon the anatomy of the testis, and then alluded to congenital and acquired hydrocele. The congenital form results from an imperfect closure between the cavities of the tunica vaginalis and the peritoneum. Acquired hydrocele occurs in children, and most frequently in early adult life. Its cause is not always known, though traumatism is probably the most constant factor in its production. In a hydrocele of small or ordinary size, the date of its origin being recent, an evacuation by means of a small trocar and cannula may be all that is necessary to accomplish a cure. Should this fail in its purpose, it becomes necessary to adopt measures whereby sufficient irritation of the tunica vaginalis may be produced to secure inflammatory adhesions of the opposing surfaces. This end is usually attained by the injection of tincture of iodine, alcohol, carbolic acid, perchloride of iron, and other substances into the sac after the removal of its adventitious contents. Among other methods of treatment may be mentioned excision, incision, and the seton. The author reported a case in which he used carbolic acid, which illustrated very nicely what can be done in the way of radical treatment in apparently extreme cases. The result was very satisfactory.

Treatment of Traumatic Cataract Attended with Rapid Swelling of the Lens.—Dr. James M. Ball, of St. Louis, Mo., held that in cases of traumatic cataract with rapid increase of intra ocular tension, an operation should be performed, and it should not be linear extraction, but an extraction made with the Graefe knife, and with the incision located in the cornec-scleral junction. The knife should cut from one-third to twc-fifths of the corneal circumference, according to the extent to which the softening process in the lens has advanced. If glaucomatous symptoms supervene with softening of only a small part of the lens, the corneal incision should be large. If the softening involve the whole of the lens, the incision should be of less extent. The chief merit of the operation lies in the avoidance of the valve which is produced by the linear method. In other words, the author's method permits of free evacuation of all the lenticular substance with the least amount of traumatism. An iridectomy is not made. All débris is removed at once. This cannot be accomplished by the linear method.

Some Observations on Sore Throat Due to Concretions in the Tonsils.—Dr. Lewis C. Cline, of Indianapolis, Ind., read a paper in which he said that every experienced practitioner could recall cases of recurring tonsillitis or sore throat that often developed without any apparent cause, but which were doubtless due to chronic inflammation of the follicles, altered and retained secretions. It was to this class of cases that the essayist invited attention. His remarks dealt more particularly with the cheesy bodies, and not the calculi, which are probably the outgrowth of the long retained cheesy deposits acting as a nidus for the deposit of the more solid materials, as phosphate and carbonate of lime, iron, soda, and potassa, etc. These concretions are doubtless the result of a catarrhal condition of the mucous lining of the follicles, often coupled with a uric acid diathesis. Some writers believe them to be parasitic in origin. They predispose to attacks of quinsy, and in the author's judgment are the cause of the majority of these cases, and they can be permanently cured by carefully searching for and destroying all the crypts and pockets in which these bodies are formed. The author reported several interesting cases, and closed by stating that perverted secretions of the follicles of the tonsils from catarrhal inflammation resulting in cheesy concretions were the cause of more sore throats and quinsy in adults than any or all other causes combined.

Fourth Day, Friday, November 23d.

The Removal of the Auditory Ossicles for the Relief of Chronic Deafness and Other Abnormal Conditions.—Dr. Robert C. Heflebower, of Cincinnati, contributed a paper with this title, of which the following were the conclusions: 1. No bad results attend the excision of the malleus and the incus, but removal of the stapes is not without the most serious danger, both to life and hearing. 2. That the removal of the malleus and incus alone is far preferable to the removal of the stapes. 3. The operation is of extreme service in chronic suppuration in suitable cases, frequently avoiding mastoid and other serious disturbances of an equally serious nature. 4. It should be performed in cases where there is a high perforation, or where the membrana flaccida is perforated, and where the ossicles are necrotic. 5. Tinnitus, headaches of ear origin, and vertigo are relieved. 6. In suitable cases it is invaluable for relieving deafness, whether from chronic suppuration or from chronic catarrh and sclerosis.

Circumcision.—Dr. Bransford Lewis, of St. Louis, Mo., read a paper on this subject in which he detailed a method of performing that operation, for which he claimed many advantages. The operation was done with the assistance of two instruments, a clamp and prepuce tractor, which enabled the operator to carry out the following

steps of procedure: 1. The prepuce is drawn strongly forward, the traction being applied to its inner surface by means of the serrated tractor mentioned. 2. The glans penis being repressed, the curved, fenestrated clamp is applied. 3. With these as a support and guide, ten per cent. cocaine solution is injected between the two layers of foreskin, anterior to the clamp. 4. After effective anæsthesia has been secured, six double length (ten inch) catgut sutures are run clear through the clamp-fenestra and the four layers of foreskin. 5. With strong scissors the latter is cut off at one sweep. 6. Tractor and clamp being removed, the double-length sutures being divided, two additional sutures are placed at the dorsal and frenal sites, previously occupied by the tractor. 7. The vessels are secured and sutures tied all around.

The Treatment and Management of Corporeal Endometritis was the title of a paper read by Dr. William H. Humiston, of Cleveland, O., in which the author said that nine-tenths of all cases that he treats suffer from some form of endometritis, and its baleful influence on the sympathetic nervous system is marked and manifested by numerous and varied symptoms.

The first and important principle in treatment is to relieve the passive congestion of the uterus, and this is accomplished by medicated tampons. The first tampon should be medicated with boro-glyceride, iodo-glycerine, or ichthyol-glycerine, and supported by sterilized, non-absorbent cotton tampons. The septic cases must be treated on modern surgical principles — rest, asepsis, drainage, and curetting. When the cases are diagnosed early and the proper treatment instituted, the author says the abdominal surgeon will not have his belt hanging full of suppurating tubes and ovaries.

The Relation of Residual Urine to Vesical Irritation.—Dr. G. Frank Lydston, of Chicago, contributed a paper with this title. He said it is generally accepted that most of the symptomatic disturbances incidental to certain chronic bladder diseases, especially in cases of prostatic enlargement, are dependent upon the accumulation of residual urine. The author has long been impressed with the idea that residual urine *per se* is not as important a factor in genito-urinary irritation as is or dinarily believed. He is satisfied that in a large proportion of adult males there is always a greater or less residuum of urine remaining in the bladder after micturition. If prostatic enlargement or other obstruction attacking the mouth of the bladder develop, we have the typical accumulation of residual urine characteristic of such cases. It will then be seen that there may be, at varying periods of life, extreme differences in the degree of accumulation of residual urine. The author believes that the residual urine is simply an incident upon which, if taken alone, the symptoms of vesical irritation in no wise depend. Ideally perfect drainage of the bas-fond can only be accomplished by thorough drainage from above the tube through the trigone and out of the rectum. There were certain objections to this method which the author said it was not necessary to dilate upon. He simply stated as his opinion that only by some such procedure can the bas-fond be thoroughly drained.

Laparotomy for Pelvic Diseases is no Longer a Necessity.—This paper was contributed by Dr. R. Stansbury Sutton, of Pittsburg. The assertion found in the text of the paper was founded upon the following argument: 1. We have a substitute for laparotomy in total extirpation of the uterus and appendages by the vagina, either with or without morcellement. 2. The operation has already been proven to be effectual and successful by many in Europe and in the United States. 3. Total extirpation of the uterus and appendages per vaginam gives a lower mortality than laparotomy for the removal of the appendages alone. Morcellement of small fibroid tumors gives a lower mortality than laparotomy for the removal of similar tumors. 4. These operations by the vagina shorten the convalescence of patients, who are out of bed on the seventh day. 5. In all cases of gonorrhœal, tubercular, or other infectious type of endometritis with chronic salpingitis and chronic ovaritis, a cure is not effected save by total extirpation of the uterus and appendages. The vaginal route is the best. 6. In all cases of fibroid tumors of the uterus, not reaching above or quite to the umbilicus, when the uterus must be sacrificed, total extirpation of the organ, tumor, and appendages by morcellement can be best effected through the vagina. 7. Small cysts of the ovary or broad ligament, or solid tumors of the ovary can be reached and, by morcellement and puncture, be removed through the vault of the vagina, leaving the uterus and opposite ovary and tube intact. 8. In all cases of pyosalpinx or of multiple pus centres, with coexisting solidification of the pelvic roof, total extirpation by morcellement per vaginam is the only feasible operation, and it cures the patient. 9. Total extirpation per vaginam is followed by a cure in the greatest majority of cases, as compared with laparotomy. 10. The following sequelæ after laparotomies do not occur after total extirpation by the vagina: cancer of the uterus, adenoma of the uterus, tuberculosis of the uterus, gonorrhœal infection, hemorrhages of the uterus, filthy catarrhal discharges from the uterus, ventral hernia, fecal and other fistulas, the mark of a wound on the abdomen. The nerve-storms subsequent to total extirpation are not as great as after laparotomy. The patient is restored to perfect health. This is not the case in more than fifty per cent. of laparotomies for pelvic diseases. 11. The bacteriology of infectious diseases demands removal of the uterus with the appendages. 12. Total extirpation by the vagina is in strict conformity to anatomical relations. 13. The physiological results following total extirpation are free from jarrings, and the patient is functionally a smoothly running mechanism. 14. Laparotomy for these diseases is followed by all manner of physiological disturbances which affect the vascular, muscular, nervous, and digestive systems. 15. In the face of this argument, laparotomy for pelvic disease is no longer a necessity, but in the author's opinion should be abandoned excepting in very rare instances, indeed.

Modern Surgical Technique.—Dr. Henry O. Marcy, of Boston, emphasizes the importance of a most careful bacteriological training on the part of him who would become proficient in surgical practice. In the preparation of the operating-room, Dr. Marcy pointed out the ease and safety with which an ordinary living-room, by preference the kitchen, is made comparatively sterile, when from necessity the surgeon is called upon to act promptly and suddenly. In abdominal wounds, where irrigation is not advised, he substitutes for it a slowly flowing stream of oxygen gas from a compressed cylinder. This sterile gas is heavier than atmospheric air which it displaces, and as a consequence renders the wound less likely to infection from the products of respiration and atmospheric contamination. Dr. Marcy reiterated his well-known views upon the value of tendon sutures, buried in all aseptic wounds for the approximation and reinforcement of the structures, emphasizing the importance of abandoning the drainage-tube in all aseptic wounds, and hermetically sealing of the same with iodoform collodion. Aseptic wounds made in aseptic structures aseptically closed, and sealed, are always followed by primary union.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. W. H. Wishard, of Indianapolis: *First Vice-President*, Dr. Thomas E. Holland, of Hot Springs; *Second Vice-President*, Dr. Charles B. Parker, of Cleveland; *Secretary*, Dr. Frederick C. Woodburn, of Indianapolis; *Treasurer*, Dr. Harold N. Moyer, of Chicago.

The next meeting will be held in Detroit, Mich., September, 1895. Chairman of Committee of Arrangements, Dr. H. O. Walker, of Detroit.

Dr. William P. Overton, president of the Queens County Medical Society, died recently at his home in Cold Spring Harbor, L. I.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, November 12, 1894.

W. W. Van Arsdale, M.D., Chairman pro tem.

Lead-pencil in Axilla Mistaken for Fracture of Clavicle.—Dr. Sinclair Tousey presented a young man who, prior to the time when he saw him, had been going around for about six weeks with a broken lead-pencil, four inches long, in the axilla, which had been mistaken at different hospitals for fractured clavicle. At one of the larger hospitals an abscess had been opened under ether, but it was decided to wait until the supposed fragment of clavicle had separated before an attempt should be made to remove it. When Dr. Tousey saw the patient the probe introduced into one of the sinuses came in contact with a substance which felt like bone, and as it was quite movable he administered an anæsthetic and took out what proved to be a piece of lead-pencil. The patient then remembered that it must have entered when he slid down a lamp-post and caught the pocket containing the pencil on a projection. What appeared to be a scratch marked the point of entrance.

Dr. Francis H. Markoe had seen a somewhat similar case, the accident occurring at the elbow. A door had shut as the patient was passing through, striking her arm and shawl. She consulted Dr. Markoe next morning on account of pain. He found no bruise, no abrasion, no fracture, but a hard body could be felt lying across the elbow-joint. Under ether a long shawl-pin was extracted. It had felt much like a bony fragment.

Carcinoma of Transverse Colon; Excision; End-to-end Anastomosis with Murphy's Button.—Dr. H. Lilienthal presented a strong-looking man, of middle age, who prior to the time he first saw him, in May, had been ill fourteen months, with variable pains in the abdomen, paræsthesia, gurglings, marked emaciation. In May a tumor could be felt, the size of a large egg, apparently in the transverse colon. Its location was confirmed by an operation. It was removed, with about four inches of the gut, and the divided ends were united by a Murphy button of very large size, so large that it was of tight fit and caused some fear that it might not come away safely. As it had not passed on the eighteenth day, he had gentle massage made over the abdomen from right to left and an enema given. Soon afterward the button passed, and a little blood with it. The patient had been given solid food from the sixth day. Some of the mesenteric glands were found enlarged, and a relapse was to be expected, although at present the patient was in good condition. The tumor was cancer.

The danger of using too large a button was shown in a second fatal case. The woman had a fecal fistula which had led him to make an artificial anus, and subsequently she had submitted to laparotomy seven times at the hands of different surgeons. As she wished the artificial anus closed, Dr. Lilienthal made use of the Murphy button to establish end-to-end anastomosis and then closed the wound. The gut below was much atrophied, and the button proved a tight fit, so tight indeed that it led to gangrene and death, the button having partly passed out along with fæces into the peritoneal cavity. In a third case he hesitated, but the patient insisted on having his artificial anus closed. After the experience with the second case Dr. Lilienthal used a button a quarter of an inch less in diameter, and did not at once close the artificial anus, but introduced a strip of gauze drain down to the lower segment of gut, which, as in the other case, was atrophied. This patient got through all right, the button being passed on the sixth day. Dr. Lilienthal thought there was more danger from sepsis in anastomosis for closure of artificial anus than in other forms of intestinal resection because of the difficulty of cleansing the wound thoroughly in the former, whereas Dr. Van Arsdale, during the discussion, expressed surprise at this statement, since he believed operations for closure of artificial anus gave the best results.

Dr. Willy Meyer thought the button shown was enormous, and that if we would follow the directions given by Dr. Murphy, using only the sizes which he had indicated, and made in the manner which he had described, our results would be equally satisfactory. The button should always be at hand on going to laparotomy cases.

Dr. Van Arsdale had had a case of gastro-enterostomy go wrong in spite of the button, the man dying of inanition; nothing—no gangrene—found at the site of the button to account for death.

Dr. Lilienthal said this sized button had been made by instruction of Dr. Gerster. It was, however, too large except for anastomosis of the rectum, and there even a larger one would be required if one would avoid forming a constriction in the ampulla.

Case of Ideal Cholecystotomy.—Dr. C. L. Gibson presented seven gall-stones, as large as hazel-nuts, removed from the gall-bladder and duct at a single operation. Vague gastric symptoms had existed several months before the patient entered the hospital. A tumor was felt in the region of the right kidney, and was thought to be cystic kidney, the mistake clearing up only on exploratory operation, when it was found to be the distended gall-bladder. Convalescence had been uneventful.

Dr. Dawbarn said that about the time when the Murphy button was first used in New York he sent to Chicago and got one which he used in a case of gall-stone, the diagnosis having been confirmed by the operation. The gall-bladder seemed remarkably friable, and at autopsy—death having occurred in forty-eight hours—a distinct tear was found at the edge of the button. There was also a diffuse form of cancer of the liver, and this had probably led to the friable condition of the gall-bladder, although this viscus was not carcinomatous. He had sent an account of the case to Dr. Murphy before the latter had reported a collection of one hundred successful cases, and had afterward written Dr. Murphy to learn why this fatal one had been omitted. The answer was that he did not suppose the author of the case would care to have it reported since it was unsuccessful, and also because it was an attempt to unite a cancerous gall-bladder with the duodenum, which was not true.

Resection of Rectum for Malignant Growth; Persistent Neuralgia in Scar.—Dr. Van Arsdale presented a man, fifty-four years of age, about six inches of whose rectum he had excised through the sacrum, for carcinoma, in 1892. The proximal end of the gut was drawn down and sutured to the anus, a secondary operation was done the same summer, and in March, 1894, two small carcinomatous nodules were removed from the rectal mucous membrane. Since then the man had been in good health, and had control over the bowel. Advice was asked with regard to the relief of pain which existed along the line of union between mucous membrane and skin.

Case of Volvulus of the Sigmoid Flexure, with Comments.—Dr. Francis H. Markoe said it had been his intention to present a paper on intestinal obstruction, based on sixteen cases which had come under his observation, but for lack of time he limited himself on this occasion to a recent one of volvulus of the sigmoid flexure, with comments. The man had had symptoms of intestinal obstruction about eleven days before he was brought to Bellevue, where Dr. Markoe saw him, there having been no passages since the third day. He found the abdomen much distended, especially on the right side. High rectal injection was made in the knee-chest position, but nothing came away. He then opened the abdomen and found a loop of the large gut completely turned upon itself and greatly distended with gas. This was gently untwisted after letting out the gas. An ecchymotic spot, the size of a silver dollar, was found and the loop was secured at the bottom of the wound by a gauze strip

passed through mesentery. There was no evidence of congenital or acquired stenosis. The patient improved steadily for four days, and on the night of the fourth day had several passages in response to small doses of calomel. On the fifth day he suddenly collapsed, colotomy was performed in the attached loop, but he died soon afterward from perforation at the ecchymotic spot, which had become gangrenous. Dr. Markoe asked discussion on how to prevent recurrence.

Dr. De Garmo inquired whether the gangrene took place at the point of puncture for letting out gas. He had observed tendency to gangrene even after puncture with very small trocar.

Dr. Markoe thought the question a pertinent one, but in this instance the gangrene had occurred at the point of doubtful vitality, a little above the puncture.

An Improved Method of Radical Operation for Carcinoma of the Breast.—Dr. Willy Meyer read the paper. See page 746.

Dr. H. J. Boldt said he had not removed the breast in one mass as described in the paper, but in two cases he had performed the operation as radically, removing muscle. One patient had died. The other, who was operated upon two months ago, could not use the arm as well as before, and had some interference with the circulation. He did not doubt the superiority of removing all that it was intended to remove in one piece.

The Axillary Operation Needless.—Dr. Thomas H. Manley said that according to his own experience it was entirely needless to go up into the axilla in removal of cancerous breast. Going down to the pectoral muscle increased the danger to life—danger of injuring the axillary vessels and brachial plexus. When the parts were closed in, the scar held the arm down and interfered with the circulation in the axilla. Moreover, the theory on which such extensive removal was based, that cancer was a local disease, had not been proven. He remembered a statement made by the elder Markoe, some years ago, when removal of the axillary glands was coming into vogue. Dr. Markoe had said he did not believe in it, for the axillary enlargement was only due to tumefaction, and this went down as predicted, in the case on which he was operating, after he had removed the diseased breast. Unless it were in special cases, Dr. Manley did not think such extensive dissection as had been described by Dr. Meyer was necessary.

The Axillary Operation Imperative.—All the remainder of the speakers took pains to combat Dr. Manley's view, that removal up into the axilla was not necessary. Even where no infiltration in the axillary glands had been apparent, microscopic examination had shown the presence of cancer cells. The statistics of cures had been much better after the more radical excision than previously. All thought well of Dr. Meyer's procedure, some claimed to have been in the habit of removing muscle along with the gland tissue, and the question of priority was raised even as to removal in bulk, commencing in the axilla. The speakers were Drs. Dawbarn, Gallant, Morris, Fowler, Lloyd, Van Arsdale, Meyer. Dr. Francis H. Markoe said that in a recent conversation with his father the latter had admitted the superiority of the radical operation as having been proven by recent statistics.

The Tenement-house Commission appointed by Governor Flower last spring, in accordance with a bill passed by both houses of the Legislature, find that a new list of more than five thousand houses require especial investigation. They further find that three-fourths of this city's population live in tenements. Of course a large deduction may be made in favor of high-class flats and apartment-houses, but the law does not discriminate between Fifth Avenue and Chrystie Street. Three or more families constitute a tenement according to the legal definition.

Correspondence.

OUR LONDON LETTER.

GLADSTONE ON CLARK—DRUGGIST APOTHECARIES AND SIR B W. RICHARDSON—THE MARYLEBONE EPIDEMIC—TESTIMONIALS—LISTER — HUGHLINGS JACKSON — WALTER RIVINGTON—MEMORIAL TO BEAVEN RAKE—DEATHS OF ALBERT NAPPER AND SURGEON GENERAL FRASER—MEDICAL COUNCIL — SMALL-POX — DIPHTHERIA AND ANTITOXIN — CLINICAL EVENINGS AT THE SOCIETIES — INTERESTING EXHIBITS AT THE MEDICAL AND CLINICAL SOCIETIES—OPENING THE CÆCUM—LARGE CALCULUS—HEREDITARY SYPHILIS—CRETINS—RUPTURED NECK OF BLADDER—EXCISION OF SCAPULA—EXTENSIVE TUBERCULOSIS OF PERINEUM, PROSTATE, AND RECTUM—TREPHINING FOR EPILEPSY—CURIOUS NODULES, ETC.—MEDICAL DEPUTATION TO THE HOME SECRETARY—MARRIED WOMEN AND FACTORY WORK — DEATH CERTIFICATION — MASSAGE SCANDALS — LONDON DEATH RATE — PUBLIC HEALTH—DEATH OF DR. DICKSON, R. N.

London, November 24, 1894.

I HEAR that Mr. Gladstone is about giving to one of your American magazines some reminiscences of his late friend Sir Andrew Clark. This reminds me that the considerable fortune left by the respectable medical baronet has given rise to much gossip as to its origin. It is not infrequently said that the sum was accumulated from practice, and as it exceeded £200,000, that is enough to make any physician's mouth water. I happen to know, however, on the best authority—Sir Andrew's own—that he was careful and fortunate as to investments, and to them we must attribute a considerable share in the accumulation. A daily newspaper has lately discussed the "Fortunes Left by Doctors," but without affording any important information.

Sir B. W. Richardson has returned in his last *Asclepiad* to his proposal to legalize druggists as counter-prescribers. He would have an order of "pharmaceutical apothecaries" to occupy itself with inferior practice as well as dispensing, and pretends that such an order would quickly accept medical etiquette and submit to the rule of their professional superiors. It is a pity that, with all his abilities, Sir Benjamin should have such self-consciousness as to fancy he has only to speak to settle any difficulty. It is a wonder that his love of admiration did not prompt him to drop his proposal when he saw how unpopular it was. But he has spoken and seems to think that is enough. He will perhaps yet see his error. The idea of relieving the overcrowding and resulting degradation of the profession by flooding it with unqualified practitioners, is original enough, and worthy of the fertile fancy of the *Asclepiad*. Why does he not also offer to take in our sanitary inspectors? These persons, elect of our vestries, are forging ahead, and in some districts evidently intend to assume as many as possible of the functions of the medical officers of health. Perhaps they hope to become the chief advisers of our sanitary boards. Let Sir Benjamin extend his hand in time and recognize them as specialists in preventive medicine. Then hygeia would indeed be established, and physicians might be relegated to an inferior order.

During the late outbreak of small-pox in Marylebone Dr. Greenwood vaccinated 1,725 persons and revaccinated 2,306. There was in fact a local scare, and a rush to obtain the protection which had been so much neglected. It appears from Dr. Greenwood's report that about twenty-six per cent. of the inhabitants had been guilty of such neglect. After the performance of these operations only two or three cases of small-pox occurred in the whole number, and these were already incubating the disease. The anti-vaccinators will find small comfort in these figures, but I suppose will not cease to propagate their pernicious prejudice. Perhaps an occasional scare of this kind is the only way to teach

them the futility of their fad when the public finds danger approaching.

Testimonials are much in vogue, and make no small demands on the often too slenderly furnished purses of medical men. Just now three important ones are before us—one to Lister, one to Hughlings Jackson, and one to Rivington. All three desire the support of those whose finances make it easy to subscribe. It may be thought that Lister has already received all the honors that are necessary during life, and that the rest might be left for posthumous commemoration; but no doubt the ever-widening circle of antiseptic surgeons, at any rate the prosperous ones, will hasten to enroll their names. Hughlings Jackson has also done a great and lasting work, and neurologists everywhere will be glad of the opportunity to honor him.

Walter Rivington's work has been so closely connected with the London Hospital, and he has been so favorite a teacher, that it was only natural for his numerous pupils and admirers to seize the occasion of his retirement from active service to testify their esteem. Accordingly he was entertained at a dinner last week, and presented with a silver tea and coffee service. Mr. Rivington thanked the numerous friends who had gathered to honor him, as well as those who were unable to be present but had subscribed to the handsome testimonial —adding with the sly humor which never fails him, "and also those who had judiciously refrained from doing so."

From testimonials to the living, it is natural to pass to memorials to the honored dead. The work of the late Dr. Beaven Rake, of the Trinidad Leper Asylum, is worthy of admiration, and his premature death, leaving a widow and children but ill-provided for, is the occasion of a proposal to raise a sum of money for their benefit. It is impossible not to wish success to the subscription. The scientific spirit was strong in Dr. Rake, and he died too soon to make suitable provision for his family—a too common occurrence in our ill-remunerated calling.

The death of Mr. Albert Napper took place last week, somewhat suddenly, in the seventy-ninth year of his age. He will be remembered as the Founder of the Cottage Hospital system, now so generally in vogue that, to the younger members of the profession it must seem strange that one life should cover the time since there were no such institutions. Mr. Napper's earnest advocacy and unfailing perseverance succeeded in establishing the system which everyone now admires.

Another veteran also died last week, Surgeon-General John Fraser, aged seventy-five. He had seen much service, including the Crimea and the Indian Mutiny. He had received various honors, and on his retirement a distinguished service pension.

Next week the General Medical Council will be in session.

The public health continues good. The small-pox epidemic, in London, has apparently subsided, and diphtheria deaths have diminished. In regard to the last the serum treatment is occupying great attention, and is being tried wherever a supply can be obtained. The successes reported are very striking, and it is to be hoped the British Institute will soon be in a position to meet the demand for the new remedy.

What are called clinical evenings at the societies are becoming very popular. They are devoted to the exhibition of cases and specimens with a few remarks to explain them, and attract larger attendances than set papers. The Medical Society of London has begun to hold such meetings, as the Clinical has long done. Both these had such evenings at their last meetings, and both were well attended and the exhibits were of great interest. Thus at the Medical Society, which met on Monday last, Mr. Harrison Cripps gave an account of a most interesting case of intestinal obstruction in a woman, aged thirty-one, who had sustained two severe operations, but ultimately made a good recovery and is now in good health, and has resumed her occupation as a domestic servant.

Mr. Goodsall showed a man who had come to him with intestinal obstruction due to cancer of the rectum. He performed left inguinal colotomy to relieve the obstruction, but the colon was so distended and packed with putty-like fæces, that he was unable to draw the gut out of the wound. He waited for seven days in the hope that some bulging would take place, but as the patient at that time began to get into a serious condition, he decided to attack the cæcum. He found this filled with the same putty-like fæces, but managed to pull it out, and he opened it forthwith, with a satisfactory result. This was the third time he had opened the cæcum, and he was inclined to regard this operation in certain cases as presenting advantages over colotomy. Among the other cases shown was one by Mr. Astley Bloxam, in which thirteen ounces of calculus were removed by him through a lumbar incision. The curious point about the case was that the symptoms at no time suggested the presence of anything approaching so large a mass of calcareous deposit.

Dr. Hall showed a boy sixteen years of age, who had developed hereditary syphilis as late as in his eighth year of age. Some other late cases were mentioned by those present, one of whom said he had seen it as late as the twentieth and even thirtieth year of age.

Mr. Clutton showed a boy thirteen years of age, who had had the humerus dislocated, and the surgical neck of the bone fractured. The fracture and joint were exposed, ivory pegs employed, etc., and perfect movement of the joint resulted.

Some cretins were exhibited. Thyroid gland treatment had produced excellent results in some of them.

The Clinical Society of London held their meeting on Friday, November 9th. Mr. Hurry Fenwick showed a patient with traumatic rupture of the prostatic neck of the bladder, who had been buried while excavating. Twelve hours after the accident suprapubic incision revealed the condition, and the bladder was drained through a perineal incision. Mr. Fenwick urged that in all doubtful cases suprapubic incision should precede the opening of the peritoneum, and he believed that most extra-peritoneal uncomplicated ruptures ought to bec ured.

Dr. W. P. Herringham gave an acount of a case of scleroderma in a seaman, thirty-nine years of age, who had been for sixteen years a diver.

Mr. Watson Cheyne showed a man, fifty years of age, from whom he had removed the scapula five weeks previously, on account of a large enchondromatous tumor of seven years' growth, involving the whole bone and projecting forward into the axilla. The tumor weighed over ten pounds. The wound healed by first intention, and the patient left the hospital sixteen days after the operation. The movements of the arm are steadily increasing in range and power.

Mr. Arbuthnot Lane showed a case of extensive tubercular disease of the perineum, prostate, ischio-rectal fossa, and rectum, which he treated successfully by the introduction of glycerine and sulphur into the cavities; which was begun on September 4, 1894, when he weighed eight stone eleven pounds; now he weighs ten stone, and is free from pain.

Dr. Barlow showed a case of extensive primary atrophy of the muscles of the limbs and trunk, with lordosis and some contraction of hips, in a lad five years of age. No particular muscles were atrophied more than others, the atrophy being pretty general, but in some respects the case resembled pseudo-hypertrophic paralysis, but was difficult to classify; and Dr. Ormerod suggested that it belonged to the "myopathic" group of pseudo-hypertrophic cases.

Mr. Butlin showed a man in whom he had performed trephining for traumatic epilepsy following a fall of eight feet, the head striking against the mantel-piece. He removed a second piece of bone, but discovered nothing further. He let out the fluid in the subarachnoid space, and the man made a good recovery, though

his mental condition remained unsatisfactory for some time.

Mr. Gould mentioned a curious case of a man who had struck his head in a bath. After operation he appeared to be better, but his mental condition never became satisfactory, and he was not altogether free from fits. He was lost sight of for a time, but Mr. Barker said the man had come into the hospital under his care some days since. He gave an altogether misleading history of himself, denying ever having had fits or having been operated upon. The examination of the scalp led one to think that there was a depressed fracture, but on receiving the real history the idea of operating thereon was abandoned, the supposed depressed fracture, on shaving the scalp, being obviously the scar of Mr. Gould's operation.

Mr. Jacobson showed a man who had been operated on for bullet wound of the parietal lobe, inflicted while skirmishing on the west coast of Africa, where he was struck by a bullet which lodged in the lower part of the left parietal lobe, or at the junction of this with the temporo-sphenoidal. He became unconscious, and after five weeks he returned to England, his wound closing for a time, then, reopening, giving exit to pieces of bone and discharge. During this period there had been no hemiplegia, no hemianæsthesia, no crossed amblyopia. Severe headaches frequently occurred when the wound closed for a time. On June 27th an attempt was made at Plymouth to remove the ball, but as brain matter escaped this was desisted from. Save for the headaches his general health was excellent. On October 19th the opening was exposed and enlarged, when one came upon the mouth of a sinus-like track in the dura mater, blocked with granulations. This membrane was quite healthy all round. Two small pieces of bone were removed from a spot about three-quarters of an inch from the mouth of the sinus. Two inches further in, the probe struck the bullet, which was removed by the aid of a sharp spoon. He made a rapid recovery, and has since entirely lost his headaches.

Dr. Hale White showed a boy aged ten, who, when near the end of a first relapse of typhoid fever, developed a severe eczema which rapidly spread—the whole face and ears were covered, the eyes being affected with conjunctivitis—and slowly subsided in about six weeks.

Dr. Harry Campbell showed a case of acromegaly in a man aged forty-six.

Dr. Scanes Spicer showed a case of incomplete Graves's disease with nasal polypi, in a young woman. After removing a large number of polypi, the patient had improved in some respects, and he thought that the connection between these two conditions was something more than a coincidence.

Dr. G. Stoker said he had had a case of goitre along with intra nasal growths, in whom the treatment of the nasal condition was followed by the disappearance of the goitre within two months.

Mr. Godlee showed a man aged twenty-eight, with multiple nodules of doubtful nature which began in April. There were numerous hard nodules in the eyelids, on the forehead, jaw, arms, condyles, etc., and on the knuckles. Microscopically, the nodules were said to be composed of fibrous and not lymphatic tissue.

Mr. Boulby showed a man, aged fifty-eight, with Charcot's disease of the hip with dislocation. The evidences of tabes are as follows: Lightning pains in limbs, dim vision, and gray atrophy, absence of knee jerks, and inability to stand with the eyes shut.

Mr. Edgar Willett showed a similar case.

On Wednesday, November 14th, Mr. Asquith received at the Home Office a deputation got up by a committee of the British Medical Association. The object was to influence the minister on three questions, viz., the employment of married women in factories, death certificates, and the factory laws. The injury to children from the employment of their mothers in factories has often been brought forward as an argument in favor of legislative prevention, and Dr. Reid urged this view on the Home Secretary with considerable force, estimating that the infant mortality was twenty eight per cent. greater in factory towns than in other parts. He insisted that women should be prohibited from such work for three months after the birth of a child. Mr. Asquith asked if the month before birth was not equally important, but was told that was a separate question, and apparently the deputation were not agreed upon it. The minister has evidently thought out the subject, and the newspaper reports show that, although he grasped and sympathized with the object of Dr. Reid, yet, looking at the matter from a broader standpoint, he saw some difficulties in the way. Thus, though employers are generally ready to keep a woman's place open for her return, it is by no means certain they would do so for a period of three months. Again, he remarked that, although it was a good thing to check improvident marriages, it would be the reverse to engender a feeling that the child was in the way. Then, as to *crèches*, there was a rather strong prejudice against them, and though only a prejudice, yet its existence was a fact to be reckoned with. Mr. Asquith said he did not make these remarks in a hostile spirit, but they were objections that must be carefully weighed, and he promised that the subject should be carefully considered.

As to death certification, assurances were offered on the part of the government of their concurrence, saving the question of cost, and whether the time of Parliament would suffice. There was also little difference as to the factory acts.

Of course Mr. E. Hart was much *en évidence*, and he seized the opportunity to mention the massage scandals lately reported in the *British Medical Journal*, and which he is continuing to publish in very short instalments double leaded and "to be continued," after the manner of sensational chapters in "penny dreadful" periodicals.

Mr. Asquith expressed his disinclination to deal with such a subject in public, and said it was not in his judgment fitted for such an occasion; but as Mr. Hart had chosen to introduce it, he would simply say he was willing to receive any authenticated information to show there had been, or was likely to be, any breach of the law. He pointed out that the police are not guardians of morality and could hardly interfere on moral grounds unless the law was infringed; but Mr. Hart might rely upon the co-operation of the police within their proper functions. The view of the home secretary is naturally unsatisfactory to Mr. Hart, who is evidently already tired of the sensation he has tried to get up. Accordingly I see the *Journal* to-day says it is "eminently desirable that the police should take this matter off our hands as speedily as possible."

No doubt that would be a course to afford gratification to others than the staff of the *Journal*, but the probability of such success should have been weighed before embarking on so dangerous and disgusting a course of sensation. Nevertheless all may hope that good will come out of the exposure that has been made, and some way of dealing with the subject arrived at.

The public health continues to be excellent in spite of the most trying weather. Last week the death-rate in London was only fifteen, although diphtheria still lingers with us. But the cases are diminishing week by week.

The Registrar-General reports that last quarter (ending September 30th) was the first summer quarter since 1837 that the annual rate fell below 15 per 1,000. This last it only reached 14.2. Yet the summer was marked by low temperature, excessive rain, and deficient sunshine, and though we are still having what is generally declared "most unseasonable" weather, the mortality returns are most favorable.

Dr. Walter Dickson, R. N., medical inspector of H. M. Customs, died on the 9th inst., in the seventy-fourth year of his age. He was a man of considerable learning and literary tastes. He had done no little service in the

Royal Navy, and had received many medals and other recognitions.

His published writings and addresses were numerous, and all were characterized by a thorough grasp of his subject, which he put in an attractive form.

MALARIA AND DRINKING-WATER.

To the Editor of the Medical Record.

Sir: I have noticed several articles on malaria as a water-borne disease in the Medical Record of the last few weeks.

Allow me to side with Dr. Dalrymple, and suggest a few more objections to the theory of Dr. Daly's.

I lived as a boy in Southwestern Missouri, when that portion of the State was metamorphosing from a stock-raising to a farming community, and am familiar with about all forms of malaria, and speak from personal experience. I have seen families drinking surface water remain free from all infection, only to become prostrated as soon as they began breaking land. This was not in a few instances, but was the regular thing.

The old settlers, who lived on the creek-bottoms and who arose early, before the sun had dissipated the morning fog, were always sick, while their neighbors living higher on the hills, and who awaited the rising sun before beginning work, would frequently escape. Sleeping on the ground would always bring on an attack of the chills, while sleeping twenty feet above the surface gave immunity even when the same water was used.

Intermittent fever has followed the settlement of this country from Indiana to California, keeping pace with the turning of the sod.

It was also noticed that in Ohio and Missouri, during the time of making maple sugar, to use the sap with anything like freedom was invariably followed by intermittent fever. This was well known and added zest to every swallow of that exhilarating fluid. This was before the advent of the plasmodia malariæ into medical literature, and was a curious clinical fact with no tenable theory to support it then.

It has seemed to me, too, that the persons who used sorghum molasses freely were rather more susceptible to the poison than others, and that the young and growing, who needed sugar to keep up muscular growth and activity, were more likely to become intoxicated with the poison.

I have never seen any account of cultures of the plasmodia, but I could venture a guess that it would only grow in a medium containing an appreciable percentage of sugar.

The value of the eucalyptus-tree as a prophylactic, as proven by the experiments made near Rome, must rest on the germicidal qualities of the rootlets—in the oil that they contain—and not in the minute particles of that oil given off by the leaves to the passing breeze.

I think quite likely that the home of the plasmodia is in the sap of vegetable life rich in sugar. While water is the frequent, perhaps common, source of infection, yet I know that it does enter the system from other sources as well.

Rawlins Cadwallader, A.M., M.D.

Fall River Mills, Cal.

THE MARRIAGE OF SYPHILITICS.

To the Editor of the Medical Record.

Sir: In your issue for November 24th, under "The Marriage of Syphilitics," Dr. W. K. Otis, of New York City, criticises the "positive stand" taken by myself, in a previous issue, on the above-named subject. Whether my replies to Dr. Burnside Foster are satisfactory to him or otherwise, I leave for him to answer for himself. If my answers to Dr. Foster's queries are not acceptable to himself, he certainly had better continue his investigations far enough and thoroughly enough to satisfy himself that "allowing our syphilitic cases to marry" and procreate is, at all times and in nearly all cases, a hazardous thing to do.

Dr. Otis says, "Unfortunately Dr. Maine has taken a very positive stand in this matter, and one that is *wholly* (italics mine) *unwarranted* by either authorities or facts." I desire right here to ask, "unfortunately" for whom? Certainly not for myself, and most assuredly not for all good and honored representatives of pure American citizenship.

If "unfortunately" for the band of syphilitics who would prey upon innocent purity through the sacred marriage contract, or "unfortunately" for the physician who would sanction such marriages, and overlook the greatest good to the greatest number, and cater to the selfish purposes of thoroughly selfish unfortunates, I glory in the "unfortunately" "positive stand" I have taken.

When Dr. Otis says, "Wholly unwarranted by either authorities or facts," I take again my "positive stand," and am ready to take issue with the doctor and declare that both "authorities and facts," in far more than the average, fully bear me out in the "positive stand" I have taken.

Yes! I have taken a "positive stand" and am ready, were it necessary, to stand alone for what I believe to be right (but I have not found it necessary to stand alone, as I have already received many words of commendation and encouragement from numerous sources), and in the defence of pure marriages and the propagation of a race that shall be an honor to the nation.

I desire, furthermore, to be understood as to the sources from which I have gleaned a large percentage of the "facts" which have led up to the formation of my opinions and my "positive stand:" 1. To the evidences furnished by a careful study of the works named by Dr. Otis, to which list I also desire to add the names of Fournier and Wood. 2. Considering the guarded manner in which all present the conclusion "that it may in certain instances be safe for syphilitics to marry." 3. To this strong line of evidences, that there is danger in permitting syphilitics to marry, I attach the evidences gathered from journal statistics published during the past twenty years; and 4, last and least, my own experience ranging over a longer period than that, which (though, since graduation, I have not had the advantage of "study of the disease in the rich fields for research only obtainable in great cities") have yet been sufficient to teach me, at least, the dangers of syphilitic marriages. But I do not want Dr. Otis to think that the "great cities" have all the "luxuries," for even in my own "small city" the vile enemy to health, happiness, and home lurks; and, sad to relate, we have rich fields for study, and have plenty of material from which to observe and draw conclusions respecting that blight and blot on everything good and pure that it touches (syphilis), even in the country districts.

Having thus briefly stated the sources from whence I have drawn the "facts" which have led me "to feel justified in presenting my opinion" (no matter to whom it is in opposition), simply passing the doctor's comment on my mention of scrofula, with the sole explanation that in my former paper I merely referred to it as one of the conditions handed down from past generations; barely adding that I have at my command the latest "works on general pathology" and am able to see that opinions differ in respect to the subject, I will pass on and draw a few conclusions:

1. No writer says every syphilitic can marry.

2. Every writer declares great care should be exercised in permitting the marriage of syphilitics.

3. Every writer who has carefully compiled statistics (so far as I can find), has followed but the first two generations, except in a very few special instances not amounting to three per cent. of the total.

4. The average ages of the children, or second generation, when pronounced apparently healthy (by all statistics at my command), is a little over fourteen years.

5. In a little over fifty-three per cent. of the parents (first generation) who had suffered from syphilis previous to marriage, the cases have shown unmistakable evidences of syphilis subsequent to the birth of said "apparently healthy child or children."

Now, allowing a moderate average, say fifty per cent., of the said remaining, forty seven per cent. might have died from other causes without showing a recurrent syphilis, but would had they lived, and taking out twenty-five per cent. more of the remaining forty seven per cent. as having passed out from under observation (and that is small enough), and we have left a very small percentage as even questionably safe to permit marriage to be contracted; and who is competent to select that small percentage in the early days of the syphilitic cases? I acknowledge that I am not, and statistics show that others have made serious mistakes.

6. If a parent who, apparently cured, procreates (and these conclusions are arrived at from the printed statistics of writers favorable to allowing "the marriage of syphilitics" under certain conditions) children who at ten, twelve, or fifteen years are apparently healthy, and then the parent, in from one to twenty years thereafter develops unmistakable evidences of syphilis in the later types of brain degeneration, cerebral and spinal gumma, syphilitic nodes of various bony structures, or other equally or more grave lesions of syphilis, does any physician believe that that child of such parent has no syphilitic taint lurking in its economy? Does any physician believe that that child will not some day show unmistakable signs of syphilis, unless specific treatment has been kept up during gestation or for the child after birth? Does any physician believe that the third generation, or child of that child, will be an honor to the human race? I, for one, do not.

I quote Dr. Otis's own words: "Some of the most healthy persons of my acquaintance have been born of parents, one of whom, at least, had been a sufferer from syphilis before marriage; nor have I observed the slightest trace of the disease in any form passed down to the third generation." I must ask then: 1. What can be the condition of health of the people of Dr. Otis's acquaintance who have not been "blessed" with one parent, at least, who has suffered from syphilis?

2. What would have been the health of those "most healthy persons" of his acquaintance, had both parents been "blessed" with pre-nuptial syphilis?

3. Dr. Otis's experience, in his field of observation, being so different from that of all writers down to the present time, will the readers of the MEDICAL RECORD be willing to accept his conclusions and opinions, which almost place a premium on people who have had at least one parent who has suffered from syphilis before marriage?

4. Is it possible, in the great field for observation which New York City furnishes, that the doctor has not "observed the slightest trace of the disease, in any form, passed down to the third generation?" I must infer that he has either shut his eyes to the bare-faced facts which are constantly confronting all his brethren in the profession; that his experience has been very limited; or that he has not seen the third generation yet born. Conclusions drawn from a few special cases, when the facts and experience of thousands of cases in opposition as observed by every-day experience, are at hand, would form a precedent unwarranted, and one which might lead, yes, would lead, to untold misery if generally followed by the profession, and the unlimited marriage of syphilitics be permitted. It is the general public we are to defend for the best good of all, and deal with those who are a menace to the general good in such a way as shall best fulfil that purpose.

I now reach the doctor's conclusion, and with all respect to the titled author of those closing words, I must take my positive stand once more and first of all say: If syphilitics must be satisfied, let that satiety be in whoredom and concubinage, its honest birthplace and proper habitat, and not in the home which is the avowed heart of a nation, and on which a nation's welfare depends. Let us not be blinded by individual calamities and thereby bring national degeneracy.

The doctor's last clause, of his quotation, reads, "Would probably not in the least diminish the prevalence of syphilis." I admit the force of this argument, and again I say, let it remain where it belongs and not let it enter the sacred home of the pure and innocent, and bring upon such misery and death, or what is worse than death.

By all that is good in man, by all that is dear to woman, by all that is sacred of home, let this nation be populated from the homes of purity, or else let it follow, as it certainly will, the course of some of its "illustrious" predecessors.

FRANK E. MAINE, M.D.

AUBURN, N. Y., November 28, 1894.

THE CAUSE OF BERIBERI.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Siegfried, in an article published in your journal of December 8th, declares it his opinion—and let me say the opinion is not new—that the chief causative element in the etiology of beriberi is "the lack of the nitrogenous foodstuffs, particularly of the fresh flesh sorts, in the habitual diet of the natives" affected by this disease.

I beg Dr. Siegfried to see how he can reconcile the following facts with this theory: Baelz says "that the Japanese diet, far from being wanting in albumin, is, for the lower classes, at least as rich, perhaps richer, in albumin than the food of the poor in most European countries." "That rice," he says, "cannot produce kakke in any manner, is distinctly shown by the circumstance that in the interior, where rice is a much more important factor of the popular diet than on the coast, where fish is abundant, the disease is incomparably rarer than on the littoral." Of course the interior is the region of high ground.

"Persons of strong constitution are more frequently affected," says Baelz, "than weak persons; likewise persons placed in favorable social conditions more frequently than those belonging to the lower classes. Of 626 policlinic patients, there were 593 of strong constitution, 27 of middle constitution, and 6 of weak constitution. Such numbers," says Baelz, "are simply annihilating for the theory according to which kakke is the result of insufficient alimentation and consequent weakness. Simmons also speaks very earnestly against that theory."

"The best fed, the best nourished, and best cared for are usually the most frequent subjects of the disease, while the weak and destitute are only exceptionally attacked by it."

"According to some physicians fat people are quite peculiarly disposed to kakke."

"The adzuki bean enjoys a great repute as a food for beriberi patients, which is well deserved by its unquestionable diuretic properties, so important in this special disease."

"Among the Japanese, the flesh eaters, that is soldiers and sailors, the best nourished part of the nation, are more affected by kakke than the rest."

Even with the addition of the adzuki bean diet, it is considered essential by every Japanese, or foreign, doctor in Japan to send the patient to a high elevation. And why is elevation so important? Are patients better fed on elevated ground? Why does not an analysis of the blood show a deficiency of red corpuscles?

Yours truly,

ALBERT S. ASHMEAD, M.D

NEW YORK, December 8, 1894.

The Irish School of Medicine is said to be declining both in the quality of its teachers and the number of its students.

THE PRESENCE OF ALBUMIN AND CASTS IN THE URINE OF FOOTBALL PLAYERS.[1]

BY ANDREW MACFARLANE, A.B., M.D.,

INSTRUCTOR IN PHYSICAL DIAGNOSIS AND CLINICAL MICROSCOPY, ALBANY (N. Y.) MEDICAL COLLEGE.

WHEN in 1827 Dr. Richard Bright announced the clinical unity of dropsy, albuminous urine, and disease of the kidneys, the significance of albuminuria became at once apparent. Since that time the importance of the examination of the urine and the diagnostic value of the determination of its proteid constituents have held high place in clinical work. The effect of the discovery of this association of symptoms, however, was to lead to the inference that the presence of albumin in urine always indicates renal disease, and renal disease with a rapidly fatal termination, a belief which prevailed until about twenty years ago. But in the past two decades a number of distinguished clinicians, Leube, Senator, Posner, T. Grainger Stewart, Saundby, Mahomed, and others, have found that albumin was at times found in the urine of people in whom there was no detectable disease of the kidneys. Some have even asserted that albumin could be found in the urine of every person if sought for with sufficiently delicate tests; thus Posner found an albuminous body in the urine in all of seventy persons; Chateaubourg in 592 cases out of 701; T. Grainger Stewart in 275 healthy soldiers, and in seventeen per cent. of 50 children.

This claim of physiological albuminuria has, however, had many opponents, and to-day the latter hold that renal albuminuria always indicates diseases of the kidneys, which, though concealed for a time, will eventually reveal itself. They assert that Bright's disease develops intermittently by acute periods of inflammation interrupted by remissions more or less complete, which may last for years, during which time the albumin entirely disappears, due to the cicatrization of the lesion; that granular kidney seems to date its existence to some period of anxiety or worry, and that increased tension of the pulse is met with in certain states of nervous excitement. Temporary albuminuria of the neurotic is likely, therefore, in their opinion, to have a serious even if remote ending.

The believers in a physiological albuminuria claim that albuminuria frequently occurs without present or future disease of the kidney, and unless accompanied by other symptoms has no pathological significance. They maintain that the albuminuria which occurs in conditions of nervous excitement, after physical exertion, from the consumption of egg albumin, after baths, after sexual excitement, at the beginning of puberty, after marked sweating, does not indicate a lesion of the kidneys.

This incomplete summary indicates briefly the general character of the opposing opinions as to the significance of albuminuria. That this subject is one of the deepest interest to all physicians is self-evident. It must be a matter of some importance to all of us, and of the deepest concern to our patients, that we properly interpret a condition which may be either the danger-signal of an incurable malady or a trivial occurrence of no special significance.

It will not be necessary to consider in detail the different kinds of albuminuria, but merely to recall them to your recollection. I shall, however, take the liberty of considering more at length a cause of albuminuria which, although always recognized, does not appear to have been sufficiently investigated.

The forms of albuminuria are naturally divided, for clinical purposes, into two great classes—accidental albuminuria and renal albuminuria.

Accidental albuminuria is the result of an admixture of albuminous fluids, as blood, pus, chyle, with urine itself free from albumin. In such cases the urine usually contains a small quantity of albumin, and invariably a sediment of elements characteristic of the fluid admixed, as blood-cells, pus cells, etc. To this class—the accidental albuminurias—belong many cases which, I believe, have too often been denominated functional or physiological albuminuria. Sir Andrew Clark, with his remarkable medical acumen, recognized this fact, and stated that "in some young men excited by sexual desire and denying it indulgence, there was secreted from the urethra or its adjacent glands a fluid which, mixing with the urine, yields evidence of the presence of serum albumin" (albumose?). Sir William Gull probably had this same fact in mind when he said, "albuminuria is almost as common in young men as spermatorrhœa." Many of the functional albuminurias of puberty, and probably also a number of the cases of neurasthenic albuminuria properly belong to this class.

Renal albuminuria may also, for clinical purposes, be subdivided into—1. Albuminuria, due to a primary lesion of the kidneys. 2. Secondary or complicating albuminuria, due to (*a*) circulatory derangements, as in cardiac disease—this may, however, eventuate in renal disease; (*b*), febrile conditions depending upon changes in blood-pressure and in the epithelium of the kidneys, and also the result of the excretion of the toxines of disease; (*c*), changes in the composition of the blood, as in anæmia and chlorosis. 3. Functional or so-called physiological albuminuria, the result of muscular exertion, mental strain, cold and cold bathing, diet, and without any other symptom of Bright's disease. Of these only the so-called physiological albuminuria need be considered, as the significance of albumin in the other forms of albuminuria is beyond question.

Functional albuminuria is commonly said to be characterized by—1, absence of all other symptoms of Bright's disease; 2, chance detection while the person was apparently in good health; 3, quantity of albumin is comparatively small, and at times in the twenty-four hours is entirely absent; 4, absence of the casts.

That albumin due to the above-mentioned causes is at times found in the urine has been known for a long time.

In Germany, albumin has been detected in the urine of soldiers after long marches. In England, Pavy found albumin in the urine of Weston, the walker; T. Grainger Stewart, in persons after violent exercise, and Mason in two out of five school boys after a run of six miles. In this country Lambert, of the Equitable Life, has found that when the temperature goes to zero or below, or when it passes 90° F., the percentage of healthy men having albumin in their urine increases from two per cent. to five per cent., until the temperature reaches nearer the mean. Gray, in a recent paper, states that he has

[1] Abstract of a paper, Albuminuria, its Detection and Significance, read before the Albany County Medical Society, November 21, 1894.

found persistent albuminuria, with frequent hyaline casts, in almost all his cases of functional nervous disease.

Unfortunately the tests by which some of these results were obtained are not given, and it is to be feared that some of these investigators used such delicate reagents that doubt can justly be held in regard to their results. In Posner's set of seventy cases, Malfatti claims that mucin had been mistaken for serum-albumin, and it seems probable that albumose, a constituent of the seminal fluid, has frequently been mistaken for albumin. This, I think, is probably the case in many young men and in neurasthenics.

There is no doubt, however, that albumin does at times appear in considerable quantities in the urine when the kidneys are apparently normal. As excessive physical exertion, mental excitement, cold baths, and albuminous diet are each individually said to be provocative of this condition, the writer thought that where all these exciting causes were combined, as in foot-ball, albuminuria to a marked degree ought to be present. An examination of the urine of nine foot-ball players passed immediately after the game was made, November 10th, gave the following results:

Case.	Reaction.	Specific Gravity.	Albumin. Heller's Test.	Sugar. Nylander's Test.
I.....	Acid.	1.020	Ring, 1/12 inch.	Negative.
II.....	"	1.017	" 1/12 "	"
III.....	"	1.025	" faint.	"
IV.....	"	1.022	" 1/16 inch.	"
V.....	"	1.022	" faint.	"
VI.....	"	1.030	" 1/12 inch.	"
VII.....	"	1.023	" 1/12 "	"
VIII.....	"	1.021	" 1/12 "	"
IX.....	"	1.024	" 1/12 "	"

In these cases Heller's nitric-acid test was employed. Nitric acid was poured into a test-tube, then urine was carefully added with a pipette, so that the urine formed an even layer above the acid. At the plane of contact a heavy white zone appeared, of varying widths. The reaction was still readily perceptible, except in the faint cases after the urine had been diluted twenty times with water.

None of the specimens showed any evidence of the presence of sugar, although they were examined for that purpose with Nylander's modification of Boettger's bismuth test. On standing twelve hours there was a heavy deposit in each case, and the microscopic examination revealed the presence of many urates, uric-acid crystals, oxalate of lime, and a large number of casts, some epithelial, a number of granular, and many hyaline casts sprinkled with crystals. The result of Heller's test was so striking that the urine of six players, excreted about three and one-half hours after the game, was examined.

Case.	Reaction.	Specific Gravity.	Albumin. Heller's Test.	Albumin. Tanret's Test.	Albumin. Millard's Test.	Sugar. Nylander's Test.
I.....	Acid.	1.025	Negative.	Present.	Present.	Negative.
II.....	"	1.030	Faint ring.	"	"	"
III.....	"	1.031	Negative.	"	Negative.	"
IV.....	"	1.030	"	"	Present.	"
V.....	"	1.029	"	"	Negative.	"
VI.....	"	1.026	"	"	Present.	"

In these six specimens albumin was detected only in one specimen with Heller's test, while Tanret's reagent showed a slight opacity in the other five. The deposit in these cases was also considerable, and on microscopic examination a few casts, largely hyaline, were found.

On November 18th specimens of urine passed immediately after the game by twenty foot-ball players were examined.[1] Every one showed the presence of albumin in considerable quantity; several after the urine had been diluted thirty to forty times, and one after the urine had been diluted one hundred times. In all the specimens casts were found; in some they were very abundant, and consisted of large and small granular, in other specimens of hyaline sprinkled with crystals, and in several of blood-casts. The microscopical examination also revealed the presence of many epithelial cells, an abundance of oxalates, urates, and uric-acid crystals, and in a few considerable blood. In all cases of casts no doubtful forms were accepted, and in more than two-thirds of the specimens two, and at times four, examiners agreed. In each case new cover-glasses and slides were employed.

[1] The writer desires to thank Mr. W. H. Conly and Messrs. Shaw and Sandford for their valuable assistance in the urinary examinations.

Case.	Quantity Passed.	Reaction.	Specific Gravity.	Albumin. Heller's Test.	Sugar. Nylander's Test.	Microscopical Examination.
I.....	Ozs. viij.	Acid.	1.018	Ring. 1/8 in.		Granular, blood, hyaline casts. Blood, oxalates, uric acid, urates. Esbach's test gave 1/10 per cent. albumin.
II.....	j.	"	....	1/16 in.		Granular, hyaline casts. Urates, oxalates, uric acid.

XVIII.	iij.	"	1.028	"		Granular and hyaline casts. Urates, uric acid.
XIX...	iij.	"	1.025	1/10 in.		Granular and hyaline casts. Urates, oxalates.
XX.....	ij.	"	....	2/8 in.		Many granular, blood, and hyaline casts. Considerable blood, uric acid, urates. Esbach's test gave 1/10 per cent. albumin.

Reaction in every specimen, negative.

These results exceeded by far anything that had been anticipated. That albumin may be detected in the urine after muscular exertion has been known for a long time, but never, as far as I can discover from my reading, has it been found in such quantities as here given. Then, too, the presence of casts of almost every kind in all the specimens examined, a condition which heretofore has only been associated with severe degenerated disease of the kidneys, overthrows a supposedly fixed clinical law—that the presence of granular casts in the urine always indicates renal disease. The fact that this condition cleared up in so short a time, that these men are all young, powerful, and healthy, indicates that the condition is a very transient one.

To explain, several theories might be advanced: First, that the albuminuria is due to the great concentration of the blood which occurs with this violent exertion, and that as the blood resumes its normal specific gravity the albumin no longer escapes. That albuminuria is attendant on the concentration of the blood is seen in cholera in which albumin, numerous casts, and renal epithelium are found in the little urine excreted. Hoppe Seyler and others have shown that the quantity of albumin that passes through a filter increases with the increase of the saline constituents. As the urine was much denser and the salts increased in amount, this would seem to offer an explanation for the condition found.

An attempt was made to demonstrate the correctness of this theory by examining, three hours after the game, the urine of two players who had refrained from drinking, the blood being then practically in the same concentrated condition as immediately after the game. Two other players were allowed to drink as much as they de-

sired, and their urine, passed three hours after the game, was also examined. The results, however, were negative. Of the players who had refrained from drinking, one showed immediately after the game only a trace of albuminuria, and none at all after three hours, while the urine of the other contained a trifle more albumin at the end of three hours than before. Of the two who were permitted to drink, one, who after the game showed marked albuminuria, later, after the drinking of six glasses, revealed merely a trace, while the other after drinking four glasses showed about as much albuminuria as before. The number of cases experimented upon was entirely too small to warrant the drawing of any conclusion.

The second theory is that the albuminuria is due to the acute mechanical congestion which ensues. The skin and the kidneys have many points of resemblance. They are both excretory organs, removing fluids and solids from the body, and are normally complimental to each other. When the kidneys do little work, as in summer, the skin does more, and *vice versa*. We also know that the external layer of the skin is all the time being insensibly shed and constantly renewed. If, however, the skin is forced to do additional work, as for instance in a Turkish bath, the external layer of the dermis, which before was shed invisibly is now cast off in large scales and flakes, *i.e.*, skin which would normally take a number of days in which to be shed is by this increased action cast off at once, leaving the skin after this great desquamation unimpaired. By analogy we are justified, I believe, in claiming that much the same process may take place in the kidneys. It is a natural inference that the epithelial cells of the Malpighian bodies and the uriniferous tubules are exfoliated, as, in various inflammatory conditions epithelial cells are present in the urine. It does not seem, therefore, a very great stretch of imagination to believe that under such conditions as prevail in football, epithelial cells might be carried off, albumin transude, casts formed, and then when the exciting cause had ceased to operate, that the organs would normally resume their function. An attempt was made to ascertain if any of the players had had scarlet fever in their childhood. But no such history could be obtained. Only a few men, however, were questioned in regard to their previous history.

Two practical questions now present themselves to us for solution.

1. Can such a condition be repeated twice or oftener a week without doing to the kidneys some damage which, although it may go for years unrecognized, will eventually lead to a serious renal change?

2. Is it not dangerous for men whose kidneys may have been weakened by previous disease, as scarlet fever, to subject themselves to such a violent strain?

Although I believe in the existence, under certain provocative conditions, of a functional albuminuria, and think that a fatal prognosis should not be rendered offhand simply from the occurrence of albuminuria, I would regard it a very great evil indeed if the knowledge of the possibility of functional albuminuria should lead anyone to carelessly view the presence of albumin in the urine. Our increased knowledge should lead us only to a more thorough examination which should embrace not only the genito-urinary system but also the entire body. Thus only shall we do no injustice to our patients either by treating as trivial what may be a danger-signal of the utmost import, or, on the other hand, unnecessarily alarming them about a condition which of itself may have no great significance.

239 Hamilton Street, Albany, N. Y.

The Sense of Smell is a faculty belonging chiefly to savage and primitive races, says Dr. Hermann, of Vienna, for man and house dogs have lost it almost entirely. It is more highly developed in the non-carnivorous than in flesh-eating animals.

PERFORATIONS OF THE NASAL SEPTUM; ETIOLOGY, CLINICAL SIGNIFICANCE, AND TREATMENT.*

By ADOLPH RUPP, M.D.,

NEW YORK.

Flattening or other deformities of the nose which have resulted from a defect or perforation of the nasal septum are met with only rarely by most general practitioners, and are not discovered very often by rhino-laryngologists.

Perforations and defects of the nasal septum are found oftener than the deformities to which they might be supposed to give rise to. Aside from all the possible cosmetic shortenings which these perforations or defects may induce, they are but rarely the cause of enough pain or discomfort to urge the patient to seek medical or surgical relief. And, no doubt, reasons such as these are sufficient to account and apologize for the material indifference of medical history concerning their existence and significance—an indifference extending over a period of more than twenty centuries. Indeed, it is only within the last fifteen years that perforations of the nasal septum have attracted scientific attention, thanks mainly to the investigations of Austro-German writers, Weichselbaum, Zuckerkandl, and Hajek, and clinicians in the United States, England, Germany, Switzerland, France, and Russia.

Most frequently these perforations and defects are discovered in the course of routine clinical work. They are usually associated with other nasal diseases, of which they may or may not be a result, or which they may or may not complicate; or they may have nothing at all to do with the pathological processes for which the patient is being treated, but are merely a mark of a process that has long since run its course. Sometimes, though rarely, they of themselves give rise to clinical phenomena which call for medical examination and treatment. Furthermore, they become of considerable importance, once their existence has been discovered, because the opinion which the examining physician or surgeon may form concerning their origin, will not be a matter of indifference for the patient's welfare, either individually or socially. The shape assumed by septal perforations depends on the pathological cause, as well as whether they be located in the osseous or cartilaginous portion of the septum. In the bony portion their form may be irregular, and usually is so; but in the cartilaginous portion of the septum they are nearly always round or oval in shape. As a rule they occur singly; but exceptionally two or more may be found together. Perforations of the osseous portion are very rare; and most of the septal perforations found are in the cartilaginous part. Either portion of the septum may be perforated without involvement of the other; and exceptionally, the perforation or defect may involve both.

Frequency of Occurrence.—McBride[1] says he has frequently seen perforations of the cartilaginous portion of the nasal septum "in the course of routine examination of patients for aural disease." Very few aural surgeons outside of Scotland can claim as much. This statement is no doubt what lawyers, with commendable exactitude, love to call an impression, and is not an indubitable fact. Zuckerkandl[2] found such defects eight times in as many subjects in one hundred and fifty autopsies. And in two thousand one hundred and thirty six autopsies, Hajek[3] found perforations and ulcers in various stages of development on the way to perforation, only thirty-three times, and that too after special search for them had been made. Turning from autopsy finds to clinical observations, it will be found that Max Schaeffer[4] (Bremen), in the course of ten years, saw only twenty cases of perforation of the nasal septum. And, after examining over two thousand nose and throat cases in the course of three years, at Vienna, Chiari[5] tabulated, under the heading of ulcers, cicatrices, and defects of the nose only seventy-

* Read in part at the October (1894) Meeting of the Charity Hospital Alumni Society, and the Laryngological Section of the New York Academy of Medicine, November 28, 1894.

seven cases, not a dozen and a half of them being perforations of the nasal septum. In ten of these seventy-seven cases a perforation of the septum was found without any sign of ulceration or necrosis at any other point within the nasal cavities. Jurasz,[6] in ten years' time, at Heidelberg, examined over four thousand nose and throat patients, and noticed perforation of the nasal septum in only thirty-seven of them, and then only once was the osseous portion found perforated. Hermet,[7] in the course of a discussion on this subject at a meeting of the Laryngological Society of Paris, asserted that perforations of the nasal septum are very rare in France. They are not of frequent occurrence in New York City. Taking eight annual reports of the New York Eye and Ear Infirmary (1874–80–84–85–87–88–89, and 1890), it will be found that ten thousand cases of nose and throat diseases were recorded, two thousand one hundred and nine of which were diseases of the nose. And only twenty cases of perforation of the nasal septum are recorded. During the year ending May, 1894, at the New Amsterdam Eye and Ear Hospital, four hundred and ninety-three cases of nose and throat diseases were examined, and only three times were perforations of the nasal septum recorded. There have been years at the New York Eye and Ear Infirmary when not a single case of septal perforation was seen. Certainly these figures prove this much—perforations of the nasal septum, though not of exceptional occurrence, are by no means common or frequent.

Sex.—Schaeffer found his twenty-two cases seven times men and fifteen times women. In this respect the experience of Weichselbaum, Hajek, Jurasz, others, and my own, has been the contrary, that is, about two to one in favor of males.

Age.—Jurasz found the ages of his patients ranging from ten to over seventy years. And Hajek found septal ulcerations and perforations oftenest in those between twenty and fifty years of age—that is, during the most active and most exposed period of life.

Side of Development.—Perforations develop from ulcers on either side of the septum, or from both sides simultaneously. Rossbach found their point of origin oftenest on the right side; but Hajek found it to be on the right side five times, on the left side nine times, and on both sides simultaneously six times.

My Own Cases.—During the past two years I have had, in private practice, seven cases of perforation of the nasal septum in my care. Five were men, and two were women. The ladies were respectively thirty-one and forty-eight years old. Two of the men were in the fifties, two in the forties, and one was eighteen years old. In five the cartilaginous portion of the septum was the site of perforation. In one case the bony portion only was perforated, and that was a case of very late tertiary syphilis. The seventh was a traumatic case, and the perforation involved both the bony and cartilaginous portions of the septum. Two of the cases were seen while still in the ulcerative stage, and several months before perforation at last took place. In these cases—the one syphilitic and the other non-syphilitic—the trouble began on the right side of the septum. The syphilitic presented extensive infiltrations over the right middle and inferior turbinated bones, and later on ulcerations, besides perforation of the hard palate. Necrotic pieces of bone were taken from the palate. The palatal trouble healed up quite rapidly. The cartilaginous part of the septum remained unaffected while the patient was under observation, and the trouble remained limited to the palatal and vomer bones. Infiltration and ulceration were much more marked in the right than in the left nasal cavity.*

* This man, aged fifty, at first denied ever having had syphilis; but finding his assurances disbelieved, he finally acknowledged having been treated for the disease while soldiering in Russia and Siberia twenty-five years ago. Within the last three years two of his infant children have died of hereditary syphilis. The one when nine months old, and the last when three weeks old. I saw the first child only twice before it died. This child was supposed by the parents to be sick with only diarrhœa. It had coryza, headache, and anal condylomata, besides a roseolaceous rash on the buttocks which shaded off down the thighs. Its life ended in convulsions. The last child was plump and apparently healthy when born; but soon it had a coryza and a sore anus, and it died soon of syphilitic marasmus. The mother nursed neither of these children. A girl six years old betrays none of the ordinary well-known signs of hereditary syphilis. The mother is a strong woman, and she states never had any miscarriages, etc.

In only one of the other five cases was it possible, from the character of the existing ulcerative process, to determine that in all probability the trouble began on the right side of the septum. The other three cases—not counting the traumatic one—presented perforations in such a perfect state of finished development, that it was impossible to say whether the perforations began on the right or the left side, or on both sides simultaneously. In the one woman the cartilaginous portion of the septum was bent into the left nasal cavity, but not enough so as to block up entirely the respiratory passages, and in this case it was plain the ulcerative process began on the right or concave surface. Once the perforation was associated with atrophic rhinitis and pharyngitis; once with hypertrophic rhinitis; once, as already mentioned, with extensive syphilitic infiltrations (syphilis nowhere else than in the nose, mouth, and throat) and ulcerations; and once the perforation complicated fracture and dislocation of the cartilaginous portion of the septum. Only two of the cases applied to be relieved from nasal symptoms that were directly due to the ulcero perforative process, which was limited, and on the cartilaginous portion of the nasal septum.

In the course of an interesting and instructive essay on bacteria and cocci in the nasal cavities, Doctor Jonathan Wright[8] says, "The day of theorizing has gone by. A theory now-a-days should be considered as little better than confession of ignorance"—mere words. With great truth has it been said that there are more false facts than false theories. The fallacies of a theory do not worry us much, and never for a long while. Life itself is theory, and we can no more escape from the necessity of theorizing than we can from the necessity of quoting others, unless we end by suicide. Such a thing as the "scientific imagination" has been spoken of by many scientific and unscientific orators, and in varying senses. As a not exact expression for the highest kind of mental activity, it may be allowed to pass unchallenged. All the sciences and all the arts owe much to it, and so does rhinology. The scientific imagination revels in attempts at unravelling the riddles that confront and puzzle us. It builds theories by combining the facts that are seen by all with those that are forgotten or have never been known before. It finds and marshals facts into their co ordinate places. It breathes life into facts that seem dead. It organizes knowledge and makes it all-powerful. And yet, as has been said over and over again for hundreds and hundreds of years, to quote Glanvill, "we *erre* and come short of science, because we are so frequently misled by the evil conduct of our imaginations; whose irregular strength and importunities doeth almost perpetually abuse us." A comparative study of rhinological writers on perforations of the nasal septum reveals to us that they have been and are thoroughly human, and that they have seen and reported facts often enough, only partially, not to say falsely; and they have not failed to build theories which have crumbled away under the grinding weight of time. And so, by the irregular strength and the importunities of the imagination—not because of any theory as such, however fallacious—writers who meant well have imposed on the often too ready credulity of those who must needs consult them for professional mental fodder, or ready-made opinion. Let us see:

Etiology.—The study of the causes of perforations of the nasal septum may be considered conveniently under five heads, namely: 1. Congenital or developmental influences. 2. Traumatisms. 3. Contiguous pathological processes. 4. Diseases that engender such constitutional and local conditions peculiar to syphilis, tuberculosis, lupus, scrofula, rheumatism, diphtheria, fevers, etc. 5. Local inflammatory and allied processes.

Congenital or Developmental Causes.—Hilderbrandt (anatomist) had a hole in the anterior portion of his nasal septum, which he considered congenital because he was not able to account for it in any other way. In the course of many years Hyrtl observed such perforations three times in anatomy subjects. He too considered them congenital in origin. Bosworth [9] quotes Schmiegelow as having seen a perforation which was believed to be congenital, and in which case a large portion of the cartilage was wanting. Without giving specific instances or references to such, E. Klebs [10] states, "roundish holes in the nasal septum are observed in fœtuses—the borders of these perforations are covered with a smooth membrane, and it has not been demonstrated beyond a doubt whether these holes are caused by some fœtal ulcerative process or by arrested development." And no less an anatomist and rhinologist than Harrison Allen [11] says, "Congenital defects in the nasal septum are apt to be multiple, and the septal opening to be associated with the presence of a hyperostosis in the roof of the mouth, or asymmetry of the facial bones." Congenital defects are, says Harrison Allen, as a rule in the cartilage, although they may be found in the perpendicular plate of the ethmoid bone. A case of congenital defect is quoted from Germs by Beely; [12] parts of the vomer in the child were missing, and the nasal cavities of both sides communicated. In this case the hard palate was very much arched, and thus in a manner compensated for the deficiencies of the vomer.

Traumatic Causes.—Bosworth [13] has seen perforations of the nasal septum result from injuries to the nose. In those cases splinters of bone (the vomer) ulcerated away and left a defect in the bony portion of the septum. My case, mentioned above, was a man over fifty years old, and the victim of a runaway accident. Being jerked from the carriage seat he struck his face against the pavement. The septal cartilage was dislocated antero-inferiorly into the right nasal cavity, and above into the left nasal chamber, besides being bent or broken longitudinally, the convexity of the cartilage jutting against the turbinated bone of the left side of the nose. The anterior portion of the lamina perpendicularis was fractured. A probe could be passed through from the right into the left nasal cavity, above and behind, near where bone and cartilage join. The dislocated and fractured parts were easily replaced and fixed by means of long and firm pledgets of absorbent cotton and borated gauze. The result is good. There is no visible external deformity, and there is no obstruction to nasal respiration. For four weeks after the accident a healing ulcer was seen at the point where the probe had been passed through the septum. The ulcer was seen longest on the right surface of the septum, where it had always been larger. The accident had caused much hemorrhage from the nose, and considerable flattening, besides a good deal of dizziness, which persisted for weeks afterward.

An interesting case of bullet traumatism mentioned by Löri,[14] may be quoted here: A soldier who had been shot years ago through the nose, the bullet having entered a little below the glabella, and, without injuring the hard or soft palate, penetrated into the pharynx, from whence it was expectorated. An irregular fleshy mass extending from the lower nasal passages away up into the attic of the nose, was found on both sides. At the posterior parts occupied by this mass of granulation tissue, the septum was found to be defective.

According to Harrison Allen,[15] imperfect surgical operations may give rise to septal perforations. Zuckerkandl [16] quotes a case from Velpeau, in which the operating surgeon put a hole through a very much bent septum which he had supposed was a polyp.

It is well known that certain barbarous people perforate the septal cartilage for the purpose of wearing decorative rings, and for purposes of religious ceremonies.

There is one other instance of septal perforation, alleged to be due to causes which are traumatic rather than anything else. I refer to Professor Bosworth's theory,[17] by which he not only explains the cause of nasal hemorrhages, but also the manner in which round or oval perforations are developed in the cartilaginous portion of the septum. The theory is simple enough, but so purely mechanical as to deny life to the septum, and reduce it to the grade of an inorganic partition without the power of reacting against injury. It is simply frictional erosion, sans ulceration, sans inflammation, sans constitutional taint. The theory is novel in rhinological and pathological literature. Cognizant of the eminence of the author, it is only just that he be quoted verbatim et literatim: "The most common cause of this perforation is to be found in the projection of the cartilage into one or the other passage, whereby its prominent portion becomes subjected to the current of inspired air, laden as it is with dust and other impurities, whereby a process of erosion is established, under which the cartilage is gradually worn away until an opening occurs. This is a purely local process, and involves no suspicion of a systemic taint. The existence of the erosion is attended with annoying crust formation over its site, causing a frequent picking of the nose, by which the process of erosion is much hastened. This process, as we see, is really a conservative effort on the part of nature to relieve the patient of an obstructive lesion in the nose, and one, moreover, which I have frequently seen attended with signal success, since the removal of the obstruction seems to be the primary effect of the process, while the establishment of a perforation is to an extent adventitious. I cannot agree with Zuckerkandl in the view that these cartilaginous perforations are due in a large majority of instances to an ulcerative or inflammatory action, in that the simple erosion in my experience is never attended with either of these processes." Reading all this simple talk of Bosworth's makes one think of a saying of Emerson's—"power and purpose ride on matter to the last atom." But it is all too good to be true. McBride criticises the theory quite mildly by calling its assumption of a projecting cartilage arbitrary. There are many points of cartilage in the nose that jut out into the current of inspired air, but they remain intact and are not filed away by the dust-laden impure wind; perhaps so, for the sole benefit of the operating rhinologist. Then, too, according to pathological specialists, an erosion is a superficial ulcerative and inflammatory process, in which the tissues that are being subjected to erosion are bereft of regenerative, but not reactive, capacity, because the destructive agents are slowly, but surely and continuously, at work (Weigert). Thus, this theory of Bosworth demands concessions that cannot be granted, for it seeks to explain a biological question by ignoring biological factors, and thus runs short of science, and becomes a mechanical mystery.

Contiguous Pathological Phenomena.—It is known that a rhinolith, or a polypus, may cause a perforation of the septum to take place, apparently by continuous pressure against the septum. Jurasz [18] reports having seen a case of each.

Influences Engendered by Constitutional Diseases, Scrofula, Lupus, Tuberculosis, Syphilis, Rheumatism, Diphtheria, Fevers, etc.—Scrofula, lupus, and tuberculosis, though related affections, and believed to have been such long before their consanguinity was accentuated by Koch's discovery of the bacillus tuberculosis, differ sufficiently in their clinical phenomena to justify the conclusion in the minds of very capable clinicians (Kaposi and Voltolini among others) that they are not identical maladies. They affect the mucous membrane and other tissues of the nose, and particularly the septum. They give rise to a catarrhal condition, to infiltrations, to tumors, and to perforations.

Scrofula: Maldenhauer [19] describes a septal perichondritis, due to scrofula, which ends in the formation of abscesses, and perforation of the cartilaginous portion of the septum. Sir James Paget [20] describes a similar condition. These abscesses may come on spontaneously, or a slight, under other circumstances indifferent, injury

to the nose may start them. The anterior portion of the septum is usually affected, and as a rule on both sides. Paget's description is: "Small abscesses form between the mucous membrane and the septum. With these the portion of cartilage beneath may be softened or ulcerated; and it may be perforated when similar circumscribed abscesses form on both sides of it; but when the pus is discharged there does not, I believe, follow any extension of ulceration in either the cartilage or the mucous membrane, and they heal leaving a small thin-edged opening in the septum." Maldenhauer's description differs somewhat from Paget's, being more acute and involving a larger area of surface; and patients apply for relief usually when the cartilage has become disorganized, and a perforation permanent. Maldenhauer states, what older writers have too, that the bony portion of the septum may become defective through scrofulous disease.

Lupus: Max Bender found the mucous membranes involved one hundred and seventy-five times in three hundred and eighty cases of lupus collected at Doutrelepont's clinique. In thirty-one per cent. of all cases the disease began in mucous membranes, which, says Crocker,[21] is by far more than is usually supposed. Only six times were the mucous membranes alone affected. One hundred and fifteen times the mucous membrane of the nose was involved. Crocker says that lupus is almost rare in America, and is seen less often in England than on the continent of Europe. It is more frequently seen in women than in men. Carl Seiler [22] says that he has never seen a case of lupus of the nasal mucous membrane. And Sir Jonathan Hutchinson [23] tells us that he has seen as many as three cases with septal perforation in one day. Such is the irregular run of practice. I have seen three cases of lupus in which the mucous membrane of the nose was affected, but in none of them* was the septum perforated. My friend Professor George T. Jackson† knows of about a dozen cases of nasal syphilis that had been diagnosticated as lupus. Two such cases, he says, had been operated on by competent surgeons who supposed that they were dealing with lupus. Mistakes of this kind, Jackson holds, only show that the differential diagnosis of syphilis and lupus is not always an easy matter. Ausspitz and Schuster, and other syphilographers, would agree with him. So much for the rarity of lupus, and the difficulty of recognizing it.

Medicine, especially clinical medicine, is still so imperfect in its methods of investigation and demonstration, that the name of a teacher often does duty for alleged facts or the validity of a theory. And sometimes such facts and theories are circulated by other teachers with their endorsement and commendation. At other times such facts become distorted, and the original teacher is falsely quoted, and approximate, not to say true, science comes short. In so far as lupus of the nose is concerned, this has been the case with the honored name of Kaposi. A number of respected rhinologists (Schech and Macdonald among others) have quoted Kaposi [24] as saying that the bones of the nose do not suffer in intra-nasal lupus. Kaposi says nothing of the kind. He simply makes no mention of bones when speaking of lupus of the mucous membrane of the nose. He does say on a previous page that lupus spreads via connective tissue, and that there are no grounds for asserting that muscles and bones directly succumb to lupus. Further on in this same article he says, concerning the bones of the extremities, periostitis, ostitis, caries, and necrosis, occur when no evident preceding inflammation or infiltration has taken place in the superjacent skin. Rosenthal [25] makes the general and unsubstantiated remark that it is an undecided question whether or not lupus affects the bones of the nose. Haughton,[26] Crocker, Schuster, and Ausspitz, and Klebs [27] affirm that the bones as well as the cartilage of the nose may become implicated in the lupus process and drop out. Kaposi says that the septum cutaneum is less frequently affected by lupus than by syphilis. He also observes, what others have remarked, that fungous lupous granulations may conceal a perforation of the septum.[28]

Tuberculosis of the mucous membrane of the nose is very rare, and perforation of the septum due to it much rarer. In sixteen hundred autopsies Williglk found four hundred and seventy-six tubercular subjects, and in only one of them tuberculosis of the nasal mucous membrane. It is believed that primary tuberculosis of the nasal mucous membrane has been observed, but such observations are not beyond question. Up to 1889, Seifert [29] was able to collect only thirty-eight cases of intra-nasal tuberculosis.

Greville MacDonald saw a case of tubercular perforation of the nasal septum (case 31, p. 339, Treatise on Diseases of the Nose); and others have reported similar cases. Such perforations exist in connection with other tubercular ulcerations, infiltrations, and tumors in the nose.

From the foregoing remarks on scrofula, lupus, and tuberculosis, it may be concluded that only very rarely can they be the causes of septal perforations. But that they do give rise to such perforations cannot be denied; and that even the osseous portion of the septum may be perforated by them must be allowed as a possibility. And however rare an eventuality they must needs be taken into account when the differential diagnosis of any perforation of the nasal septum is being considered.

Syphilis.—In 1885, G. H. Makenzie (Edinburgh) claimed, what many practitioners believe to be the case to-day, that perforations found in the septum are probably always symptomatic of syphilis; and McBride [30] stated, about the same time, in criticising Makenzie's claim, that most specialists (rhino-laryngologists?) look upon them with suspicion, but not as being pathognomonic of syphilis.

This is not an unimportant question. The gravest family complications may arise from the assertion that septal perforations are always syphilitic in origin. One of my cases, a lady engaged to be married to a lawyer, was told by me, that besides other troubles for which she was being treated, she had a hole in the septum of her nose. Innocently enough she told the lawyer of this, and he wasted no time in calling on me to have the significance of the perforation explained to himself. I could positively say that the hole had no particular significance, and had nothing to do with syphilis, hereditary or otherwise. Not only a patient's family and social group may be upset by the announcement of a mistaken diagnosis, but the physician or surgeon may come to grief because of it. Chiari [31] in his group of seventy-seven cases of "ulcers, cicatrices, and defects" of the nose, found sixty-two of these lesions caused by syphilis, five by lupus, four by scrofula, one by blenorrhœa, one by tuberculosis, one by diphtheria, and two were due to causes that could not be found out. These figures illustrate approximately the relative frequency of syphilis as a probable cause of perforation of the nasal septum, as compared with the possible etiological value of the other diseases already reviewed.

Syphilis, when it attacks the nose, like scrofula, lupus, and tuberculosis, shows a conspicuous liking for the anterior portion of the septum. In fifty-five cases of nasal syphilis recorded by Jurasz, thirty-one times the septum was attacked, and only once the bony portion. Twenty times in thirty-seven cases of septal perforation, syphilis was found to be the cause. Only in three cases out of sixteen of septal perforations could A. B. Thrasher [32] (Cincinnati) get an undoubted history of syphilis.*

Moritz Schmidt [33] would hesitate in calling a perforation syphilitic in origin if it did not involve the bony part of the septum as well as the cartilaginous portion. This assertion ignores much common experience, and,

* All women, two of German and one of Irish extraction.
† Oral communication.

* Dr. St. C. Campbell saw thirty-five cases of septal perforations—all in the cartilaginous portion, and their chief causes he believed to have been, 20 syphilitic, 9 anæmia, 5 ozæna, and 1 tuberculosis.—W. J. Swift (Lefferts) Reference, International Centralbl. für Laryngologie, etc., vol. viii., p. 9.

though it may be based on much individual observation, it would lead into many diagnostic and unfortunate therapeutical mistakes if depended on as a diagnostic mark. Bresgen [34] would have the favorite site of syphilitic ulceration (and consequently of perforation?) to be at those points where bones and cartilage unite. Kaposi [35] claims that the dormal, cartilaginous, and osseous parts of the septum may become perforated, and that syphilitic perforation will oftenest take place at the junction of the cartilage and skin portions. These observations may be supplemented by one of Bosworth's,[36] that "syphilitic ulcerations show a marked hesitancy in transgressing anatomical boundaries." All these observations are more or less true, but anybody with no very extensive experience will have learned that they must be taken and depended on with caution. Most perforations that are discovered are round or oval, but McBride [37] quotes Michelson who says that, "syphilitic perforations are usually longitudinal, and tubercular ones round or irregular." McBride neither denies nor does he confirm this assertion of Michelson's, he merely passes it on. Jurasz [38] tells of a case of perforated septum—cartilaginous portion—which had been published in the journals by another physician as being non-syphilitic; but which, from facts subsequently elicited, was believed to be syphilis after all, not, however, because of any particular shape of the perforation. Another interesting case reported by Jurasz may be referred to: A young man, aged nineteen, had luetic infiltrations on both sides of the septum. There were deep ulcerations besides, and the cartilage beginning to become denuded, necrosis and perforation threatened to take place. Iodide of potash brought about a comparative normal condition in a short while—the ulcerations healed and no perforation developed. A case of no less interest just because its history is somewhat indefinite, and reported by Dietrich [39] (Elbing), is instructive: Widow, aged forty five, moving in good society, whose husband had been an official. A nasal catarrh had been treated with questionable success by another medical man. Recently she had slight repeated nasal hemorrhages. In the cartilaginous portion of the septum anteriorly, there is now a perforation about the size of a half-dime. Its borders are irregular and dirty in appearance, with here and there small dirty-brown crusts. The ulceration bleeds when touched with a sound. There is a moderate amount of chronic naso-pharyngeal catarrh, but the breath is not fetid, nor is there any loss of the sense of smell. Syphilis not being suspected, the ulcerating perforation was looked upon as simple, and cure was thought certain within a short time. The ulceration was treated galvano caustically according to Voltolini's recommendations; but, instead of healing, the ulcerating perforation slowly but surely enlarged, and the nose had become slightly flattened. Syphilis was now looked for, but nothing pointing that way, except that the lady was childless and had aborted four times, could be found. She was given iodide of potash, and immediately everything prospered to a surprising extent. The ulceration began to heal, and finally cicatrized perfectly; and the chronic catarrh also improved very much.

These cases, aside from their intrinsic interest, offset the *obiter dicta* of the distinguished authors quoted a while ago; but in connection with Dietrich's case, a reflection from Sir John Hutchison [40] is worth remembering; even when there is a clear history of syphilis, "if the ulceration be slow, and without tendency to diffuse inflammation, or exfoliation of bone, it will usually be found that the internal treatment by specifics does very little good, while local treatment will cure."

May not a perforation have existed before syphilis was acquired? And, is it not a valid question to put, may not perforative influences work their effects, even while syphilis is doing its share of evil in the same body? A syphilitic history surely does not make all pathological phenomena syphilitic.

Rheumatism may give rise to septal perforations due perhaps to a rheumatic perichondritis. Mackenzie [41] refers to French journals on this head, and quotes a case from Roger: Young man, severe articular rheumatism and well marked cardiac symptoms, lost a portion of the cartilaginous septum, the size of a grain of rice, two months before he died.

Typhoid, typhus, and other fevers may give rise to ulcers on the nasal septum which end in perforation. But these are very rare and exceptional eventualities. Gelli [42] reported a case of a young man of sixteen, who, during an attack of typhoid fever had a good deal of nasal hemorrhage, from the beginning to the end. During the fever he emaciated very much. The nasal septum was thin. In this case the septal ulceration progressed, and perforation of the septum was the result; and all because, it was supposed, the patient picked his nose so much.*

Diphtheria gives rise to extensive intra-nasal ulcerations and even necrosis of the bones. Chiari reports such a case. This disease may just possibly give rise to septal perforations.

Carcinoma has been known to perforate the septum. Hajek [43] came across such a case. Metastatic carcinomatous deposit in the septum broke down and left a hole.

Local Inflammatory and Allied Processes.—In the course of his description of the sequelæ and complications of chronic coryza, Massei [44] says that ulcers develop under crusts deposited on the surface of the mucous membrane, and that this occurs oftenest in people whose labor obliges them to inhale air laden with irritating substances. He also avers that the lower turbinates are the common sites of this process, but that the same process may take place on the septum and perforate it. These ulcerations and perforations, says Massei, may affect the lamina perpendicularis of the ethmoid bone and the vomer, and that the lower anterior portion of the septum almost always escapes.† This may be true for Italian noses. Moritz Schmidt, on the other hand, locates the encrusting and erosive process at the anterior cartilaginous portion. Bresgen and others, ditto. J. Solis Cohen [45] has a description all his own under the heading of Chronic Coryza, and the sub-heading, Fetid Coryza, which reads (after mentioning that the disease having existed some years, destroying mucous membrane and bones), "so that the cartilaginous septum is in many instances found to have been pierced through, sometimes in one or two small perforations, but more frequently in a single large irregular hole, perhaps admitting the end of the little finger, or the end of a larger one, and looking as if it had been gouged out with some rude tool." [46] These two pictures of "chronic coryza" ‡ strike one as being made up of different and distinct diseases, are confused and exaggerated. They differ as to the location of the ulcero-perforative process.

D. Newman, of Scotland, and J. N. Makenzie, of Baltimore, Md.,[47] have found the anterior (cartilaginous) portion of the nasal septum perforated in laborers working in chromic-acid factories. Toeplitz, of New York,[48] examined thirty-nine laborers employed in a single arsenic (Schweinfurth Grün) factory, and found nineteen of them with perforations in the cartilaginous portion of the

* Dr. George F. Shrady has kindly given me permission to mention the following case of perforation of the cartilaginous portion of the nasal septum due to typhoid fever, which occurred in his practice years ago. The patient was a girl (the child of a friend), about ten years of age. The fever was of a prolonged tedious type, but the temperature of which never at any time went above 102⅘° F. About the fourth week of the fever, nasal bleedings occurred, and an ulcer was discovered on the cartilaginous portion of the septum. This was readily noticed because the child had wide and prominent nostrils. In a short time the ulcer developed into a perforation. Dr. Shrady is positive that nose-picking had nothing to do with causing the ulcer to develop into a perforation.

† Note to Massei.—On page 124 Massei has a section devoted to "simple catarrh," in which crusts develop on the anterior portion of the septum which irritate, and which in connection with nose-picking with the fingers result in ulceration and perforation of the nasal septum.

‡ Note to Cohen.—Both Cohen's and Massei's pictures refer apparently to the same mixed pathological conglomeration of diseases. It is proper to state that both M. and C. are cognizant that they are depicting mixed pathological conditions.

septum. Eight others who had not been employed for so long a time in this factory had ulcers varying in size and depth on the septum, apparently on the way to perforation. In none of these arsenic cases were the bones affected. Alexander G. R. Faulerton,[49] of England, found a hole in the cartilaginous portion of the septum (anteriorly) of a man who happened to be a cement worker. On this single observation speculations as to the rise and progress of septal ulcers were based that have been quite generally adopted, even by Zuckerkandl, as though Faulerton's assumptions had the sure basis of comparative statistics and wide discriminating observation. He stated, without giving any proofs, that such septal perforations are found often in cement workers. So much made "sure," a "rationale" was easy to manage, and thus: Cement dust causes rhinitis; then formation of crusts; irritation from these which is relieved by picking at the nose, then ulcer in consequence, finally further nose-picking, until ulcers become perforations. This is simple, but all on the surface, and leaves much out of account. However, R. Otto,[50] of Dorpat, Russia, after having examined thirty cement workers, found only one who had a perforated septum.

The number of people who bore about in their noses is very large, and yet in comparison how few septal perforations are discovered. No doubt after an ulcer has been started, whatever the cause be, digging about in the nose may accelerate a progressive ulcerative process. As a rule, people do not hurt themselves when they can avoid it, and when picking into the nostrils for the removal of crusts or for counter irritant effect, hastens or favors perforation, some grave pathological change in the septal tissues may be assumed. Normally the mucous membrane heals very rapidly and thoroughly, and when it will not do so something is wrong with it, and the rhinologist will not use his drills, chisels, saws, scissors, knives, and cauteries. Surely picking at the nose does not determine tuberculosis, scrofula, lupus, and syphilis to seek the cartilaginous septum for ulceration and perforation. Furthermore, do not catarrhal ulcers so-called heal in spite of nose-picking when they occur in healthy people? Yes. Perichondritis and abscess of the septum not due to scrofula, Friedreich[51] said, almost always end favorably, and without leaving deformity of the nose. But Wunderlich[52] and Duchek[53] affirmed, in a general way, that those affections may leave a perforation of the septum or destroy it entirely, and leave the nose flattened and deformed. These processes may obstruct the nasal passages partially or entirely, they may affect only one side of the septum or both sides, they may be located high up and posteriorly, or inferiorly and away to the front. So said Wunderlich. These observations have been confirmed by rhinologists of our day, and from cases that they have reported, I shall refer to one of D. Bryson Delavan's.[54] An otherwise healthy girl, sixteen years of age, had a very severe septal perichondritis and abscess on both sides of the septum, and perforation took place near where the bone and cartilage unite. After proper treatment the perforation closed up and only a scarcely noticeable amount of flattening remained. Whether or not oval or round openings of a permanent character remain after the acute symptoms of these maladies have subsided, it is impossible to affirm positively.

Theodore Harke,[55] in his post-mortem examinations, came across an interesting case of facial erysipelas and hemorrhagic naso septal lesion that may be mentioned here. Erysipelas affected the right ear and the face. The mucous membrane of the nose was generally red and congested, and covered with muco-purulent masses. Under the mucous membrane and perichondrium of the left side of the septum, a diffuse hemorrhage had taken place, involving all the cartilaginous and one half of the bony portions of the septum. There were no signs of abscess formation. The covering mucous membrane was of a dark-greenish color. Would necrosis and perforation have followed in this case if the patient had lived? It is possible.

Perforating Ulcer of the Nasal Septum.—Weichselbaum, Voltolini, Sir J. Hutchison, Sir James Paget, Jessop, Hajek, Zuckerkandl, Rossbach, Freudenthal, and others, have reported cases of perforating ulcers of the nasal septum. Analogically, they have been compared to perforating ulcers of the foot and those of the stomach. All authors agree that they have necessarily nothing to do with syphilis or tuberculosis. The majority of German writers opine with Weichselbaum and Hajek, that they are a local affection due to parasites. Taking all the developmental theories and their shortcomings into account, one may conclude that the real or essential causes of perforating ulcers of the septum are unknown, or else a number of various causes and influences have to do with their origin and development.

These ulcers are found in people who have neither syphilis nor tuberculosis. They are found in people who have died of tuberculosis and were suffering from tertiary syphilis. They have been found in those who have had syphilis; and in those in whom syphilis is active. One-third of Hajek's [56] cases of septal perforations were tubercular subjects, and all of Weichselbaum's [57] sixteen cases had succumbed to tuberculosis. None of my five cases were tubercular. These perforations may vary in size from that of a lentil to that of a twenty-five cent piece. Usually there is only one, but two and more have been observed in the same septum.

Their pathological history may be divided into three stages: A preparatory, an ulcerative, and a perforative stage.

As to the first stage, a number of opinions, none of them even similar, have been advanced. A favorite opinion is hemorrhagic, after some manner or other. Voltolini [58] fancied that hemorrhage from some ruptured venule or arteriole was the origin of the progressive ulcerative process, with the vesicular or arterial break as the centre of ulceration. Nasal hemorrhages are very common and frequent, and usually from the septum; but septal perforative ulcers are rare and uncommon in comparison. This theory of Voltolini is a mere guess; and Voltolini did not think of explaining or guessing at the tissue changes in the vessels that must precede the vesicular break and predispose it to spread peripherally, nor did he enlighten us about the causes that must be at work after the ulcer was progressing, nor finally by which influences it was stopped short. These ulcers begin on both sides, at symmetrical points, simultaneously sometimes; and, in such cases we should be obliged to assume like conditions on both sides. And nobody ever saw such a condition of affairs.

Dietrich's [59] theory is an advance on the logic of Voltolini. He posits that the nasal septum is very vascular and the circulation slow, and thus prone to thrombotic and depraved local nutritive troubles. If injury to the mucous membrane like that caused by nose-picking starts an ulcer, then the succeeding steps of the progressive ulceration, it is supposed, are easily imagined. And that is not the case. This theory, too, ignores many antecedent and post-ulcerative influences. Dietrich holds that the presence of bacteria in the ulcer is accidental and not essential or causative.

Zuckerkandl [60] has given us the most elaborate and plausible of all the hemorrhagic theories; but his theory is weak and comes short of science, because it does not in most instances cover clinical experience. After long mechanical injury of some kind, as boring about in the nose with the finger or inhaling irritant substances, hemorrhages into the mucous membrane take place, and at last a condition known by him as zanthosis is developed. The mucous membrane assumes a yellowish appearance and has become atrophied. The blood vessels have in the meantime undergone degenerative changes. If bacteria and cocci now get a chance to invade the parts, they overcome tissue resistance so successfully that perforation quickly follows ulceration. Most cases of perforating ulcer reported by clinicians have not shown up that way. At any rate, my five cases did not.

Rosenfeld's[61] (Stuttgart) theory is not hemorrhagic, but neuropathic. It is traphoneurotic; and it is peculiar because he locates the ulcers so high up as to be out of the reach of the finger nail, and from the fact that he claims to have seen these ulcers develop from within outward; that is, it is said that he has seen cases in which perforations developed under necrotic mucous membrane. This theory hobbles along without the help of germs, primary degenerative vascular changes, or sinister hemorrhages, or finger-nail pickings, or finger-nail toxic local infection. This theory, too, accounts for but little that clinical observation uncovers—it is but a match struck in the dark, and just lets us know how dense the darkness is.

And now for the bacterial theories. Frankel's[62] opinion respecting parasites carrying havoc and destructive ulceration, and finally perforation, into Jacobson's organ, runs counter to so much clinical experience, that merely to be mentioned is about all the attention it deserves.

Hajek's theory also limps. As the first step he finds a limited area of mucous membrane, or dotlets thereof, discolored a dirty gray, due to the formation of a pseudo-membrane and degeneration of the epithelium. There is nothing passive about this discolored spot. It is destructively active, and it is assumed that the greatest amount of activity is at the central parts. The membrane becomes disorganized, and makes room for the ulcer, which has sharply defined borders. This ulcer shelves off toward the centre, where it is deepest. In time the ulcer becomes something like a terrassed cone—the point at the centre, and its base bounded by the borders. At the beginning of the ulcerative period detritus of pseudo membrane and coagulated blood may be found hanging to the surface of the ulcer or to the borders. Later on muco-purulent crusts may form over them and hide them, but the destructive process continues; and scarcely ever is this known to the patient. The mucous membrane, the perichondrium, and the cartilage having become perforated, healing may set in and become complete by leaving a thin tapering-edged hole in the septum. Possibly healing may take place before the perichondrium has become implicated, but if this does occur, it does so for reasons unknown. Often these perforations are seen with their edges still ulcerating at points, and necrotic cartilage jutting beyond the mucous and perichondrial coverings of the septum. Before complete healing has become established, it is said the mucous membrane may or can be lifted from its subjacent tissues, and the perichondrium from the cartilage. This could not be done in any of my cases. This malady does not go on without some reaction at or near the borders of the ulcer, and around the blood-vessels; but for the most part the process, taken as a whole, simulates a local gangrenous process. And all these changes, say Weichselbaum and Hajek, are caused by bacteria and cocci; especially, according to Hajek, to streptococci pyogenes and staphylococci pyogenes aureus. Those cocci do not wander away from these foci of ulceration, but continue to play high jinks there until perforation has taken place; and the edges of the perforation having become healed, they

> "Fold their tents like the Arabs,
> And as lightly steal away."

These ulcerative perforations constitute a disease sui generis—a specific disease, and says Sir James Paget, "the definite shape (of the perforation) may be a characteristic of their being due to parasitic influence, just as are the definite shapes of parasitic diseases on leaves." However all this may be, neither Weichselbaum's nor Hajek's bacteriological investigations have disclosed anything of a specific nature. The clinical significance of what has been said concerning perforations of the nasal septum may be summarized by saying that they vary according to their etiology and pathology:

1. Congenital or developmental perforations are extremely rare; and, if we must believe authorities, they are of two kinds at least: (*a*) Those due to perverse or arrested development, such as are hinted at by Harrison Allen, and of which Germs' case is an instance; (*b*) those due to a pathological process implanted on the developing tissues, such as are hinted at by Klebs, and which a number of observers believe they have seen. Concerning this field of observation we know positively very little, and large opportunities here await the scientist.

2. Perforations due to severe direct violence, and contiguous pathological processes must tally with the injury received or the growth giving rise to them. These also are rare occurrences.

3. Perforations due to constitutional influences are usually accompanied by the signs and symptoms peculiar to those diseases, respectively, while the perforation is developing. Besides, the various local manifestations of the respective constitutional diseases crop out at other points of the intra-nasal mucous membrane, although that of the septum is a favorite site with all of them. They very rarely develop septal perforations, and when they do, other manifestations, peculiar to any special one of them, show up with the perforation. In most cases even syphilis is no exception to this last remark; although syphilis may leave a perforation which bears all the marks of the so-called "perforating ulcer of the nasal septum," according to Jurasz and other observers. However, the clinical history, and a course of experimental therapeutics, will differentiate them when any doubt as to their respective character exists. The mere existence, however, of a history of syphilis in a patient is not positive proof that the perforation has been caused by syphilitic influences.

4. Purely inflammatory affections of the septum—perichondritis and abscess—may give rise to perforation (even to the extent of nearly half an inch in diameter, as in Delavan's quoted case) during the inflammatory process, but the defect is apt to heal up again with more or less or no deformity. It may be just possible for a typical roundish or oval perforation to result; but whether such have been seen is not certain.

5. Most perforations that are discovered by many observers are almost always found located in the cartilaginous portion of the septum, and are roundish or oval-shaped, their long axis being parallel with the long axis of the cartilaginous portion of the septum. According to the majority of observers, they have nothing to do with syphilis etiologically in most instances. They are in most instances probably purely local gangrenous manifestations, possibly due to bacterial influences, possibly due to local tropho neurotic causes, possibly to a combination of many causes; but the true nature of this disease still remains to be discovered. There has been nothing wrong with the mucous membrane or the other intra-nasal tissues beyond the ulcer or ulcerating perforation, in many of the cases that have come under observation, according to the testimony of a number of authors.

Therapeutics.—Patients with ulcerations on, and perforations in, the nasal septum, when these lesions are not discovered casually, come to be relieved from the nasal discomfort caused by crusts blocking up the nasal passages, etc.; or they come to have small intermittent nasal bleedings checked; or else, in rare instances, on account of whistling noises which occur when the air is quickly or forcibly inspired, and such cases have been observed by Bosworth, L. Bolton Bangs, Hutchison, Jessop, and others.

The successful treatment of ulcers demands, first of all, that the causative pathological influences be done away; and next, that the best favorable conditions be established, with local and general remedies, for aiding the recuperative forces of the local tissues to cover the losses they have sustained. When this is not or cannot be done, cure will be impossible.

The aggregate experience of all observers allows the conclusion to be drawn that simple perforating ulcers and perforations cannot always be differentiated, by

appearances, from those developed by syphilitic influences. When this happens, specific treatment with mercurials, and iodide of potash, etc., will, so far as is known, clear up the diagnosis. The syphilitic ulcerations will heal under the influences of the specific drugs that have no appreciable effect on the simple perforating ulcer. Although simple perforating ulcer of the nasal septum has a stage of growth and development that prepares local conditions which favor subsequent ulceration and finally perforation, its therapeutics, unfortunately, cannot be considered after any such methodical manner. Our present knowledge of this malady obliges us to follow up the process by attacking it with only such general empirico-clinical remedies which have been found effective in other cases of tissue destruction of a non-specific character.

Freudenthal [63] reports the case of an otherwise healthy girl, twelve years of age, who came to him to be cured of persistent epistaxis. On the anterior portion of the septum a dirty grayish-white patch or deposit was discovered, besides some superficial ulceration. The borders of this ulceration were found to be congested. These finds were considered typical of the early stages of simple perforating ulcer. The remedies applied were mild astringents, which and in what strengths are not mentioned. Freudenthal saw the case only four times, and, when last seen, the ulcer seemed to be doing nicely, and, the patient not returning again, the doctor concluded that the ulcer must have healed. All of us may not concur in the diagnosis nor accept the assumed therapeutical optimism. However, a case of mine, already referred to, will not be out of place alongside of this one of Freudenthal's: A young man and student, aged eighteen, quite a cigarette smoker, came to me on account of bleedings from the nose, besides (right) orbital pains that radiated from the nose. Examination revealed a flat triangular ulcer on the anterior portion of the right side of the septum. The ulcer (very superficial) was about the size of a three-cent piece, with sharply defined borders that were not particularly congested or swollen. Its surface was very finely granular, but did not bleed when touched with a probe. There was some hyperæsthesia at and near the borders, but not over the surface of the ulcer. There were no crusts, nor pseudo-membranal detritus, nor dried blood on or about the ulcer. He admitted that he picked his nose, but only to get rid of crusts; and then his nose would bleed, after which the orbital pain would subside considerably. This young man was not strong and robust, but not any more anæmic than one would expect to find in a person confined to rooms. He complained of malaise which might be attributed to tobacco or malaria. There was a slight amount of naso-pharyngeal catarrh.

To the ulcer itself I applied a scruple to the ounce solution of nitrate of silver; and to the nose and pharynx a three-grain solution of the same metal. Internally he was given

Ext. nux vomica,	
Ext. hyoscyamus	āā gr. ½
Quinine sulphate	gr. iij.

four times a day. He was given general and local advice, and

Hydrarg-rub. oxidi	gr. v.
Vaseline	ʒ j.

M. Ft. unguentum,

to be applied to the ulcer. Two weeks later I saw him again. Generally he felt better. Locally, appearances seemed better, although the ulcer had not diminished in size; it had not bled because crusts had not formed as often as had been the case before, and besides he had not been tempted to pick at his nose as often. The orbital pain was still present, but came less often, and was not nearly so severe as it had been. He now went off on his vacation to the mountains.

The ulcer was thought to be simply catarrhal; and its size was attributed to the finger-nail injuries. There was no sign of zanthosis here, nor interstitial hemorrhages, nor pseudo-membranal deposits, nor varicosities. I hoped with better air, more exercise, etc., the young man would return to his studies in the fall with an intact and sound nasal septum. But when he returned, several months later, I was surprised to find an oval perforation in the septum, and other typical appearances. During his vacation his nose did not trouble him in any way. At places the mucous membrane had healed over the cartilage, but at other points the necrotic cartilage jutted beyond the perichondrium and mucous membrane, and the tissue struggle for cicatrization was going on. This condition of affairs reminded me of a case of gangrene of the auricle in a child that I had treated at the New York Eye and Ear Infirmary. This gangrene originated from chicken-pox. And here, too, the cartilage (necrotic, of course) jutted beyond the limits of the skin and perichondrial tissues.

For hastening the process of cicatrization in these cases, scraping away necrotic tissues, and applying nitric acid have been recommended and practised by Jessop. Others have used the solid nitrate of silver. Sir J. Hutchison has used and recommended the acid nitrate of mercury. The electro-cautery was recommended by Voltolini and others. Hutchison [64] also used the yellow oxide of mercury salve. Whatever active treatment in the way of curetting and caustics is resorted to, too much irritation and destruction of nutrient tissues (mucous membrane and perichondrium) must be scrupulously avoided. And even then, in spite of careful constitutional treatment and observant local care, this healing process will sometimes continue to remain tedious, and even refuse to heal; because we fail to influence the cause, of which everybody is, as yet, ignorant.

HINTS ON THE TREATMENT OF ECZEMA.

By MARTIN F. ENGMAN, M.D.,

ASSISTANT DERMATOLOGIST TO DEMILT DISPENSARY; LATE ASSISTANT DR. UNNA'S KLINIK, HAMBURG; EX-HOUSE SURGEON NEW YORK SKIN AND CANCER HOSPITAL.

In giving the treatment of different forms of eczema, a classification according to its etiological factors and a short and concise description of the different forms so classified, will assist us materially.

Eczema is a word applied to a class of skin affections of which we know too little. The definition given by most of our standard authorities is, that it is a catarrhal inflammation of the skin producing a multiformity of lesions, papules, vesicles, pustules, etc.

With an eczema we should have in some part of its course a discharge of some character, either serous or pustular. The term is one that has been and is too widely used to express conditions which do not fill all that the definition requires. A thorough knowledge of the pathology of many of the so-called eczemas, I am sure will take from this wide cover-word some of its oldest occupants, and give us a more exact and practical knowledge.

Eczemas are popularly divided into acute and chronic, and subdivided into papular, vesicular, or pustular, according to their clinical and objective symptoms. They are also named from their location and manner of progression. This classification gives us some forty different forms. Of course such terms are very well for methods of description and give us an exact idea of the condition and its appearance. Yet for one who is not familiar with all of these technical terms, it is bewildering and confusing; so for matter of convenience, of the moment, I will give below a simple classification according to the etiology, and try to give in a few words a description of the different forms.

In treating an eczema or any pathological condition of the skin, one must not forget that it is an important and active organ of the body; having its work to perform, through its glands, vessels, and nerves, as the liver or kidneys. It is an excretory organ of the greatest importance.

Again, one must remember that it is subject to all the external influences, heat and cold, irritants both organic and inorganic. No portion is free from organisms. If scrapings be taken from any part of its large surface and examined, cocci and bacilli will be found in great quantities. Therefore in treating and observing the condition and course of an eczema, we must take into consideration all of these influences. Many of the complicated appearances of an eczema are produced by calling into active life some of these many organisms, as the catarrhal inflammatory condition gives them soil and food for growth and development, while some internal derangement may be at the same time producing these suitable media. Again the eczema may be alone caused by the organism or organisms having been brought into activity or contact with the skin from unknown external causes.

We will divide eczema into two general classes, any form may of course be acute or chronic, according to the duration: 1. Neurotic eczema. 2. Irritative eczema; *a*, caused by irritants or poisons from within the body (internal); *b*, caused by irritants or poison from without the body (external).

As was said before, to conform to our standard definition of an eczema, one should have a catarrhal inflammation associated with papules, vesicles, or pustules. The so-called trade eczemas are from traumatic or chemical influences and should be classed with the dermatites.

In giving the above division we do not, of course, include all the varieties in an exact and precise manner, but for the purpose, as to hints for treatment, it will suffice.

1. Neurotic eczema is a catarrhal inflammation of the skin produced by reflex or neurotic causes. It is symmetrically distributed, more or less in the course of the nerves, has marked exacerbations and remissions. Occurs mostly in children, but affects also adults. The disease is typically eczematous, the papules forming quickly into vesicles, which easily rupture and discharge freely. The crusts are very thick and tough, as the serum seems to quickly dry, covering the surface. The disease occurs more or less in patches, of varying size from that of an inch in diameter to the covering of a whole limb. The patches are rather sharply defined with vesicles and papules at the periphery. There is great pruritus, and from inoculation by the scratching the crust soon becomes very black, from the dirt and organisms. If the crusts are removed a weeping, inflamed surface is exposed, but the discharge again rapidly crusts. The pus organisms seem to find favorable soil in the discharge, as one often sees punched-out ulcerations on removing the crusts.

It may be located anywhere upon the body, but usually seeks the external surfaces of the extremities, and the head and face. In children we see it located mostly on the face or head; occupying the cheeks, chin, but leaving peculiarly the region immediately around the mouth perfectly free. There is a very little thickening of the skin, as it can be pinched up easily if the thick crusts are thoroughly removed. I think here the crusting and scaling is quicker than in any other form of eczema. We have though in adults, in the nervous and debilitated with cold and clammy hands and feet, a form of neurotic eczema, whose only exhibition is a few transient vesicles very itchy and troublesome, with possibly a little scaling.

If each case of a symmetrical eczema answering to the above description be carefully studied, one will find exacerbations and remissions occurring with some derangement of the health, maybe only some slight thing, but will act powerfully reflexly.

I have seen many cases where the eczema will clear up on the cutting of a tooth; when another is forcing itself through the gums a fresh attack will occur. In children it occurs with the numerous bowel disorders, diarrhœa or constipation, with indigestion. Cases have been cured by thorough stripping of an adherent prepuce or circumcision, the adherent prepuce and retained smegma causing violent reflex irritation. I have now such a case under observation, which has entirely recovered after circumcision, without any local treatment whatever. In women we have the disease occurring with the menstrual flow, and with ovarian troubles.

It is of course often very difficult to find the cause of the reflex irritation, but in a catarrhal inflammation of the skin, symmetrically distributed over the body, with papulæ and vesicles which quickly discharge and crust we should look for a cause of reflex irritation, which may be one or more of the many disorders that affect the economy. Such should be looked into and treated as they generally are, using such remedies on the skin as will reduce the itching, influence the vessels, prevent crusting, and render the subjective discomfort of the patient more endurable. In other words, use sedative astringent applications as in any acute or subacute eczema. (Dr. Dyer, of New Orleans, and Dr. Barham, of Pittsburg, have written some interesting papers on neurotic eczema; the former on the disease in children and the latter in adults.)

2. *Irritative eczema* is a catarrh of the skin produced by poisonous or irritative influences: (*a*) from within the body, as those occurring in Bright's disease; in rheumatism and gout; in cirrhosis of the liver and other hepatic diseases; in ptomaïne poisoning and disturbances of the chylopöetic system.

(*b*). From without (external), which are parasitic in origin.

(*a*) It would be very difficult, moreover dogmatic, to draw a sharp line of clinical difference between the first subdivision of irritative eczema and that of the neurotic type, yet I think there are certain points which are distinctly different and assist one to a proper etiological diagnosis.

How the irritant or poison acts in being excreted, I am unable to say, but that such poisons do cause eczematous conditions clinical experience teaches every day. The skin being an active execretory organ, is inflamed and irritated generally, or in certain parts by these pathological products.

This being the case we, of course, would expect to find the disease occurring at points of active secretion, which is generally so, but I believe external irritation, mechanical or chemical, is a most important determining factor; the skin being in such a condition from the constant irritation of these poisons that the slightest violence to its texture will cause an outbreak of an eczema. In many cases we find it occurring on the instep or ankle, from irritation and rubbing of the shoe where ordinarily such irritation would cause no disturbance whatever. Again, it is frequent on the neck from the collar or shirt. In like manner in any situation that may be subject to irritation; the scratch of a pin or prick of the nail causing or starting an outbreak, which may slowly extend over the whole or part of the body, the action of the deleterious products remaining the same.

The clinical symptoms of an eczema so produced are not widely different in their ensemble from one of the neurotic type, yet there are some characteristic features which point to its proper diagnosis.

The disease may occupy any portion of the body; it is indolent in character, the inflammation starting with mild burning and itching, gradually increasing in intensity to papulation, vesiculation, and weeping. The outbreak is not acute and violent, covering large areas at once, as in the neurotic type. The patches are not sharply defined but shade off into the apparently healthy skin. The itching is of moderate intensity. The impetiginous element is very rare, as the discharge does not seem to be as suitable for the propagation of the organisms as in the neurotic, in which we find thick, dirty, pustular crusts.

Crusting and scaling is not so marked, the crusts being thin and moist, of yellow color and easily detached, leaving a reddened weeping surface. There is generally thickening from the beginning, which increases more rapidly than in any other form of eczema. The inflammatory changes here are deeper than in other forms, and there is a greater cell diapedesis and infiltration. The infiltration gradually shades off into the healthy skin, and can always be readily made out; in fact, the whole tendency of the process seems to be toward a subacute or chronic type.

The principal points of difference between this and a neurotic eczema, are: (1) The location, not following at all the course of the nerve distribution. (2) The patches are not sharply defined, but gradually shade off into the healthy skin. (3) The subjective symptom is more of a burning sensation than an itching. (4) The crusts are yellow, thin, and moist, not dry and thick. (5) The skin is found to be infiltrated after removing the crusts. (6) The indolence of the process. (7) It is found most frequently in adults, and those who have passed middle life.

The treatment of such inflammatory conditions should be both internal and local.

The history of the patient should be carefully inquired into and a thorough examination made of the general health. The urine examined for albumin, casts, and sugar, for urates and uric acid, etc.; any abnormal constituents being carefully noted.

In old drinkers we find cirrhotic changes with probably albumin in small quantities, with casts. In the rheumatic and gouty, highly acid urine with full, excited pulse; often such individuals will predict a crop of eczema by the color of their urine, noticing it to be highly colored and "burning." In the later cases of Bright's disease, where little urine is passed, and the kidneys thoroughly inactive, we often see very severe cases of eczema. I remember three cases of Bright's where death occurred after a violent outbreak of eczema.

It would be useless here to go into a *résumé* of the treatment of gout, rheumatism, and Bright's disease, for I merely wish in connection with this form of catarrhal inflammation of the skin, to point out the importance of careful research into the general health of the patient.

(*b*) The second subdivision of our irritative eczemas, that is, those caused by the effects of external irritants, is comparatively a new field in dermatology, and one which promises much for the future.

With this class are included the parasitic eczemas. As was said before, the so-called trade eczemas should be classed with the dermatites and not here. Although, as in many other diseases, the parasites for these several conditions have not been isolated, yet there are sufficient clinical reasons for treating them from a parasitic stand-point, and often be surprised with the happy and rapid results.

In this class would be included the eczema seborrhicum of Unna, who, in 1887 read a paper before the Congress of Washington, demonstrating this affection, beyond a doubt, to be a catarrhal inflammation of the skin, probably of parasitic origin, and showing the erroneous ideas of the old masters in relation to the so called seborrhœas. From further study and research Dr. Unna is more convinced of the correctness of his observations in this matter, and also of the parasitic origin of eczema seborrhicum, believing his Morrorcocci to be the specific cause, as he finds them in the scales and horny layer of the diseased patches. The disease begins as a pityriasis of the scalp, which may have existed for years, extends down over the face, neck, or it may invade any portion of the body, but a pityriasis or "dandruff" of the scalp will always be found accompanying it. The eczematous patches may vary from a small, greasy, scaly, yellow patch to one of intense weeping, with highly marked inflammatory symptoms.

The disease is generally characterized by well-defined patches, varying in size, with abrupt borders. The patch is covered by yellow, greasy scales, which are easily detached. It spreads peripherally, clearing up somewhat in the centre; therefore one or more patches may coalesce, forming patches of various shapes. Its favorite location is the neck, face, back, and chest, but may occur in any portion of the body. There is not much itching except when the patient is overheated. The disease is generally superficial, with no marked thickening of the skin, but often there are patches of infiltration resembling a psoriasis lesion.

Another type of parasitic eczema to which I can only here briefly refer, is a form that was first pointed out to me by Dr. George T. Elliot, of this city. Since then I have studied the condition closely, and thoroughly agree with him in considering it of undoubted parasitic origin and differing markedly in its clinical appearance from the eczema seborrhicum of Unna.

The majority of cases that I have seen occur in varicose conditions of the legs, and an eczema here, we all know, to be of a very stubborn and persistent character. These cases, which have existed for years under soothing applications, internal medication, and bandaging, I have seen markedly benefited and cured by active parasitic remedies. The leg is, of course, subject to other forms of eczema, but I have found the parasitic vastly in the majority, from the non resisting powers of the cells of the leg in those past middle life. Again, it is very frequent in those whose hands are frequently exposed to water, in housewives, working-girls, barkeepers, waiters, etc.

The disease occurs as an undermining of the epithelial layer, a splitting or peeling up of the epidermis, with few papules or vesicles here and there, all enclosed in sharply defined patches.

The intensity of the process and the objective symptoms depends, of course, somewhat on the activity and amount of the poison; on the location and on the peculiar idiosyncrasy and susceptibility of the individual. Therefore we may have a sharply defined patch of the disease, with only slight scaling and a peripheral undermining and splitting up of the epidermis, to an intensely inflamed one, raised slightly above the surface, deeply red, with hemorrhage into the follicles, and the characteristic progression by splitting up the horny layer at the borders.

The disease though as usually seen consists of well-defined red patches, varying in size, slightly scaly, dotted here and there with papules, but with relatively few of the latter. The borders sharp, and if closely noticed the horny layer will be found to be loosened, peeled up, and can be pulled off in large, thin laminæ. There is very little itching or burning. The patches spread peripherally, several may coalesce, but there is generally only one or two in a locality, the disease spreading from these over a leg or arm in a more or less serpiginous manner. The milder cases have a tendency to heal in the centre leaving a slightly yellow pigmentation. The whole affection, as usually seen, is very dry and only slightly scaly unless it is greatly inflamed.

The favorite location is the hands and arms, legs and feet, the face, as these portions of the integument are more exposed to external influences. But I have seen the disease generally scattered over the whole person in small, sharply defined red patches. It can readily be differentiated from eczema seborrhicum by 1, the color of its patches, which is decidedly red, while that of eczema seborrhicum is yellow; 2, the scales here are dry, and not yellow and greasy; 3, the characteristic undermining and splitting up of the epithelium in this form, which you do not see in any other form of eczema. It mostly resembles the orbicular eczema of the text-books.

The disease is undoubtedly a parasitic one from its clinical manifestations, and is readily cured by proper parasitic remedies.

I bring these few points forward, not to stand on a high pedestal of dogmatism and to grandiloquently wave each case, after a mere glance, to its proper etiological division, but hoping that they will help some one to a more definite and comprehensive knowledge of the subject.

131 East Thirty fourth Street.

Progress of Medical Science.

The Relation of Chololithiasis to Primary Carcinoma of the Gall-Bladder.—According to Dr. Ames two directly opposite views are held respecting the relation of gall-stone formation to cancerous growth in the gall-bladder. According to such men as Klebs, Von Schupple, Murchison, Durand-Fardel, Krauss, Zenker, and others, the new growth may be directly attributed to the prolonged irritation produced by gall-stones, especially in persons predisposed to cancer. Zenker holds that an adenoma develops by irritation, and that it changes into an adeno-carcinoma, which is the primary atypical growth. On the other hand, Lutton, Lancereaux, Lang-Heinrich, Förster and others hold that the presence of the neoplasm favors the formation of calculi, and is the cause, not the result, of gall-stone formation. It is a well-recognized fact that biliary concretions are found in a very large percentage of cases of carcinoma of the gall-bladder. In Courvoisier's list, the percentage in which stones were actually found was 91 per cent. There is good reason to believe, however, that these figures should be larger, as in a number of cases in which calculi were not found there were such evidences as scars and strictures of the ducts to show the former existence of chololithiasis. In Musser's cases the percentage was 92 per cent., while in those that I have collected stones were found in 20, were noted as absent in 1, and were not mentioned one way or the other in 7, making the percentage of cases with, to those without, concretions, 95.4 per cent. These figures are too great to allow us for an instant to suppose that the association of these two conditions is merely accidental. The most important point to be settled, and the one which it seems would be conclusive, is whether the formation of gall stones precedes or follows the cancerous degeneration. Evidence in favor of the former view is plentiful, while that to support the latter is very meagre, though there are a number of theoretical considerations used as arguments that it will lead us too far to discuss here. I have been able to find but one case, *i.e.*, that of Ord, cited by Musser, in which a calculus existed which was definitely proved to be post-cancerous in its formation, and this stone was not a cholesterin formation, but consisted of phosphate and carbonate of lime with altered mucus. On the other hand, there are numerous observations that go to prove the existence of stones prior to the carcinomatous growth. In one of Zenker's cases, for example, fragments of calculi were found, and in the first case I have reported this evening the calculi were much disintegrated, which would seem to point to a degeneration, not to a formation of gall-stones. This fact, in connection with the long-standing history of biliary colic, is conclusive, and would lead us to believe that in all cases when there has been a previous history of biliary colic, and when no stones are found at autopsy, they have existed, but have undergone some such disintegration before the death of the patient.

Again, in one of the cases reported by Klobe an old stone was found with commencing cancer of the neck of the bladder. Klobe states it as his belief that the small size of the gall-bladder in many cases of cancer would be against the formation of calculi, while Zenker holds that the growth in the bladder and ducts would tend to prevent the bile entering the bladder, and so prevent the formation of stones. Quetsch reported a case in which stones had been passed by a biliary cutaneous fistula for

three years prior to any signs of cancer; and cases are reported in which stones were found although the cystic duct was occluded; they have also been found buried in the mass of the neoplasm. From all these facts it would seem that if we are justified in ascribing a causative influence to local irritation in case of cancer in other situations, we should look upon gall stones as exerting the same influence in these cases. Finally, in closing, we may briefly summarize the most important points, following closely the conclusions reached by Dr. Musser, as follows: 1. Primary carcinoma of the gall-bladder is much less uncommon than was formerly believed. 2. It occurs most frequently in women, the ratio being 3–5 : 1. 3. It is a disease more particularly of the middle decade of life. 4. Gall stones are found in from 91–95 per cent. of the cases, and probably bear a causative relation to the disease. 5. Metastasis is not extensive; invasion of neighboring organs by continuity common. 6. Adhesions to adjacent organs frequently occur. Ulceration and perforation are more rare. 7. Pain, jaundice, cachexia, emaciation, tumor, indigestion, nausea, vomiting, constipation, or diarrhœa, with occasional ascites and œdema, are the chief symptoms. 8. Pain occurs in 62 per cent. (Musser). 9. Jaundice occurs in 69 per cent. (Musser.) 10. Tumor occurs in 68 per cent. (Musser). 11. The disease is always fatal, and usually in a short time, the average duration varying according to the best authorities from 3 to 6⅔ months. 12. Death is due to exhaustion, peritonitis, metastasis to other organs, and to biliary obstruction.—*Johns Hopkins Hospital Bulletin.*

Intracranial Aneurism.—The subject of intracranial aneurism was discussed by Dr. Bradford, who presented the history of a case, and by Dr. White, who related the history of two cases in young subjects unaffected with syphilis or malignant endocarditis. Dr. Bradford's patient had slowly developing symptoms such as vertigo, noises in the head, and later, occipital headache and stiffness of the neck. A severe attack of vomiting was followed by intermittent pulse and retention of urine; later in the same day he became comatose, with irregular breathing, and death quickly followed without the occurrence of convulsions, or pupillary changes. The autopsy revealed a ruptured aneurism of the basilar artery.

In the cases reported by Dr. White the symptoms set in suddenly. The first patient fell off her chair while at dinner and became insensible. After regaining consciousness she had headache, vomiting, bradycardia, and a few days later retraction of the head and pain down the spine. A week later complete paralysis of the left third nerve. Then a week after this, a fit, and two days afterward she suddenly became worse and died in ten minutes. There was an aneurism of the left internal carotid near its termination. There was a large amount of clot on the under surface of the brain; it extended to the fourth ventricle, and was one-eighth of an inch thick all down the spinal canal in the subarachnoid space.

The second case was a man, who had no symptoms except slight frontal headache, until he fell down unconscious. Then the pupils became dilated and immobile, right external strabismus, and occasional spasm of extremities. On the outer side of the optic disk was a large subretinal swelling. The drawn-off urine contained sugar. Death followed rapidly after the development of symptoms. There was found on post-mortem examination, a small ruptured aneurism of the right internal carotid artery.

The Treatment of Typhoid Fever.—Of all the branches of the medical sciences it is hygiene upon which we have to look as the most promising study and the branch of medicine to which belongs the future; for, notwithstanding the great progress that has been made within the last few decades in the etiology of diseases, the treatment in many instances is not much further advanced than it was several decades ago. We still have to rely more upon scientific nursing than upon the healing powers of drugs, and in many instances the patients will do better without any medication whatever, excepting, perhaps, when it is used for the psychical effect upon the patient. The rules laid down by Sir William Gull could not be improved upon at the present day. Gull's views with regard to the treatment of typhoid fever were as follows: 1. Typhoid fever is a disease which runs a more or less definite course. It cannot be stopped or cured by medicines. 2. The chief thing to be done at the outset of an attack is to send the patient to bed, so as to save strength from the beginning. 3. No strong purgative medicines are desirable. 4. As the fever develops and the strength grows less, light food should be given at short intervals —*i.e.*, water, toast water, barley-water, milk and water, light broths (not made too strong or too gelatinous). 5. If there be restlessness or much agitation of the nerves, wine (port, sherry, or claret) or brandy in moderate doses as short intervals. This must be directed medically, but in general it may be said that the amount required is that which induces repose and sleep. 6. The bowels may be left to themselves. If unmoved for twenty-four or thirty-six hours a lavement of warm water may be necessary, but this will be directed medically. 7. The restlessness or wakefulness in fever is best remedied by the careful giving of wine or spirit with the food, or in hot water. Sedatives such as opium are inadmissible—mostly injurious. 8. The bedroom to be kept at a temperature of 62° to 65° F. 9. Great care is necessary to keep the bed clean and sweet. This is most easily done by having a second bed in the room, to which the patient can be removed for two or three hours daily, while the other is thoroughly aired and the linen changed. 10. All fatigue to be sedulously avoided. No visitors admitted, and no other person but a nurse and one attendant to help her. 11. Patient's room never to be left unattended for a moment, as in the delirium of fever patient may jump from the bed and injure himself. 12. As to medicines and the treatment of complications, the immediate medical attendant must be responsible. 13. As it is possible that the discharges from the bowels in typhoid fever may be a source of contagion, it is desirable that before being thrown down the closet they should be largely mixed with Condy's fluid or some other disinfectant. On the same principle the strictest cleanliness must be observed in the sick-room. 14. There is no reason to believe that typhoid fever is contagious from person to person, in the ordinary way. The largest experience shows that it does not extend, like an ordinary contagious disease, to nurses or others attending upon patients suffering under the disease.—*Medical Review.*

Jejunostomy.—According to Dr. Hahn the fistula must be made high up in the small intestine, otherwise death will occur from inanition. The author refers to the recorded cases of jejunostomy, especially by Maydl. He thinks that the making of a fistula in the duodenum, as has been proposed, is undesirable, owing to the difficulty in the operation and to the impossibility of the patient feeding himself. Dr. Hahn gives details of five cases in which he has performed jejunostomy. Case I.—A man, aged sixty-nine, suffering from gastric carcinoma, recovered from the operation, but died a fortnight later with increasing weakness. Case II.—A patient with œsophageal carcinoma improved after the operation. Nine weeks later the fistula closed, and the feeding took place exclusively by the mouth. Case III.—A man, also with malignant disease of the œsophagus, died four days after the operation of increasing inanition. Case IV.—A girl, aged nineteen, attempted suicide by means of strong acid. Nearly two months later only a fine œsophageal bougie could be passed. As the sounding was followed by some bleeding, jejunostomy was performed. She made a good recovery. The fistula closed about a month after the operation. She was in good condition some three years later. Case V.—A girl, aged twenty-three, also drank sulphuric acid. About three weeks

later an obstruction was found about thirty centimetres from the mouth. There was great wasting. Jejunostomy was done a fortnight later, but the patient died some eight days afterward. The indications for the operation are, according to Dr. Hahn, the following: 1, Corrosion of the stomach and œsophagus when a fatal result is to be feared, as in the above cases; 2, carcinoma involving the cardia and lower end of the œsophagus when gastrostomy is impossible; and 3, carcinoma of the pylorus where no other operation is possible. The incision should not be too small, so that the commencement of the jejunum may easily be found. If the nutrition of the patient permit of it, the intestine need not be opened for several days, otherwise this must be done at once or after twenty-four hours.—*Deutsche Medicinische Wochenschrift.*

Diphtheritic Conjunctivitis.—In the *Gazette des Hôpitaux*, April 24, 1894, the subject of diphtheritic conjunctivitis is treated at some length by Gilbert Sourdille, who defines diphtheritic ophthalmia as the infection of the conjunctiva by the Klebs Löffler bacillus. There are two distinct kinds of pseudo-membranous conjunctivitis: the croupous form, characterized by a thin, elastic, shining, opaline false membrane, leaving on removal an almost normal mucous surface; and the true diphtheritic form, a profound interstitial infiltration, making the conjunctiva look like bacon rind, thick, blood shot, dirty-yellow, and dotted with ecchymotic spots. Unlike the croupous form, there is no detachable membrane. The first condition is benign; the second of special gravity, owing to constitutional states, to climatic influences, to various chemical and physical agents. According to Mackenzie the nature of diphtheritic conjunctivitis lies in some inherent disposition of the mucous surface itself. A question arises, as to whether these two conditions are not different degrees of the same morbid state; clinically, the croupous variety appears to be the superficial form of the same disease, of which the second is interstitial or diphtheritic (Venneman, Gerke, Kam, Uhthoff, Moritz). If these are really distinct entities, then diphtheritic conjunctivitis may be said to be very rare; but if the so-called croupous condition enters into the group of affections due to the presence of the Löffler bacillus, the disease is at once recognized as relatively common.

Diphtheritic conjunctivitis may be the first point of localization of this special bacillus, and is then a primary disorder; or it may be an extension of the diphtheritic process elsewhere, and is then secondary. It is usually a primary affection, seldom occurring with the ordinary diphtheritic angina, about once in two hundred cases. It occurs most frequently in cold, damp countries, as Germany is, especially in the city of Berlin. In Paris, it appears with relative frequency, and at Nantes some condition favors its appearance still oftener. Both sexes are equally afflicted, from two to eight years of age being the period of predilection. It is also seen in adults and in the new-born. Previous conditions of health are important factors in its production. Infectious diseases, especially measles and whooping-cough, are among the general causes. Much of the purulent ophthalmia of infants is in reality diphtheritic conjunctivitis. Diphtheria of the ordinary form is comparatively rare in nurslings, but in the eye the disease manifests itself among them with greater frequency than is usually supposed.

In the superficial or croupous form of the disease, a trifling catarrh first appears, with sensitiveness of the eyes to wind, artificial light, weeping, a sensation of sand in the eye, etc. Then the discharge becomes muco-purulent, gluing the eyelids together after sleep. Careful examination shows this discharge to be more fibrinous, more coagulable, than that of ordinary catarrh. The conjunctiva is red, vascular, sometimes ecchymotic. That inside the eyelids is even redder, injected, and œdematous. This state lasts from twenty to thirty-six hours. Then the epithelium of the palpebral conjunctiva undergoes a rapid change. It takes on a brilliant varnished appearance. A fine layer of transparent mucilage seems spread over it. This is the beginning of the false membrane. The eyelids are more or less œdematous, the ciliary border takes on a violet tinge, and the secretion is citrine in color. As in the insterstitial form, the false membrane is confined almost always to the mucous surface of the lid. If the conjunctiva of the globe is involved, it is by extension, and never primarily. The false membrane is thin, elastic, and adherent. It can be rubbed off with a piece of linen or removed by forceps. Sometimes the membrane is shed in bits; sometimes in unbroken form, giving a perfect cast of the parts involved. Underneath, the membrane is supple, congested, bleeding on the slightest friction, without apparent fibrinous infiltration. Yellowish spots, here and there, that bleed less easily than the rest of the surface, suggest the beginnings of such infiltration. This period of the disease lasts from three to ten days. Then begins the purulent or third period, characterized by purulent discharge, decrease of pain that has been pretty severe, and a reddened granular condition of the palpebral conjunctiva, now denuded of the false membrane. Too energetic treatment will now bring back the false membrane and cause it to persist with more or less obstinacy. Suppuration diminishes rapidly, and the disease is ended in about two weeks, leaving no scars. During its entire course there is scarcely any fever, some slight emaciation, and a certain uneasiness. In spite of this apparent benignity, serious complications may arise at any moment, especially morbid conditions of the cornea.

In the interstitial form of diphtheritic ophthalmia, the onset is variable. Sometimes it begins by the superficial or croupous form just described, differing only by the shortness of duration of these three stages, that may follow each other so rapidly as to escape observation. Then, again, it appears suddenly as a full fledged infiltration from the start. The eyelids are swollen, œdematous, overhanging, purplish, and the seat of an acrid burning. The surface thermometer may show one and a half degree of abnormal heat. The lids are often one centimetre in thickness and of cartilaginous hardness. The discharge is not abundant. It is citrine in color, dull, flecked with opaline *débris*, with a fetid sanguinary odor. The inside of the lid is thickened, smooth, yellowish-gray, ecchymotic, exactly like a bit of ham rind. It is perfectly bloodless; and cross-rubbing and scarification fail to draw one drop of blood. The fibrinous exudation pervades the entire conjunctiva, implicating the blood-vessels. In certain cases this infiltration is disseminated, appearing in localized patches surrounded by a reddened and vascular mucous membrane. The bulbar conjunctiva is at first slightly injected. Then it is secondarily invaded, though the false membrane never equals in thickness that on the palpebral surface. Symptoms increase in severity. There is considerable fever, loss of appetite, insomnia, emaciation, and albumin in the urine. This stage lasts a week, during which the condition is one of uniform severity or of aggravated symptoms. If there is perforation of the cornea, as often happens, the situation is pitiable in the extreme. The eye, seen as at the bottom of a deep sewer, moves in a mass of bloody corruption. By degrees things improve, the swelling diminishes, the discharge changes in character and is less profuse, the patches disappear, and the patient generally recovers if no secondary infection occurs.

Professor E. Klebs, formerly of Carlsruhe and now of Strassburg, claims to have obtained most satisfactory results from the use of his antiphthisin in the treatment of tuberculosis. The antitoxin has also been tried to some extent in America, those who have used it speaking most enthusiastically of its action. Professor Klebs is now in this country.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 22, 1894.

THE REDUCTION IN THE MEDICAL CORPS OF THE ARMY.

THE American Congress is often foolish in its extravagances, but it never betrays a greater imbecility than in some of its attempts at economy. One of the most short-sighted and unnecessary of these penny-wise efforts was the reduction in the army medical staff, passed last winter, whereby the country is saved $30,000 a year, and the efficiency of the medical department is seriously threatened. In the annual report of the Surgeon General just issued this subject naturally receives some attention. The members of the Committee on Military Affairs of the House of Representatives, upon whose recommendation this measure was adopted, had better have given no reason for their action than to put forth what they did. One of their arguments was that there were 210 military posts in the country in 1870, and but 120 in 1894; "if 193 officers in this department were sufficient when the number of posts and stations was 210, there can be as great a reduction as is proposed in this bill when the number of posts and stations is reduced to 120."

The fallacy of this is shown by the fact that there were then 184 acting assistant-surgeons in addition to the regular staff, while now there are none. The committee suggested that, if there were not enough army surgeons to attend to all the garrisons, private physicians living in the neighborhood could be called in and paid by the visit. In reply to this the Surgeon-General shows that the expense to the Government in paying for medical attendance by the visit would in most posts be greater than the pay of an assistant-surgeon.

"Moreover, a post medical officer has various and important duties to perform in addition to caring for the sick. In fact, his presence as a member of the garrison is more important than that of any other officer, for no other officer can perform his duties, whereas any line officer present can perform the duties of quartermaster, commissary of subsistence, adjutant, or commanding officer of a garrison."

But it is mainly as injuriously affecting the efficiency of the medical department in case of war or active service, that the parsimony of Congress is to be deplored. The Surgeon-General very justly says that the weakness of a Medical Department, consisting in part of medical men attending and paid by the visit, would be mainly felt when troops were ordered out for active service. The principal reason for supporting an army in time of peace is that an efficient organization may be maintained which will be ready for service in any emergency, and serve as a nucleus for the larger army which will be required in case of war. This applies to the Medical Department as well as to the fighting force. The duty of our medical officers is not only to attend to the sick at their stations, acting at the same time as health officers for their command, but to be prepared, and to prepare their Hospital Corps detachments, for any emergency, and especially for field service. The call to service in the field is more common in our army than is generally supposed. During the year 1893 the number of medical officers who were out with the various detachments which constituted the average field strength was 69. The largest number of medical officers out in one month was 23, in September, with detachments aggregating 2,954 men, and giving an average strength for the month of 1,663 men. It is for such field service that the need of the junior officers of the Medical Department is chiefly felt. In 1892, 76 medical officers were on field service, the average number of men thus serving having been 1,010. In 1891, 93 medical men were out with various detachments of troops having an average strength of 899 men, and in 1890, 143 medical officers with an average strength of 1,210 men. If attendance on the sick at military posts be made the gauge of the strength of the Medical Department, no provision of medical officers can be made for troops on active service unless certain posts be deprived of their medical officers.

"It must be remembered also, that medical officers are as liable as other officers to break down under the exposures and accidents of field service, or from other causes. During the past three years a little over five per cent. of them have been constantly non-effective from sickness, or 10 officers out of the 192 allowed by law up to the time of the passage of the current appropriation bill. Again, these officers are as much entitled as other officers to leaves of absence; but inasmuch as the Regulations of the Army prescribe that leaves will not be granted 'so that a post will be left without competent medical attendance,' many of the medical officers have to do, year after year, without leaves such as are enjoyed by others. During the past ten years the leaves of absence granted to medical officers were equivalent to an average leave annually of a little less than fourteen days for each. To enable the Department to permit its officers to have one month's leave annually, and at the same time provide competent medical attendance at post, a strength of 8.3 per cent. is needful over and above that necessary to man the post."

"In view of these considerations," Dr. Sternberg concludes, "I regard with regret the policy which has cut off fifteen officers from the Department."

The regret will be shared by all who have been accustomed to point with pride to the efficiency of our army medical service.

The New York Orthopedic Dispensary and Hospital has received from Mrs. Richard T. Auchmuty, $10,000, to endow two free beds in perpetuity, in memory of her husband; from Mr. James H. Jones, $5,000, to endow a free bed in perpetuity; from "a friend" $4,000, to build a modern operating room; and from two of the trustees, $500, to furnish and equip the same.

TYPHOID FEVER IN THE DISTRICT OF COLUMBIA.

The city of Washington has long had the unenviable reputation of being one of the cities most visited by typhoid of any in the country. The Medical Society of the District of Columbia recently appointed a committee to investigate the causes for the prevalence of the disease there, and to suggest measures adapted to its suppression. In the search for these causes the committee investigated especially the water-supply, the drainage, and the milk-supply. The water-supply of the District is derived from the Potomac River and from wells. The water derived from the first source is comparatively good, as the river flows for the most part through a mountainous country, and there are no large cities on its banks above Washington. The water of the wells, however, is almost uniformly bad, sewage bacteria having been found in a great majority of the samples of well-water examined. This is readily understood from the condition of the soil, saturated with fecal matter escaping from leaky sewer pipes and overflowing privies. A study of the geography of the typhoid districts has shown that there is a coincidence between a soil polluted with the leakage of the excreta from typhoid fever patients, the drinking of infected well-water, and an extensive distribution of typhoid fever; that where these first two conditions exist to the greatest degree typhoid fever is most prevalent.

The committee concludes, as a result of its investigation, that "the daily pollution of the soil by the fecal discharges of our patients suffering from typhoid fever, with the resulting contamination of well-water, must be recognized as the chief source of the diffusion of the disease. It is a case of auto-infection. We are daily breeding the poison which poisons us, and the inevitable round from intestine to soil, from soil to well, and from well back to intestine, goes on and on with the most tragic uniformity. We sustain all the conditions favorable to rapid and perfect propagation of the bacilli. Granches and Deschamps have experimentally shown that typhoid germs placed on the surface of frequently moistened ground will penetrate nearly two feet into the soil, and will there retain life for five and a half months. They multiply rapidly in illy drained soil, live for an indefinite time in privy vaults, and have a much longer existence in cisterns and wells than in running water. In Washington we supply all these necessary conditions—leaking privies for the reception of the excreta and their contained germs, a damp and illy drained soil for their reception and rapid growth, neighboring wells for the resulting, the inevitably resulting, contamination of drinking-water consumed by a thirsty population. What more conveniences can we supply? What more successful means can we adopt to raise our mortality to a point higher than that of Brooklyn, New York, Baltimore, and Boston? We are among the most successful cultivators of the deadly bacillary plant in this country."

To remedy this condition the committee urges the abandonment of all wells within the city limits, the sedimentation and filtration of the Potomac water, the purification of the existing sewerage system, and the building of new sewers in parts not yet supplied with drainage, the suppression of all privies in the city, and finally the careful inspection of dairies and regulation of the sale of milk. There is no innate reason why Washington should not be one of the healthiest cities in the country. A great deal has been done for the sanitary improvement of the city in the past thirty years, but much yet remains to be done. It is a hopeful sign that the Medical Society of the District has taken the matter up, and if the District commissioners will but follow the recommendations of the Society, one of the chief causes of mortality in the city may be suppressed.

THE LIVER AND ITS GLYCOGENIC FUNCTION.

Dr. Pavy has recently made some rather radical statements regarding the functions of the liver in its relation to sugar and to the pathology of diabetes.

This distinguished investigator asserts that there is no increase of sugar in the blood leaving the liver, that glycogen is not converted into sugar, that sugar does not disappear in the circulation, and that it is all excreted by the liver. The liver in fine has no more to do with sugar than other tissues, and not so much perhaps as the muscles.

Dr. D. Noël Paton, however, in an article on the "Physiology of the Carbohydrates" (*Edinburgh Medical and Surgical Journal*, December, 1894), denies seriatim these views of Pavy, and says that not one of them is proven. "The evidence for the constant production of sugar in the liver," he says "the evidence that glycogen is a source of sugar, the evidence that sugar disappears in the general circulation (I do not say is used in the tissues), is overwhelming, and thus the glycogenic theory of Bernard holds its ground unshaken."

Dr. Paton further asserts that one of the great functions of the liver is to produce sugar will not, at the present time, be denied by any physiologist. The theory of Pavy, repeated in nearly every text-book, that the liver is a sugar-destroying and not a sugar-forming organ, rests on so unsubstantial a basis, and has been so completely refuted by the work of Seegen and other investigators, that it need not be considered.

When experts disagree, it is difficult for those who are not in possession of special physiological knowledge to decide. We trust, however, that the truth will soon be reached, for there are few questions of more practical interest than that of the physiological chemistry of sugar.

FILLING FORCED VACANCIES.

The trouble in Philadelphia concerning the dropping of an attending physician from the staff of the Philadelphia Hospital, has a wider significance than that which pertains to the results of an ordinary election of officers. In this instance the Commissioners of Charities and Correction, who make such appointments, presumed to decide upon the merits of a vital and scientific question of medical treatment, without consultation with the staff, and in an under handed manner to elect another gentleman in the place occupied by the alleged offender. This rebuke was made more pointed by re-electing all the other members of the medical board. It is surprising to learn that the medical board had no disposition to resent this insult, and still more so to know that a good man could be found to accept the position thus made vacant,

and thus tacitly acknowledge the validity of the principle.

Dr. Walk, who was the only member of the board of trustees to support Dr. Daland, very properly maintained that the question of medical treatment in the hospital was a technical matter, and that laymen were not competent to decide it. If the board had any objection to any method of treating patients, it should have had a commission of physicians to pass upon it. It was, in fact, not within the sphere of the board.

Such doings are, fortunately, not common, and generally occur when managing boards are ignorant of their duties and when a staff lacks pluck and spirit. There are always men waiting for vacant places, no matter how they are created. Managers know this and act accordingly. The principle involved is one thing and the place is the other. Usually they do not come near enough to each other to get acquainted.

A BELATED ASSAULT ON THE GERM-THEORY.

We do not know whether anyone pays attention to the attacks of Mr. Lawson Tait upon vivisection and the germ-theory of disease. At any rate, no one who reads this gentleman's last criticism of microbic pathology, "based on the Baconian Method," will entertain any longer the idea that Mr. Tait understands what he is writing about when he takes up this subject. His "Baconian" argument is that, because his own surgical mortality is light, therefore the germ-theory is false, strikes one as possessing simply the merit of an infantile simplicity. The germ-theory of disease, or of some diseases, is as firmly established as any fact in human science, and Mr. Tait's mortality-rates must be made to fit the facts; the facts are not to be stretched to the Procrustean bed of hospital statistics. Evidently Mr. Tait believes that "the sun do move."

FURTHER REPORTS OF THE ANTITOXIN TREATMENT.

Reports regarding the use of the antitoxin of diphtheria continue to come in from all parts of the world. In Paris, Roux's serum has reduced the mortality fifty per cent. according to published statistics. In London "good results" have been obtained at St. Bartholomew's Hospital in cases not too far advanced. The investigations of the efficacy of the serum are, however, being conducted with much secrecy, according to the *British Medical Journal*. Three kinds of serum are used, Behring's, Aronson's, and that made in London. Whatever the future results will be when the remedy is widely employed, it has not yet been used enough to lessen the very large mortality from diphtheria in the city of London.

At Buda-Pesth, Professor Bokai has reported the results of the treatment of 35 cases of diphtheria with Behring's serum. The number of children who died was 5, giving a mortality-rate of 14.28 per cent. Of the 30 children who recovered intubation was done in 12. Drs. Gottstein and Schleich, of Berlin, have attacked both the theory of the antitoxin treatment and the hospital statistics which have been quoted in its support.

At a recent meeting of the Medical Society of Munich, which was attended by more than three hundred practitioners, the serum treatment formed the subject of a prolonged discussion. Professors Buchner, von Ranke, and C. Seitz presented a report on the subject, and resolutions were passed to the effect that the time was not yet ripe for a definite judgment as to the value of the method, and that trials of the remedy on an extensive scale would be necessary to settle the question. It was considered important that this view should be impressed not only on the profession, but on the public. A committee, consisting of Professors Buchner, von Ranke, Bollinger, Oertel, C. Seitz, von Kerschensteiner, and Wertheimer, was appointed to study the whole question thoroughly.

In France, the War Department has authorized the antitoxin treatment in the army; the cities of Lille and Havre have voted money for undertaking the new treatment.

In Belgium, a sero-therapeutic service has been organized in Brussels, and similar work has been begun in Milan, Piacenza, Turin, and at Lisbon.

In this city the Board of Health has already begun to prepare the serum, and a plant is being established in Washington under the direction of the Marine Hospital Service.

News of the Week.

Dr. William H. Flint, having suffered from a bronchial ailment, since an attack of grippe which he had in the spring of this year, has decided to leave New York for some time, in the hope of regaining his health. Dr. Flint hopes to resume his practice in this city early next fall.

The Twenty-fifth Anniversary of the Northwestern Medical and Surgical Society was celebrated by an evening reception to the members, their wives and guests, on Thursday evening, December 13th, at the house of the President, Dr. W. Gill Wylie, 28 West Fortieth Street, New York. About one hundred and twenty-five persons were present, and the evening was thoroughly enjoyable. This society is one of several in this city organized between 1865 and 1870, just after the war; and its public celebrations have become famous for the generous social spirit among the members and friends.

Newark is to have a new hospital for contagious and infectious diseases.

Dr. Martin L. Ranney died at his residence in this city, 317 West Twenty-ninth Street, on December 14th, in his sixty fifth year. He had practised medicine in this city for more than forty years, and was one of the best known physicians on the west side. He was the brother of the late Dr. Lafayette Ranney. Dr. Ranney leaves two children and two brothers.

National Association of Railway Surgeons.—The following are the officers for 1894 and 1895: *President*, Dr. Samuel S. Thorn, of Toledo, O.; *First Vice-President*, Dr. N. Y. Leet, of Scranton, Pa.; *Second Vice-President*, Dr. C. H. Wilkinson, of Galveston, Tex.; *Third Vice-President*, Dr. B. L. Riardon, of Toronto, Canada; *Fourth Vice-President*, Dr. W. B. Morrow, of Walton, N. Y.; *Fifth Vice-President*, Dr. A. O. Will-

iams, of Ottumwa, Ia.; *Sixth Vice-President*, Dr. G. A. Hollister, of Toledo, O.; *Seventh Vice President*, Dr. W. R. Priest, of Concordia, Kan.; *Secretary*, Dr. J. M. Dinnen, of Fort Wayne, Ind.; *Assistant Secretary*, Dr. J. H. Ford, of Wabash, Ind.; *Treasurer*, Dr. Eugene R. Lewis, of Kansas City, Mo.; *Editor of Journal*, Dr. R. Harvey Reed, of Columbus, O.; *Executive Committee*, Dr. C. K. Cole, of Helena, Mont.; Dr. A. J. Mullen, Jr., of Michigan City, Ind.; Dr. J. B. Murphy, of Chicago, Ill.; Dr. A. A. Thompson, Waxahachie, Tex.; Dr. D. E. Welsh, of Grand Rapids, Mich.; Dr. C. D. Evans, of Columbus, Neb.; Dr. F. H. Peck, of Clinton, N. Y.; *Chairman Committee on Transportation*, Dr. W. B. Outten, of St. Louis, Mo.; *Chairman Committee on Arrangements*, Dr. A. I. Bouffleur, of Chicago, Ill.

The Promised Life of Sir Andrew Clark is being prepared by Canon MacColl, with the co-operation of Dr. W. H. Allchin. An introduction will be contributed by Mr. Gladstone. The book is not expected to be ready for some time yet.

A Typhoid Antitoxin.—A rumor was current on the Stock Exchange of Frankfort-on-Main the other day, that the Höchst Works would shortly bring on the market a typhoid antitoxin of Behring's discovery. The consequence was a decided rise in Höchst shares!

Bequests to Medical Institutions of Philadelphia.—By the will of the late Dr. William Goodell, of Philadelphia, the sum of $50,000 is donated to the Medical Department of the University of Pennsylvania. The College of Physicians will from the same source fall heir to $10,000.

Kentucky School of Medicine.—On the 22d inst. the Faculty of the Kentucky School occupied for the first time their commodious new hospital and dispensary.

Honors to Medical Men.—The Sultan has conferred the honor of Grand Officer of the Medjidieh Order on M. Monod, Director of the Assistance Publique of France; Professor Grancher and M. Roux, of the Pasteur Institute; and M. Pozzi, the well-known gynecologist. M. Martin, of the Pasteur Institute, has received the decoration of a Commander of the same Order.

Ohio State Association of Railway Surgeons.—The annual meeting of this body was held at Dayton, October 11th and 12th.

The Southwestern Association of Railway Surgeons.—The following are the officers of this organization: *President*, Dr. C. A. Smith, of Tyler, Tex.; *Vice-Presidents*, Dr. E. A. Neeley, of Memphis, Tenn.; Dr. W. G. Jameson, of Palestine, Tex.; Dr. E. F. Yancey, of Sedalia, Mo.; Dr. B. F. Eads, of Marshall, Tex.; Dr. N. J. Pettijohn, of Kansas City, Mo.; *Secretary*, Dr. J. A. Lightfoot, of Texarkana, Ark.; *Treasurer*, Dr. L. H. Callaway, of Nevada, Mo.

The Association of Military Surgeons of the United States.—The following are the officers for 1894 and 1895: *President*, George M. Sternberg, Brigadier-General and Surgeon General, U. S. Army, of Washington, D. C.; *First Vice President*, Louis W. Read, Colonel and Surgeon-General, N. G. Penn., of Norristown, Pa.; *Second Vice-President*, Albert L. Gihon, Medical Director, U. S. Navy, of Washington, D. C.; *Secretary*, Eustathius Chancellor, Lieutenant-Colonel and Medical Director, N. G. Mo., of 515 Olive Street, St. Louis, Mo.; *Assistant Secretary*, Julian M. Cabel, Captain and Assistant Surgeon, U. S. Army, of Washington Barracks, Washington, D.C.; *Treasurer*, Lawrence C. Carr, Major and Surgeon, N. G. Ohio, of 143 W. Seventh Street, Cincinnati, O. Meets at Buffalo, N. Y., May 21, 22, and 23, 1895.

A Bequest to the Massachusetts General Hospital.—By the will of the late Thomas E. Proctor, the Massachusetts General Hospital, of which he was a trustee, receives $100,000. This sum is to be held in trust until principal and interest reach the amount of $400,000.

The West Side German Dispensary.—The members of the staff have founded a clinical society styled the Society for Medical Progress of the West Side German Dispensary. The officers are: Dr. Augustin H. Goelet, *President;* Dr. Lewis Morris and Dr. V. Fuentes, *Vice-presidents;* Dr. Aristides Agramonte, *Secretary;* and Dr. H. C. Hazen, *Treasurer.*

Diphtheria in St. Louis.—Diphtheria is so prevalent in certain portions of St. Louis as to be considered epidemic. A large number of the earlier cases are said to have been reported by the physicians as "croup" or "laryngitis."

The German Medical Society of the City of New York held a festival last Saturday evening, at the Arion Club, to celebrate its thirty-fourth anniversary. The entertainment consisted of a dinner followed by a ball. Speeches were made by Drs. Jacobi, Willy Meyer, Vulpius, and Heitzmann.

Manufacture of Vaccine Virus by the State of Illinois.—A committee has been appointed by the Illinois State Board of Health to promote legislation by the next General Assembly for the establishment of a State vaccine farm. It will be remembered that within the last year efforts were made to secure such legislation in Massachusetts. These attempts, unfortunately, were not successful.

Receipts from Portrait Exhibition.—The exhibition of portraits of women, organized by a number of ladies of society, which has just closed at the Academy of Design, netted about $20,000 for St. John's Guild and the Orthopedic Dispensary.

The Antitoxin Treatment of Tetanus.—Dr. E. Schwarz reported last week on a case of tetanus treated by Tizzoni's antitoxin. The treatment was commenced on the second day of the disease, and the spasms disappeared under the treatment, but the temperature rose during this time from 37.3° C. to 40.3°, and the patient, after the fourth injection, died from heart failure. It was clear that the leucocytosis was increased in consequence of the treatment. The number of the leucocytes was 11,000 before the first injection, rising to 18,000 on the next day, and was 17,000, 16,000, and 15,000 on the following days. Dr. Schwarz recommended the use of stronger doses of the antitoxin than those prescribed by Tizzoni.

A Gold Cup for Discovering a New Microbe.—The citizens of Nagasaki have presented Professor Kitasato with a beautiful gold cup in honor of his discovery of the bacillus of the plague.

Obituary.

GEORGE A. PETERS, M.D.,

NEW YORK.

Dr. George A. Peters, one of the most prominent of New York Surgeons, died December 6th, of chronic Bright's disease. Dr. Peters was graduated from the College of Physicians and Surgeons in 1846, and his career was a most successful and interesting one. For the last four years he had retired to a large extent from active practice, but at the time of his death he was still consulting surgeon to the New York, St. Luke's, St. Mary's, and the Woman's Hospital.

During his medical course he was a private pupil of the late Dr. Alfred C. Post. After his graduation he served the prescribed period on the house staff of the New York Hospital, and a few years later he was appointed a surgeon to that institution, also to St. Luke's Hospital. Although his hospital work was wholly surgical, he was for many years one of the most successful and popular of the general practitioners of New York.

FRANK L. SIM, M D.,

MEMPHIS, TENN

Dr. Frank L. Sim, died at his residence in Memphis, Tenn., November 23, 1894. He had been in failing health for several months. Dr. Sim was born in Golconda, Ill., April 29, 1834. His literary education was received at Hanover College, Indiana. He graduated from the medical department of the University of Louisville in 1855, and a year later received an *ad eundem* degree in the Pennsylvania Medical College. Returning home in the spring of 1857, he practised medicine with his father till 1861, when he left that part of the country and shortly afterward entered the Confederate service as a contract surgeon in the army, then stationed at Columbus, Ky. Circumstances induced him to locate in Memphis, where he ever since devoted himself to the practice of his profession. He remained at his post of duty during the dark days of Memphis in the various epidemics of cholera and yellow fever. In 1882, Dr. Sim became the editor of the *Mississippi Valley Medical Monthly*, but afterward changed to the *Memphis Medical Monthly*, under which name he has continued its editor and publisher. Dr. Sim at the time of his death was Professor of the Principles and Practice of Medicine in the Memphis Hospital Medical College and was Dean of the Faculty.

Dr. C. P. Gage, of Concord, N. H , died on November 26th, aged eighty-three. He was one of the original members of the American Medical Association, and had been president of the New Hampshire Medical Society.

Reviews and Notices of Books.

Transactions of the Forty-ninth Annual Meeting of the Ohio State Medical Society, held at Zanesville, May 16, 1894. Toledo, O.: Blade Printing and Paper Co.

Contains the usual assortment of papers, many of them of considerable interest. As might be expected, tuberculosis comes in for rather a large share of attention. Papers on sterilization and immunity, and pleas for higher medical education, and for the cremation of the dead, are also noteworthy as illustrating tendencies of the times.

A Manual of Human Physiology. Prepared with Special Reference to Students of Medicine. By Joseph H. Raymond, A.M., M.D. Philadelphia: W. B. Saunders.

Believing that only the main principles of the subject of physiology can be imbibed by the medical student during the limited time of his study, the author has attempted to make these available in condensed form. Without too fully endorsing the view that students should be trained on manuals—especially in this day when the tendency everywhere is to lengthen medical courses—one may at least admit the value of concise, direct, and unequivocal elucidation of principles; and it may be freely conceded that the essentials of human physiology are compressed within the three hundred and sixty-five pages of this manual in a most attractive form. Numerous creditable illustrations—some of them colored—reinforce the text.

Fifth Annual Report of the New York State Commission in Lunacy. From October 1, 1892, to September 30, 1893. Albany: James P. Lyon, State Printer.

Judged quantitatively, this report certainly shows great advances on the part of the Commission in Lunacy, inasmuch as it is six times as bulky as the first report, issued in 1889. Considered as to quality, the advance is not so striking. Of course there are good suggestions in the report, but there is much that might advantageously have been omitted or greatly condensed—for example, the copy of the estimate for supplies, and the monthly treasurer's report of the Rochester Hospital, which fills fifty printed pages, and the endless legal papers giving details of the squabble between the Commissioners in Lunacy and the authorities of Queens County.

Whatever the failings of the Commission in Lunacy, it has never been accused of lack of self-appreciation, and in this regard the present report shows no falling off. Should the future historian come upon these volumes, he will certainly be excusable if he reaches the conclusion that in the last decade of the nineteenth century the ill-used insane had but three friends in the State of New York, these being, of course, the Commissioners in Lunacy. But should the same historian come across sundry letters and other unofficial documents relating to the same subject that may chance to be preserved, we fear he will be sadly puzzled. For in point of fact, there are other friends of the insane in New York, and not a few of them, differing very widely from these reports in their estimate of the value of the work of the Commission in Lunacy.

Twelfth Annual Report of the Provincial Board of Health of Ontario. Being for the year 1893. Printed by order of the Legislative Assembly. Toronto: Warwick Brothers & Rutter. 1894.

Contains reports on many topics having to do with sanitation, some of them only of local interest, others more general in their application, but all illustrating the wide-spread interest in preventive medicine that marks our generation.

The Principles of Bacteriology: A Practical Manual for Students and Physicians. By A. C. Abbott, M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania, Philadelphia. Second edition, enlarged and thoroughly revised. With 94 Illustrations, of which 17 are Colored. Philadelphia: Lea Brothers & Co. 1894.

Although this second edition contains double the letterpress of the first edition, the author explicitly states that he has adhered closely to his original plan, making no attempt to cover the field exhaustively, but referring only to species that "are comparatively common, or of importance in enabling the student to acquire a fundamental working knowledge, capable of wider application." It is, in short, a work for beginners and general students, and as such, of course lays no claim to originality of matter; but its method is concise and clear, and it gives just such an account of the practical manipulations of media and cultures as will prove of value to the student who must learn laboratory methods by himself. A satisfactory summary of the present status of the various theories of infection and immunity has been added to this edition.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Seventh Annual Meeting, Held in Charleston, S. C., November 13, 14, and 15, 1894.

FIRST DAY, TUESDAY, NOVEMBER 13TH.

THE Association met in Artillery Hall, and was called to order at 10 A.M. by the President, Dr. C. Kollock, of Cheraw. Prayer was offered by the Rev. Dr. Campbell, of Charleston. An address of welcome was delivered by the Mayor of Charleston. Dr. Brodie, of Charleston, followed with an address of welcome on behalf of the local profession, and President Kollock responded in behalf of the Association.

Dr. Warren Stone.—DR. WILLIAM E. PARKER, of New Orleans, read a "Memorial Address" on Dr. Warren Stone, which was prepared by the late Dr. A. B. Miles, of New Orleans. He said as Professor of Surgery in the University of Louisiana for thirty-five years, as Surgeon to the Charity Hospital for thirty-eight, and as general practitioner from 1832 to 1872, whose experience covered eighteen epidemics of yellow fever and cholera in New Orleans, the name of Warren Stone is impressed indelibly upon the local history of a remarkable period. In his surgical clinics he taught the advanced surgery of the old school. He taught the principles of drainage in suppurative arthritis, in hepatic abscesses, and in pyothorax. He advocated resection of the rib to facilitate the drainage in suppurative pleuritis. Whether in operative work or in the liberation of pus he made free incisions. He was among the first in the cure of aneurism of the vertebral artery. In the surgery of the arteries he was an expert. During fourteen years of his work at the Charity Hospital, he operated without an anæsthetic. Realizing the difficulties under which he labored, he was ready to welcome the new era in surgery then about to dawn. The lives of many men are mirrored in their books and published papers, but the writings of Dr. Stone give but meagre knowledge of his work, or his position as an authority on surgery in the South. No man in the profession was ever so universally beloved as Dr. Stone. In his relations with other physicians he was gentle and considerate, never intrusive or aggressive. Many of the physicians in Louisiana to day who knew him in life, speak of him affectionately as "Old Stone," and always with some expression of endearment and respect. His position in New Orleans may be compared with that of Physick, in Philadelphia, Mott, in New York, Lister, in London, Velpeau in Paris.

Gonorrhœa in Women.—DR. J. B. S. HOLMES, of Atlanta, read a paper with this title. He said there was no disease that affected women that should engage the serious and thoughtful consideration of the physician more than gonorrhœa. There was no doubt but that many of the chronic diseases of the ovaries and tubes that came under the observation of gynecologists were due to this disease. In the majority of cases the poor woman was ignorant of the fact that she had had or has any specific disease. Indeed, her husband might tell the physician that months or even years before his marriage he was a subject of gonorrhœa, which was cured and had since shown no evidence of a return.

The essayest could conceive of nothing more dangerous than curetting the uterus in the presence of immense pus-tubes with pelvic adhesions. The drawing down of the organ necessary for curettage may break up pelvic adhesions and pour out the contents of pus-sacs into the peritoneal cavity, which would result in the majority of cases in death to the woman. If her life is saved at all, it will only be done by a prompt abdominal section, with thorough irrigation and drainage of the abdomen. Then why not, in the first instance, when pus is detected, promptly remove it by surgical interference. We then treat the woman rationally and give her the very best and only chance of relief and restoration to health.

DR. GEORGE J. ENGELMANN, of St. Louis, called attention to the importance of differentiating between latent or chronic gonorrhœa and the acute form of the disease. He does not look upon acute gonorrhœa as a dangerous disease in women, but he does the latent or chronic form. He has not seen serious results from the acute form, but it is the infection which is not observed from a supposedly cured gonorrhœa in the male which produces the suffering in women.

DR. BEDFORD BROWN, of Alexandria, Va., took exception to the statement made by Dr. Engelmann in regard to the non-danger of acute gonorrhœa in females, and cited the case of a female in whom acute gonorrhœa ran its course, terminating finally in fatal nephritis. In this case there was first urethritis, then cystitis, ureteritis, pyelitis, and acute nephritis.

DR. RICHARD DOUGLAS, of Nashville, thought Dr. Engelmann had sounded the keynote in that there is quite a difference in the infection from acute gonorrhœa and the latent form of the disease. Infection from the latter was a mixed infection, not only with the gonococcus, but with the streptococcus and staphylococcus also, and that accounts somewhat for the virulence of the trouble. That gonorrhœa is the cause of uterine fibroids, he could scarcely accept, although he thought Dr. Price was the author of that idea.

DR. JOSEPH TABER JOHNSON, of Washington, D. C., said in the treatment of pus-tubes the result of gonorrhœal infection, the very radical suggestion of Dr. Holmes was correct, viz., to resort to abdominal section, as he was satisfied that gonorrhœal pus tubes were incurable by conservative measures. In addition to the removal of pus-tubes, if present on both sides, the uterus should be removed also, because it is through the infected mucous membrane of the uterus that the tubes themselves have become infected.

DR. WILLIAM P. NICOLSON, of Atlanta, said the general surgeon was concerned in the treatment of gonorrhœa as well as the specialist. We are told that a urethra has been inflamed and subsequently restored to its normal condition, and yet years afterward the man transmits gonorrhœa to his wife. It is hard for him to accept such a doctrine. If a man goes for months and years with a gonorrhœa absolutely producing no effect whatever, if he is not well, how are we to tell him that he is not? We are told by the essayist that gonorrhœa is contracted by the female when there is absolutely no evidence whatever of disturbance in the urethra of the male, or that there is no trouble by which he can propagate disease.

DR. A. M. CARTLEDGE, of Louisville, thought the essayist failed to differentiate between cases of subacute and chronic salpingitis and the cases of acute infection from gonorrhœa. He threw out the suggestion that physicians were not fully conscious of the great prevalence of artificial abortions in young married women of the better as well as the lower class, and he believes that in these cases of secondary infection from pathogenic organisms we have a more fertile source for the development of the tubular and ovarian disease than from gonorrhœa.

DR. W. E. B. DAVIS, of Birmingham, Ala., considered the disease a dangerous one. The views of Tait, however, in regard to gonorrhœa were extreme. We have a frequent cause of tubal disease in the puerperal state, in delivery at term or in premature deliveries, frequently in artificial abortions, brought about by mechanical means. More or less infection occurs after all cases of abortion, but if the patient is in good condition at the time, she will not be materially affected. If we have a soil that is favorable for the development of septic germs, we will get a severe inflammation—a mixed infection.

DR. W. D. HAGGARD, of Nashville, desired to place himself on record as opposed to the removal of the uterus and tubes for pyosalpinx as the result of gonorrhœa, be-

lieving that by dilatation and judicious curetting patients can be relieved of an endometritis produced by gonorrhœa.

Dr. John D. S. Davis, of Birmingham, Ala., emphasized the importance of using the microscope in connection with gonorrhœa and carefully examining the pus. Experience has demonstrated that the latent effects of gonorrhœa were not always directly due to the gonococcus *per se*, but to a mixed infection; that is, we have an inflammation as a result of the gonococcus, which is fired up by another infection from the streptococcus. When we have a mixed infection, we have as a result pus-tubes, suppurative peritonitis, and finally death of the patient if surgical interference is not resorted to.

Dr. Hunter McGuire, of Richmond, entered a protest against the doctrine that a man can have gonorrhœa and not get well. As for the idea that a man who has had gonorrhœa should not get married, it is preposterous. He had seen thousands of cases get well and remain so.

Dr. Holmes, in closing, said he was aware that many cases of acute gonorrhœa resulted in no secondary trouble, because they were recognized early and cured by judicious treatment. He wished to be understood as not indorsing the views of Mr. Tait, that gonorrhœa in the male was never cured, but he insisted that general practitioners were often too careless in advising patients who have been the subjects of gonorrhœa to get married.

Some Cases of Acute Intestinal Obstruction With Deductions was the title of a paper read by Dr. A. Morgan Cartledge, of Louisville, in which he reported six cases, three of which terminated fatally. The author said that the limited number of operated cases reported in his paper, together with an individual observation of probably as many more not subjected to operation, conform to the accepted belief of the hopeless nature of acute intestinal obstruction unless treated by early laparotomy.

While the author does not contend that we can dispense with opium in the treatment of these cases, certainly where obstruction is in the least suspected we should withhold its use until a diagnosis can be made. The practice of masking every abdominal condition characterized by pain with opium is far too prevalent, and its practice gains additional calamity as surgery advances in knowledge which refers relief of these very conditions concealed by the cloak of opium and ignorance.

The practical and cardinal points in avoiding a fatal delay and making an early diagnosis, are to be found in, sudden abdominal pain; a rapidly accelerating pulse; the vomiting of much more fluid in a given time than taken by the mouth; the green tinged character of this fluid; the anxious expression of countenance when no opium has been used, the fact that although enema may be stained by the contents of the colon there is no expulsive movement of the bowels, and the passage of no gas.

The burning question now is to educate men to know that action to be successful must be quick; that timely aid depends upon the man who first sees the case; that when a physician from any reason suspects that a patient's bowels will not move, he should drop everything else and centre all his time and attention upon that patient. He should not waste his gray matter by trying to determine if it be a probable intussusception, volvulus, band, diverticulum or what not—leave that for the operation to determine; it is the most reliable way to find out.

Second Day, Wednesday, November 14th.

Hernia of the Diaphragm.—Dr. F. W. McRae, of Atlanta, Ga., reported a case of this kind. The author brought this subject before the Association for consideration, not alone because it offered an inviting field for experiment and investigation, but also because of a recent interesting case where, without warning, he was forced to meet the emergency without time for research into the literature of the subject, and while he was not then sustained by a knowledge of the opinions of the leading authorities. He finds from subsequent investigation that the course pursued was in accord with the recommendations of such eminent authorities as Laennec, Bowditch, Guthrie, and Marcy. In the case reported, strangulation had occurred five days before the doctor saw him. Had an early diagnosis been made, he feels sure the strangulation could have been relieved and the patient's life prolonged. The opening in the diaphragm was accessible, and he believes it could have been closed with a fair chance of permanent recovery. The case serves to emphasize the necessity for early operation in all cases of acute obstruction of the bowels.

Gunshot Wound of the Spleen and Kidney.—Dr. Louis McLane Tiffany, of Baltimore, Md., reported the following case: The patient was a male negro, twenty years of age. Two hours previous to entering the University Hospital, March 21, 1894, he had been shot with a small-calibre rifle from a distance of twenty feet, the weapon being directly behind him, and he being erect. His urine was slightly albuminous; the pulse, temperature, and respiration, normal. There was a bullet wound three inches to the left of the spine just below the last rib, from which blood oozed. After properly cleansing the wound it was enlarged, and it was found that the kidney had been injured and that a bullet had passed onward, presumptively into the peritoneal cavity. The wound was filled lightly with gauze by the resident physician, and Dr. Tiffany was notified. External examination of the abdomen by touch and palpation revealed nothing, not even painfulness.

The patient was anæsthetized, laid on the belly, and the wound, after being enlarged, was examined. The upper portion of the left kidney was perforated, and dark blood flowed from the peritoneal cavity beyond. This large wound was filled with gauze, the patient turned on the back, and the abdomen freely opened along the left semilunar line. A moderate amount of blood was free in the peritoneal cavity; no wound of the intestine could be discovered, but the spleen was found perforated, blood flowing freely from the wound of entrance, as well as from the wound of exit; the latter wound, in the concavity of the organ, was slightly the larger of the two. The perforation through the spleen was about three inches from the free lower border. Unwilling to subject the patient to splenectomy, the essayist attempted to arrest the bleeding in the following manner: A long needle threaded with silk was passed entirely through the spleen central to and parallel with the bullet track; the long ligature was then tied over the free border of the organ so as to press the surfaces of the wound together tightly enough to arrest bleeding, yet not to tear through the splenic tissue; the ends of the ligature were cut short, the peritoneal cavity cleaned by copious irrigation with hot water and the abdominal wound closed. The kidney was tamponed with gauze through the dorsal wound. Convalescence was uneventful; the anterior wound healed by primary union; urine flowed from the dorsal wound for two days only, union by granulation taking place. The patient left the hospital well, April 22d.

In this case, the wound being small, hemorrhage was not profuse, and no abdominal organ save the spleen was wounded.

Nævus.—Dr. William Perrin Nicolson, of Atlanta, Ga., reported a severe case of nævus, which was only cured by the use of galvano-puncture. The case was one of a large growth occupying the groove from the angle of the jaw, up to and covering a portion of the ear, and extending out upon the cheek, the entire tumor being almost the size of a hen's egg.

Dr. Nicolson formulated the following conclusions as having been reached in the long period covered in the treatment of this case: 1. That while this treatment may not be applicable to all cases, in many of those that are reached by difficult dissection, and are subject to

dangerous hemorrhage, as well as an unsightly looking scar, this is undoubtedly to be preferred to any other surgical proceeding. The time required in a cure is more than balanced by the entire preservation of the skin and the absence of danger from operative work. 2. That as to the quantity and quality of the current to be employed, as many as six cells of a zinc-carbon battery may be sufficient in small growths, while twelve cells of the same is perhaps the maximum to which it should be carried if the current from the positive pole alone should be employed. 3. The method of applying needles. Various forms of needles may be employed, but the ordinary steel needle gives equally satisfactory results, as the eschar produced in the skin at the point of entrance is not sufficient to amount to anything, and the needles can thus be changed at each sitting. That only one of them should be inserted into the tumor, while the negative pole should be attached to a sponge electrode moistened with a salt solution, and placed upon some indifferent point, care being taken to remove it from point to point in order to prevent blistering the skin. 4. Method of attacking the tumor. Better results are obtained by passing the needle in from the periphery of the growth on a line horizontal with the skin, and in directions radiating from the circumference toward the centre. Several of these punctures should be made at each operation. The length of the entire setting should not extend to more than twenty minutes or half an hour, while intervals of two to three weeks, or longer, should be left between operations to know whether there may not be a progressive shrinking away of the tumor. 5. As to the method of cure. He thought that several elements entered into attaining the result, of which the coagulum of the blood was one, and perhaps the least. The two remaining elements were the subsequent contraction of the small eschar produced in radiating lines from the tumor, and the effect of the current upon the vasomotor nerve supply.

He felt sure that a thorough trial of this method as to the settling of the various points considered, would result in its adoption in the treatment of perhaps a large majority of these cases where we have a large elevated blood-tumor with which to deal. He also believed that perhaps pricking the surface with the needle attached to a positive pole of battery, might result in a series of small scars, which would result in removing the ugly port-wine marks so common in this trouble.

Operations for Complete Perineal Laceration.—Dr. Joseph Price, of Philadelphia, said that there are many men who, essaying to be authorities on the surgical diseases of the major order, have no conception whatever of injuries of the perineum and cervix so far as their intelligent repair is concerned. Indeed, there are many, with a large obstetrical practice, who labor under the delusion that they have never ruptured a perineum, and that all their patients have entirely normal perinea. This misconception is due to improper teaching more than to any other cause. Perineal lacerations, unless extending through the skin to or through the sphincter may escape detection unless by thorough digital examination. All these tears should be approached as distinct surgical lesions to be repaired in the line of their anatomical destruction, and not as cosmetic operations, whose object is to obtain superficial appearances without regard to perfection and utility. Heaping up of tissue outside the lines of resistance and tension, or mere thickening of mucous membrane and skin does not make a true perineum, neither does a set of outside sutures, however much they may draw the parts together, afford any anatomical counterpart of a perineum. From this basis all the so-called outside flap-splitting operations for perineal tears are only puckering operations, bringing parts within the sutures that have never been severed, and in many cases taking them out of their proper relations. Big sutures, heavy ligatures, clumsy instruments, have no more place here than in other surgery. The ordinary short, strong sewing needle fills the bill exactly in most cases, though the Emmet stray-fine short needle for general use is preferable. Silk-worm gut or silver wire is the preferable suture. The Emmet operation as originally suggested, and afterward modified by its distinguished deviser, is the foundation for all successful operations on the lacerated perineum, either with or without sphincter tear.

Dr. Price, in closing, said the tears of perinea are often unavoidable, but their restoration is always possible, and their neglect is criminal.

President's Address.—President Kollock then delivered his annual address. He first thanked the Association for the honor conferred upon him in electing him as President. He then alluded to the death of Drs. William T. Briggs, of Nashville, and A. B. Miles, of New Orleans. Dr. Briggs's life had been one of usefulness. He had done excellent and remarkably brilliant work, and had achieved an enviable reputation. Dr. Miles, who had been made Professor of Surgery in Tulane University, was a man full of youthful activity and manly vigor, who by patient study and diligent research, aided by a brilliant intellect, had won for himself a high position in the profession, and in the estimation of his fellow-men. To know him was to admire and love him. His life was gentle and the elements so mixed in him, that Nature might stand up and say to all the world, "This was a man."

While in all branches of gynecology good progress had been made, he noted with pleasure that surgery had had its triumphs. Many reports of cases show enlarged experience and continual improvement in the treatment of appendicitis, hernia, intestinal obstruction, and many other ills that flesh is heir to.

Action of Chloroform on the Functions of the Human Brain and Spinal Cord.—Dr. Bedford Brown, of Alexandria, Va., read a paper on this subject. He cited the history of two cases of extensive compound comminuted fracture of the frontal bone and serious injury and destruction of a portion of the frontal lobes of the brain as the basis of his paper. One of these cases of injury was caused by a kick of a newly shod horse, the other by a spent grape-shot in battle. The subjects of both of these injuries retained perfectly their powers of consciousness and sensation.

The fracture in the first case involved a large portion of the frontal bone. The fractured bones were driven back into the substance of the brain quite an inch in depth, lacerating the frontal lobes extensively. There was a loss of about two tablespoonfuls of brain. During the operation, which lasted more than an hour, the patient was placed under the influence of a compound of chloroform three parts, and ether one part, four different times. Through this large opening in the skull the brain could be seen perfectly and its varying changes of action under chloroform could be observed perfectly. The invariable action of the anæsthetic was to suppress hemorrhage, to quiet cerebral pulsation and to positively reduce circulation in the brain and arterial tension. These peculiar effects were observed as many as three or four different times. When the patient was threatened with collapse from chloroform, stimulants injected in the rectum produced increased circulation and arterial tension in the brain promptly.

Any struggling, mental excitement, or resistance while inhaling chloroform caused marked increase in cerebral circulation and pulsation, with increase of hemorrhage.

The second case was that of a Confederate soldier, who in battle received a spent grape-shot in his forehead, causing an extensive compound comminuted fracture of the os frontis, driving the fractured bones back more than an inch into the frontal lobes. The wound in the skull was quite two inches in diameter, and more than an inch in depth. This patient was subjected to chloroform three times during the operation, which lasted an hour. The action of chloroform on the functions of the brain in this was similar to that in the first. When under full anæthesia each time the cerebral hemorrhage ceased, the cerebral pulsations diminished to a mere

tremor, and the arterial circulation was markedly reduced. This occurred three different times during the operation. The action of alcoholic stimulants resorted to in this case to prevent collapse from chloroform increased the cerebral pulsations and circulation in a positive manner.

Hydro-Pyonephrosis; Successful Removal of a Forty-Pound Tumor of the Kidney.—Dr. Joseph Taber Johnson, of Washington, D. C., reported the case. The patient was sixty-three years of age, and had inherited and possessed until five years ago a remarkably good constitution. At this time a lump appeared in his right side in the region of the liver, and was supposed up to the date of the operation to be caused by enlargement and abscess of that organ. This lump gradually increased in size, and the patient had gradually lost flesh and strength until the date of the removal of the lump, when he could not have weighed more than eighty pounds. At no time did he suffer from pain, and only a few weeks with fever.

There were several points of interest in this case, viz: failure of a number of good men to make a diagnosis, though the patient was under observation for nearly five years. Failure of repeated examinations of the urine to detect the slightest evidence of disease of the kidney. The only explanation the writer suggests is that the disease at the time of analysis and subsequently had so destroyed the function of the kidney as to prevent the escape of any urine at all, and that the specimen examined came from the other organ, which fortunately was healthy. Failure of such large quantities of foul smelling pus to produce more sepsis. Absence all through the history of pain or fever. The median line incision, the separate ligation of the renal vessels, and the ligation and dropping of the ureter.

The writer is aware that the lumbar incision is preferred by nearly all nephrectomists, and that they often bring out the cut end of the ureter and fasten it to the abdomen. While the lumbar incision may be best in small tumors and otherwise disease of kidneys, it certainly could not have succeeded, the author believes, in a case of the magnitude of the one here reported, not only on account of its great size, but also because of its being so extensively adherent to the omentum and abdominal wall. The colon had to be carefully separated from the anterior surface of the tumor.

Gunshot Wounds of the Abdomen.—Dr. W. L. Robinson, of Danville, Va., reported two gunshot wounds of the abdomen, lacerating the liver and bowel. In neither case were the symptoms commensurate with the injury; neither shock, hemorrhage, nor pulse portrayed the necessity for operation. Yet in view of the ninety-two per cent. mortality from gunshot wounds of the abdomen without operation, he did not hesitate. The first case came so near dying on the table and his light being imperfect at 12 o'clock at night, he only found the liver wound, failing to find the hole in the posterior border of the hepatic flexure of the colon. The patient died in three days. His second case was operated on promptly, and the injury in the transverse and descending colon was promptly repaired with the Murphy button. The man was on a spree and had had no action from bowels for three days. He pressed out much fecal matter, but should have taken more time and ruptured the bowel as far as practicable. For two days no unfavorable symptoms presented themselves, but on the night of the second day distress from tympanites and pain began. He suggested to his associates the propriety of reopening the abdomen, but enemata and grain doses of calomel were tried. This, the author considered, was his fatal mistake, for the waiting of ten hours had lost him the chance of a life-saving operation. He reopened and with medium trocar emptied the bowel of gas, but exudative lymph was manifest on bowels, and obstruction of button by fæces existed. The button held its tissue firmly, and no leakage had occurred. He washed out the cavity, but patient died in ten hours of shock.

Movable Kidney.—This paper was read by Dr. George Ben Johnston, of Richmond, Va. At the outset the author emphasized three propositions: 1. Movable kidney is extremely common. 2. It is capable of producing very distressing symptoms, and in many instances is a menace to life. 3. It is curable by a simple and safe operation.

The author's own experience with movable kidney from a surgical standpoint extends back a little more than three years. Prior to the first nephrorrhaphy, which he performed in May, 1891, those cases he has met with were given little or no thought. Since the date mentioned, he has looked with more interest on his cases, and has come to marvel at the frequency of the malady. He has examined a limited number of persons likely to be the subjects of movable kidney since his first operation for its relief, and in a comparatively small number of subjects he has encountered twenty-seven cases. Edebohls, who had studied five hundred cases, fixes the rate at one for every five or six women examined. Linder gives about the same rate. Osler makes no statistics, but mentions it as a common occurrence in his hospital wards. The records of these observers and Dr. Johnston's cases justify the assertion that it is a common malady.

It occurs more often in women. He had never seen one in a male subject. Age is a factor in its production. His own cases have been in subjects varying in age from twenty to thirty-five years. In only one instance has he seen it in a women over forty. Both kidneys may be movable at the same time. The right is the one that is affected in the preponderating majority of the observed cases. This is accounted for by the relation of the kidney to the liver on this side.

Two anatomical facts help to explain the preponderance of the right over left kidney displacement. 1, The greater length of the right renal artery, and 2, the firmer attachments of the left kidney. The author has twice seen a movable kidney follow obstruction of the ureter. It happened that both of these cases were on the left side. The increased weight of the kidney due to accumulated urine and congestion must have played an important part in the etiology of the dislocation in these two cases.

In many cases of movable kidney there are no symptoms. In others, the symptoms are extremely distressing, producing great mental disquietude, as well as intense physical suffering. In a proportion of cases the symptoms are grave. Torsion of the ureter is common, partial occlusion by bending is not uncommon, inducing a distention of the pelvis by dammed up urine. Hydronephrosis may follow. Calculus is thus invited by reason of poor drainage. Apart from tumors of the kidney itself, the condition most likely to be mistaken for movable kindey is distended gall-bladder.

Nephrorrhaphy is not indicated in every case of dislocated kidney, but only in such cases as manifest distressing or dangerous symptoms. When gastro intestinal disturbance impairs the general health, when nervous symptoms are severe, when the dragging abdominal pains are constant, when disease of other organs is simulated, when hydronephrosis is threatened, when one or more attacks of torsion have occurred, the operation is imperative.

The author then outlined his method of operating on movable kidney, and closed his paper with a report of seventeen cases.

Acute Peritonitis.—Dr. Richard Douglas, of Nashville, read a paper with this title. Appreciating the condition under which the colon bacillus will escape from its natural habitat and become actively pathogenic, and knowing the supply is unlimited, the dose being governed alone by the integrity of the bowel, naturally we accord to this bacillus the first place in the causation of peritonitis.

In obedience to the teachings of experimental work, the surgeon must accept the classification of Pawlowski

of two forms of peritonitis. 1. That produced by chemical agents, with which we are not concerned. 2. That produced by infection. The latter is more tangible. It is fully in accord with our idea of the genesis of the disease. It harmonizes with clinical work. With Mordecai Price, the author agrees that every case of general peritonitis has a demonstrable cause, and that cause is septic in character. Pathological manifestations of peritoneal infection are subject to many variations which, in a great measure, indicate the virulence of the poison and guide us in forming a prognosis, but to simplify matters, the author considered it under two heads, which illustrated the microscopic and macroscopic changes the results of general peritonitis.

It is an indisputable fact that the type and virulence of the inflammation is largely dependent upon the origin, hence in our bed-side work we may consider the subject under the following etiological classification:

Infection from Without.—Immediate: This is direct infection of the peritoneal membrane through penetrating wounds of the abdomen, either accidental or surgical. Mediate: This form embraces all cases of contamination of the peritoneum occurring from extension of adjacent infected areas, as leakage from mural abscesses, or puerperal infection.

Infection from Within.—Immediate: Visceral perforation or rupture and direct inoculation of the peritoneal membrane with escaping contents, as in perforating typhoid or gastric ulcer, appendicitis, or rupture of gut and bladder. Mediate: Infection by emigration of micro-organisms through visceral wall of impaired resistance, as in incarcerated hernia, intestinal obstruction, ruptured ovarian cyst.

The author then reported a few illustrative cases. One case was reported of general purulent peritonitis. The patient recovered, and the author considers that it was due entirely to free incisions, thorough irrigation, and ample drainage.

THIRD DAY, THURSDAY, NOVEMBER 15TH.

History of Vaginal Extirpation of the Uterus.—DR. GEORGE J. ENGLEMANN, of St. Louis, read a paper on this subject, in which he stated that at the New Orleans meeting of the Association he was deeply interested in vaginal hysterectomy, which he presumed was a comparatively new operation with very recent modifications; but Dr. Lewis, of that city, called his attention to an old French pamphlet, showing that the operation had been done in the '20's. Since then he has found it was done still earlier, precisely as it is done to-day, the operation having developed step by step.

DR. LEWIS, of New Orleans, La., in the discussion stated that the first vaginal hysterectomy was performed by Dr. Dabourg in the little town of Autell, France.

Reminiscences of Dr. J. Marion Sims in Paris.—DR. EDMOND SOUCHON, of New Orleans, La., read a paper with this title (see p. 705).

Cancer of the Gravid Uterus.—DR. GEORGE H. NOBLE, of Atlanta, Ga., read a paper entitled, "A Case of Carcinoma of the Parturient Uterus, Removed Three Days after Confinement; Recovery." The woman had previously been confined, sustaining a laceration of the cervix uteri, which perhaps was a factor in the cause of the disease. In the first few months of the last pregnancy the patient was treated locally by her family physician, and there was nothing to cause a suspicion of malignancy. Almost the entire vaginal portion of the cervix was destroyed, less than one-fourth of its circumference remaining intact. The induration extended deep into the uterine tissue, but could not be felt beyond the limits of that organ. The roughened ulcerated surface was easily traced for a considerable distance within the cervix, the os being dilated to about five centimetres in diameter. Her condition was unpromising, and surgical interference was clearly interdicted, so the os and vagina were cleansed thoroughly and lightly dressed with gauze. She was then placed profoundly under the influence of morphia sulphate with a view of arresting labor, securing rest, and recuperation sufficient to permit evacuation of the uterus, which occurred spontaneously twelve hours later. The child was poorly nourished and lived only a few weeks, finally dying of inanition.

The main point in the paper was to show the feasibility of hysterectomy in the puerperal state for cancer of the uterus, as the case reported clearly demonstrated, even though it is too early to claim immunity from the return of the disease.

Ligation of Arteries.—DR. JOHN A. WYETH, of New York, reported two cases of ligation of the external carotid artery. The reason for narrating these two cases was to bring before the Association a consideration of the inflammatory changes which occur in arteries which have been ligated, and to discuss at length the best methods to pursue in these operations to secure the greatest safety to the patient.

In tying arteries, an important point to consider is the selection of a ligature. It seems to the author that in the animal ligatures, and especially in well-prepared and properly asepticized catgut is found the best ligature material. For the last ten years he had used catgut almost without exception, only once or twice using silk, and then in the ligation of the large venous trunk close to the root of the neck, in which he was fearful that the animal ligature might slip from the blood-pressure in the act of vomiting as the patients came out from under the influence of the anæsthetic.

Porta, in four hundred experiments, found that in from one to two years, seventy per cent. of catgut ligature had become absorbed, thirty-six per cent. of silk, sixty-six per cent. of hemp and flax, and twenty per cent. of horse-hair. Order of rapidity: catgut, hemp, silk, horse-hair.

Simultaneous Appearance of Cancer in Breast and Uterus.—This paper was read by DR. JAMES EVANS, of Florence, S. C. The subject of this interesting manifestation of the disease was a lady of fifty-three years of age, married, and the mother of six children. A striking peculiarity in the history of the case was, that when the disease was most active and destructive in the breast, it rather checked and retarded its tendency in this direction in the uterus. Excision of the cervix and removal of the breast were proposed, but declined.

The author closed by saying that although there is a very general concensus of opinion among surgeons that the most successful treatment of cancer affecting the breast and uterus is early and radical removal by the knife, yet it is doubtful in the opinion of the author if the operation is advisable when the disease appears in multiple form and in distant organs. When the disease is confined solely to the uterus and recognized at an early stage of its invasion, the prompt removal of the organ is usually followed by permanent recovery; in fact, recurrence less often takes place than removal from any other organ or part of the body.

Varicocele.—DR. W. E. PARKER, of New Orleans, reported seven cases of varicocele treated by incision, ligation, and shortening of the scrotum. An incision, varying in length according to the size of the varicocele is made, and the scrotum shortened by converting the wound from a longitudinal into a transverse one. All cases which recovered with union by first intention are still doing well, the period since the first operation being seven months. At the conclusion, he laid the following general indications for the treatment of varicocele. The milder form should be treated with a suspensory bandage with proper attention to diet, exercise, and bowels. A varicocele should be operated upon: 1. If it is of large size. 2. If it is painful. 3. If marked nervous symptoms are present. 4. If the testicle is atrophying. 5. If the varicocele is increasing rapidly. 6. If it is an obstacle to entering a public service. 7. If, on account of a

patient's occupation, a suspensory is troublesome and he desires an operation.

Fibroid Tumor of the Uterus with Suppurating Ovary Discharging per Rectum.—Dr. Rufus B. Hall, of Cincinnati, O., reported the following case: The patient, aged forty-four, was known to have a fibroid tumor for five years. She had suffered from sepsis for five weeks previous to the operation. In addition to the fibroid tumor was a large suppurating ovary holding about two pints of pus, which was discharged per rectum every eight or ten days. The suppurating ovary was densely adherent, and after its removal disclosed a large opening in the rectum. The operation included total extirpation of the fibroid uterus with the suppurating ovary, and repair of the intestinal rent. There was no leakage of the injured bowel after the operation. The patient recovered.

The speaker drew the following conclusions: The question of operation during sepsis is one that will admit of discussion both *pro* and *con*, but in the end it must be decided by the merits of the individual cases and not by rule. As to technique, total extirpation was given the preference, as it gives the ideal condition both theoretically and practically for after treatment. The Baer method was condemned, as it does not give thorough drainage—a thing absolutely necessary where there are extensive raw surfaces which have been bathed in pus, and no peritoneum to close off the general peritoneal cavity. The strengthening of the suture line with a tag of adventitious tissue was advised. The packing of the pelvis with gauze to protect the cavity from intestinal leakage, should any occur, and to prevent intestinal adhesions, was recommended. The gauze is usually removed on the fourth day and peroxide of hydrogen used as a wash for the cavity several times daily.

Again, forcible dilatation of the sphincter-ani muscle to cause incontinence, thus relieving the intra-intestinal pressure from accumulating gases, the doctor says, adds greatly to the chances for recovery. He first employed it for this purpose on February 6, 1893, in an operation for extra-uterine pregnancy with extensive bowel injury, the patient recovering. He says, as far as he knows, he is the first man to practice forcible dilatation for this purpose.

Pelvic Surgery.—Dr. J. G. Earnest, of Atlanta, Ga., contributed a short paper in which he reported some complicated cases of pelvic surgery. Two cases were detailed simply to illustrate a method of treatment that under certain circumstances is safer for the patient and just as apt to give relief of symptoms as total extirpation of the tumor; also to emphasize a growing conviction the author has that intestinal adhesions are frequently tinkered with when it would be best to let them alone. The essayist was no advocate of timid and imperfect surgery, but in cases where the tumor can be effectually dealt with without disturbing old, thoroughly organized adhesions, which the history and condition of the patient clearly show to be harmless, and in view of the fact that if those adhesions are loosened they will almost certainly anchor at some other point where they may be a source of constant annoyance, or even produce a fatal obstruction of the bowel, he believes it best to leave them undisturbed.

The Removal of an Intra uterine Fibroid Tumor by Morcellement without Hemorrhage.—Dr. Herbert M. Nash, of Norfolk, Va., read a short paper on this subject. In September, 1892, he saw in consultation Mrs. A——, aged about forty-two, the subject of intractable hemorrhages from the uterus, lasting from two to three weeks of each month, and which had been habitual for several years. The uterus could be plainly felt above the pubes, and by the conjoined method, sound, etc., the diagnosis of intra uterine fibroid was made. Not wishing at that time any radical procedure, she continued under the care of her physician, whose best efforts to control the hemorrhage proved fruitless. On July 11, 1893, she entered the hospital for surgical treatment.

On August 26th the essayist operated under ether. It was found quite impossible to dilate the os to the extent desired, but there was room enough for the manipulation without dividing the cervix, and no difficulty was found in seizing the presenting mass—the attachment of which to the uterine walls had been made out to be sessile—with a strong vulsellum. Upon making traction with some force, in order to determine the best method of procedure, the tissue gave way, and the withdrawn part of the detached mass was quite large, but no bleeding followed. This fact decided the doctor to proceed by morcellement, and with forceps, scissors, and the instrument he exhibited, the whole growth was removed piecemeal, and with only a slightly colored serous discharge. The previous packing had been so effectual that the growth itself, and indeed the uterine walls, appeared to have been exsanguinated. The fragments removed, when under strong compression, presented a mass of fibroid tissue nearly as large as an ordinary cocoanut. When the patient left the hospital the uterus had contracted firmly, and measured a fraction over three and one half inches in depth, occupied its proper position in the pelvis, and the patient is to day entirely well, with perfectly normal functions.

Election of Officers.—The following officers were elected: *President*, Dr. Louis McLane Tiffany, of Baltimore, Md.; *First Vice President*, Dr. Ernest S. Lewis, of New Orleans, La.; *Second Vice President*, Dr. Manning Simon, of Charleston, S. C.; *Treasurer*, Dr. Richard Douglas, of Nashville, Tenn.; *Secretary*, Dr. W. E. B. Davis, of Birmingham, Ala.

After introducing and adopting resolutions of thanks, the Association adjourned to meet in the city of Washington, D. C., the second Tuesday in November, 1895.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 14, 1894.

George C. Freeborn, M.D., President, in the Chair.

Spontaneous Rabbit Septicæmia.—Dr. Alexander Lambert reported a spontaneous outbreak of septicæmia hemorrhagica occurring among rabbits. Among the rabbits confined in the animal house connected with the pathological laboratory of the College of Physicians and Surgeons, there occurred in January, 1894, a large number of deaths from an unknown cause. These deaths were among the rabbits which had been operated upon, and among the healthy animals. The majority of these rabbits were fresh from the country, and had been confined but a few days in the animal house. Nearly thirty died within two weeks. Autopsies showed, in the majority of cases, a slight congestion of the lungs and an enlargement of the spleen. All the other organs were apparently normal. Cover glass smears and cultures of the heart's blood of several of these animals, gave a small bipolar stained bacillus, the morphology and biology of which, the speaker said, he would give later on in these remarks. In one case there was a universal exudative peritonitis. The exudate was largely fibrinous, with but little purulent fluid, and the intestines were matted together. The spleen was large and dark; the other abdominal organs were apparently normal. Both pleural cavities, and the pericardial sac, were filled with fibrinous exudate and purulent fluid. The lungs were congested.

In one other case the abdominal organs were apparently normal, except that the spleen was small and pale. Both lungs were, however, crowded and flattened against the vertebral column by an abundant exudate. The exudation in the right pleural cavity was reddish-yellow and fibrinous, and that in the left pleural cavity was a yellow purulent fluid. The pericardium was also filled with a yellow purulent fluid.

Cover-glass smears and cultures of the peritoneal and pleural exudates gave a bipolar stained bacillus, similar to that in the heart's blood of the other rabbits already

mentioned, and having the following characters: The bacillus was small and round-ended, the ends being more deeply stained than the centre. Sometimes the bacillus was uniformly stained, especially after being in contact for a long time with the staining fluid. These bacilli may present themselves as small ovoids, hard to differentiate from cocci. They stain easily with the anilin colors, but are decolorized by Gram's method. The size varies from 1.5 μ long by 0.56 μ broad, to 0.7 μ long by 0.49 μ broad, the average being 1.1 μ long by 0.53 μ broad. They appear single, and sometimes united in pairs or in rows of three to four elements. They are non-motile, and do not liquefy gelatin. In gelatin plates they form small, light yellow, finely granular, sharp-edged colonies, which, after a few days, usually show a darker yellow centre and concentric rings. The deeper colonies are of the same appearance. The colonies are often circular, often ovoid. Sometimes the colonies just below the surface seem to grow better than the surface colonies. In punctures in gelatin the growth usually commences just below the surface, extending in a thin, white, finely granular streak to the bottom of the puncture, the lower half of the growth being made of fine, separate dots. The upper half of the growth is formed by the coalescence of the small colonies. The growth remains slight. Sometimes there is a surface growth; when this occurs it is a gray-white, slightly raised growth extending but little around the puncture opening. In agar at 37.5° C., a thin, smooth edged surface growth occurs, extending not far beyond the inoculation line. This is a bluish-white by transmitted light, gray-white by reflected light. The growth extends to the bottom of a puncture, and slightly around the puncture opening. The growth is similar, but slower at room temperature. On Wurtz litmus, lactose agar, a good growth occurs, but with no change in the color of the litmus, and without formation of gas. In simple meat broth (one per cent. commercial peptone, one half per cent. salt, and meat infusion) the growth is abundant, causing a diffuse turbidity of the medium with a whitish ring around the edge at the surface of the broth, with an abundant grayish-white viscid sediment. At times the growth is more flocculent than at others. The broth remains turbid after two months. With growth for forty-eight hours at 37.5° C. in broth with one per cent. peptone, and half per cent. salt, the indol reaction is obtained by the addition of sulphuric acid without the addition of nitrites.

In a bent tube containing broth with one quarter per cent. peptone, one half per cent. salt, and two per cent. glucose, the medium becomes turbid, but no gas is formed, the growth occurring more abundantly in the open than in the closed end of the tube. In broth with 0.1 per cent. peptone, and 0.02 per cent. potassium nitrate, on addition of six drops of naphthalamine sulphate and a few crystals of sodium anilate, it gives a pink color, showing that it reduces the nitrates to nitrites. The bacillus grows in milk without coagulation, but with the formation of an acid.

As a rule, I have not been able to obtain any visible growth on potato, though a very slight invisible growth was proven to exist. The one exception to this rule was in the case of the rabbit with pleurisy without peritonitis. This single exception may have been due to some difference in the composition of the potato itself, as potatoes reacting 0.2 per cent., and 0.08 per cent. acid to phenolphtalein were used. A moderate growth was obtained in an anærobic hydrogen broth-tube.

To test the pathogenesis of the above germs, broth-cultures, grown for forty eight hours at 37.5° C., were used. Seven rabbits were given intra-peritoneal injections of 1 c.c. or 2 c.c. Two rabbits were injected with germs obtained from the heart-blood culture, 2 c.c. being given to each. Both were found dead in thirty hours. Two were injected with germs from the pleurisy cultures, one of them with 2 c.c. and the other with 1 c.c. The former was found dead in thirty hours, and the latter in thirty-six hours. Three were inoculated with germs from the peritonitis cultures, the first with 2 c.c., the second with 2 c.c., and the third with 1 c.c. The first animal was found dead in sixteen hours; the second rabbit remained alive; the third remained alive even after receiving, one week later, 2 c.c. more. The inoculations were made late in the afternoon, and on the following morning it was found that the animals had lost their appetite, that they remained crouching in a corner, and could not be made to run around, and that when laid on their sides they regained their crouching position with difficulty. When handled, they showed no evidence of pain. Two had a decided diarrhœa. The autopsies showed the animals emaciated; the bellies more or less distended; the inguinal and axillary glands enlarged and congested; the subcutaneous vessels over the abdominal wall filled with blood. Where the needle had passed through the abdominal wall was an area of purulent hemorrhagic œdema of considerable extent. In two cases this was very large. It did not infiltrate the abdominal wall itself to any great extent, but was superficial in the subcutaneous tissue. On opening the abdominal cavity, the intestines were seen to be adherent to the parieties, and glued together with purulent fibrinous masses. Over the surface of the large intestine were scattered petechial hemorrhagic spots, and large and small hemorrhagic areas. The small intestine did not, as a rule, show a hemorrhagic inflammation, though in one case it was very marked, the Peyers patches showing deeply infiltrated with blood, and the stomach on its greater curvature, and extending over on to the lesser curvatures, showing a great number of transverse hemorrhagic striations. The omentum always showed numerous hemorrhagic areas. The parietal peritoneum was congested. The fluid exudate varied from a slight increase of serous fluid to a large amount of turbid, purulent fluid, or bloody exudate. The spleen was invariably large and soft, and of a deep purple color. The liver and kidneys were normal in appearance. The lungs were sometimes normal in appearance, sometimes deeply congested. In two cases the pericardial sac was filled with turbid fluid. The thymus gland showed in all cases numerous hemorrhagic spots. The trachea and bronchi showed marked submucous hemorrhagic infiltration, except in the rabbit dead in sixteen hours, in which case they were normal. The spinal cord in the three cases examined showed petechial hemorrhagic spots on the membranes The brain of these three animals did not show any abnormal appearances.

The two animals which survived the inoculations were killed after ten days, they having shown no loss of appetite, or other symptoms. The one which had received 1 c.c., and then a week later 2 c.c. intra-peritoneally, showed no lesions whatever. The other having received 2 c.c., showed, at the seat of inoculation, a large subcutaneous abscess of yellowish white creamy pus. There was no œdema, and but very slight inflammatory changes around it. There were no other lesions. No cultures were made of this abscess, but cover-glass preparations gave the bipolar, stained, round-ended bacillus.

In the rabbits dying with peritonitis, cultures and cover-glass smears were made in all cases from the abdominal wall abscesses, peritonitic adhesions, spleen, left kidney, liver, and heart's blood, and in the two cases associated with pericarditis, from the pericardial exudate also. The cultures and cover-glass smears thus obtained showed pure cultures of the germ used for the inoculations.

Similar outbreaks of septicæmia among rabbits are described by Smith,[1] and Eberth and Mandry.[2] The germ so far described agrees very accurately with that isolated by Smith, in morphological appearance, size, culture, growth, and symptoms, and lesions induced in rabbits inoculated with pure cultures.

The bacillus of spontaneous rabbit septicæmia de-

[1] Smith: Journal of Comparative Medicine and Surgery, vol. viii., p. 24.
[2] Eberth and Mandry: Virchow's Archiv, Bd. 121, p. 340.

scribed by Eberth and Mandry, differs in its motility, culture, peculiarities, and pathogenesis for rabbits, and is a different, though closely related, micro-organism. The germ I have isolated also agrees in morphology, culture growth, and pathogenic peculiarities for rabbits, with the American swine plague bacillus described by Welch [1] in 1889. This germ appears to belong to the wide-spread family of bacteria which contains the chicken cholera of Pasteur, the rabbit septicæmia of Koch and Gaffky, the Wildseuche of Hueppe, the Rinderseuche of Kitt, the Schweineseuche of Schutz, the Buffelseuche of Oreste and Armanni, and the American swine plague.

The comparative studies of Caneva [2] and Bunzl-Ferdern [3] show the close relationship of the members of this group, and these authors consider some of them as probably identical. Hueppe [4] also believes in this probable identity, and classes these under one name, as the bacillus septicæmiæ hemorrhagicæ, from the form of septicæmia to which they give rise. Bunzl-Ferdern and Caneva further classify as belonging to the same family, but to another group, the bacillus of spontaneous rabbit septicæmia of Eberth and Mandry, the French swine plague at Marseilles, of Rietsch, Jobert and Martinaud, and the ferret plague of Eberth and Schimmelbusch.

As soon as it was appreciated that a plague was destroying the rabbits, all animals then in the animal house were removed, and the house and cages thoroughly washed out with a five per cent. carbolic acid solution. After a few days the animals were returned to their cages, and no further infection occurred.

Splenic Leukæmia.—Dr. W. P. Northrup reported a typical case of splenic leukæmia. The patient was a man thirty years of age, who had been sent to him by Dr. Toms, of Bellport, L. I., who had made the diagnosis. The man's work as an electrical engineer had exposed him to very high temperature, and to a high voltage of electricity. He had been in exceptionally good health up to six weeks before admission, at which time the present trouble was first noticed.

When first seen by the speaker his feet were greatly swollen, his skin was bronzed, his nasal respiration was greatly obstructed, and he was quite deaf. These symptoms were afterward decided to be due to adenoid growths, and to enlargement of the tonsils. There were numerous small nodules under the skin, and the parotid gland was prominent and very sharply defined. The cervical, supra-clavicular, axillary, and inguinal glands were also distinctly enlarged. The spleen was enormously enlarged, extending eleven and three quarter inches below the free border of the ribs. The ratio of the white blood-cells had been variously estimated by different observers as 1 to 3 and 1 to 4. They were largely mononuclear cells, small lymphocytes. There were few multinuclear cells. They were for the most part neutrophile; very few eosinophile. His temperature ranged from normal in the morning to 102° F., in the evening for the first week, and reached during the last five days of his illness a maximum of 103° F. The heart's action was rapid, but the pulse was full and of very lax tension. This was a very striking feature of the case. He also suffered from a marked hard swelling of the gums—a hemorrhagic gingivitis—very tender, with superficial ulcers. Night sweats were also quite severe. All that was accomplished by treatment was an improvement in the condition of the gums. Finally, he was taken with syncope, followed by marked delirium, coma, and death. When last estimated, the hæmoglobin was between thirty and thirty-five per cent.

The autopsy was made by Dr. George A. Tuttle, who found that the retro-peritoneal and mesenteric glands were enlarged. The liver was of the nutmeg variety, and weighed one hundred and one ounces, while the spleen, which was simply hypertrophied, weighed seventy-three ounces. The thymus gland was enormously hypertrophied. On section, it showed simple hyperplasia. There was no evidence of internal hemorrhage in the various cavities, as had been expected, but on the dura mater at the vortex were limited areas which appeared to be either localized pachymeningitis or lymphoid growths. There was nothing to indicate any change in the marrow of the bones. Specimens removed from the dura mater were exhibited.

Dr. James Ewing said that he had counted the blood-corpuscles in this case. At the first count there had been 425,000 white and 880,000 red, and on the second count, 430,000 white and 925,000 red blood cells.

Dr. Northrup also presented some white gall-stones which had been removed post-mortem from a gall-bladder. They were composed almost entirely of cholesterin.

A Frog with a Supernumerary Hind Leg was presented by Dr. J. S. Ely. The condition, he said, was a rare one, and had not been observed before at the college laboratory, although many frogs were kept there. The question arose—Was this frog an abnormal twin, or was this simply a dichotomy of one of the lower extremities? Bland Sutton says that all these dichotomies occur much more frequently in the lower animals than in the human subject, and he gives figures of both frog and toad showing such a condition.

The speaker said that, as to whether this was a "parasitic monstrosity" or not, he would say that, although the extra extremity seemed to be one extremity, there was at the distal portion a suggestion of there being two feet, there being six phalanges instead of five. When first seen, the frog was alive, yet no motion in the supernumerary limb had been observed, and no reflex movements could be excited.

Lipomatosis of the Heart.—Dr. James Ewing presented the specimen. The heart had been taken from a woman forty years of age, who had been received into the Roosevelt Hospital in a dying condition, so that no physical examination had been made. The heart showed the thickness of the muscle at the tip of the left ventricle to be less than one-sixteenth of a millimetre, and at the thickest portion half an inch. The muscular wall of the left auricle was almost invisible. The right side of the heart was similarly affected. There was a very moderate amount of interstitial myocarditis, and but little fatty degeneration of the muscle. The other viscera showed very advanced fatty degeneration. There was a phthisical process in the apex of one lung.

Thrombosis of the Auricle of the Heart.—The specimen was presented by Dr. George P. Biggs.

A laborer, thirty-nine years of age, was brought to the New York Hospital in an almost moribund condition, and consequently there was no clinical history. Some fluid was drawn off from the chest to relieve the urgent symptoms. At the autopsy, there was no subcutaneous œdema found. The peritoneal cavity was normal. Each pleural cavity contained about 500 c.c. of serous fluid, and the pericardium 250 c.c. of similar fluid. The heart was very greatly enlarged, and the cavities distended with blood to their fullest extent. This blood was almost entirely in the form of post-mortem clots. The distention of the cavities was greatest in the left auricle, the clot being fully as large as a man's fist. The dilatation markedly predominated over the hypertrophy. There was an unusually large appendage to the left auricle, and in this, and extending into the auricle, was a thrombus measuring 10 ctm. transversely, 4 ctm. vertically, and 2½ to 3½ ctm. antero-posteriorly. It was perfectly solid throughout, and distinctly stratified. The organ was enormously dilated, yet notwithstanding this the walls were considerably thickened. The mitral orifice was extremely narrow and the cusps were adherent, so that the orifice had been converted into a narrow slit, having extremely rigid walls. The left ventricle was very greatly dilated. The cusps of the aortic valve were thickened, and slightly retracted. The dilatation on the right side of the heart was marked, but not so ex-

treme as on the other side. The tricuspid orifice was so much relaxed that four fingers could be easily passed through it. There was also a large infarction occupying nearly one-half of one of the kidneys.

Stenosis of the Tricuspid Orifice.—Dr. Biggs then presented a specimen showing stenosis of the tricuspid orifice. In this heart the tricuspid orifice was narrowed so as to admit only two fingers with difficulty. It was removed from a woman aged twenty-seven, who had been in good health up to three years previously, at which time she had had an attack of acute articular rheumatism. She had recovered from this, but a few weeks before coming to the hospital had suffered a second attack. At the time of admission, the temperature was elevated; the heart was displaced; there were said to be double systolic murmurs present—one at the apex, and one at the base; there was slight pulsation in the veins of the neck. The urine showed only a trace of albumin at first, but later on the albumin reached as high as sixty per cent. She developed marked anasarca, and finally died with symptoms of uræmic poisoning. The chief features of the autopsy were the lesions in the heart, and an advanced chronic diffuse nephritis. The mitral, aortic, and tricuspid valves showed lesions of a similar character, consisting of some thickening, and of a number of small vegetations on the free border. The mitral valve admitted only one finger; the narrowing at the aortic and tricuspid orifices was not great. There were small thrombi in both auricular appendages in this case, and also behind the tricuspid valve. There were numerous infarctions in both lungs. The great point of interest was the appreciable narrowing of the tricuspid orifice.

Miliary Tuberculosis of the Liver.—Dr. Biggs presented still another specimen. It had been removed from a case of tuberculosis which had run a rather rapid course, with marked hectic symptoms and hoarseness. At the autopsy the larynx was found to be considerably ulcerated, and the lungs showed tuberculosis chiefly in the form of a large area of cheesy pneumonia, extending down one bronchus, and involving nearly two-thirds of the lower lobe. There were old lesions—small cavities and pigmented fibrous cicatrices—in both apices. The chief point of interest was the liver, which was very closely studded with small tubercles—a very diffuse miliary tuberculosis of the liver without similar lesions in the other organs visible to the naked eye.

The speaker said he had only seen this condition once before, and then in a case of tuberculosis presenting no unusual clinical features.

Dr. J. S. Ely said he had seen a large number of tubercles in the liver in guinea-pigs which had been inoculated with tubercle bacilli in the abdominal cavity. Of course, there was also a peritonitis under those circumstances. This had suggested to him that in the case under discussion the infection had gone to the liver by the portal circulation, and in that way had been filtered largely out of the blood.

What is the Status of the Ophthalmic Colleges?—In Chicago are two institutions, the so called ophthalmic colleges, which manufacture oculists and opticians *ad nauseam*. In either case, a course lasting six weeks suffices to lead to a diploma. This diploma is not a degree in medicine, in midwifery, in dentistry, or in veterinary science. It is *sui generis* and has no standing in law. If its possessor has been a registered physician who has complied with the medical practice act of the State in which he lives, he has a legal standing; but his diploma from the ophthalmic college does not of itself entitle him to practise. Dozens of graduates from these institutions are engaged in medical practice either as "opticians" or as "oculists." Under the circumstances we wish to know: What is the status of the ophthalmic colleges? Will the Illinois State Board of Medical Examiners please answer?—*Medical Fortnightly.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, November 22, 1894

MALCOLM McLEAN, M.D., CHAIRMAN.

Axis-Traction Forceps.—Dr. T. J. McGillicuddy exhibited an axis-traction forceps which he had devised in 1889, after a visit to Paris, where he learned that, because of certain objectionable features, the Tarnier forceps had been discarded, even by Tarnier himself. His instrument consisted of an ordinary Simpson forceps with the additional feature of short folding handles projecting backward at a right angle from the others. These shorter handles exerted traction in the axis of the brim. On folding them, the instrument could be used as the ordinary obstetric forceps. In an experience of over one hundred cases they had proven very satisfactory.

The advantages claimed by Dr. McGillicuddy for this instrument were: 1. That with its use axis traction is simple and uncomplicated. 2. That it is superior to Tarnier's, in the fact that while using it axis-traction at the superior strait is perfect. 3. That while in relation to Tarnier's instrument, a great deal has been said of the indicator, in this forceps the indicator is in the hands of the operator, and tells his *conscience musculaire* the direction of traction as well as the resistance. 4. That it does away with the trouble of Pajot's, Smith's or other methods, and in its use one has plenty of power and perfect control. 5. That it is easier to make rotation in the posterior positions with the adjunct handles, if it is thought best to use the forceps for that purpose. 6. That it is easy of application, and in its dual character it has all the advantages of axis-traction and the ordinary forceps, and saves the expense of buying two instruments where one will do.

The Tarnier instrument is complicated, cumbersome, and expensive, nullifying its good points—if it has any—and has been condemned by the Paris Obstetrical and Gynecological Society for these reasons. Its theory may be very pretty and interesting for those who have not had much experience in forceps delivery, but practically it is a useless and harmful instrument. No woman should be delivered except by axis-traction, and with these axis-traction handles you can determine the exact amount of resistance and the proper amount of force to employ, and readily and easily use it.

Dr. Leischman, in writing of the long forceps and high operation, says: "It is now very generally believed by those who have had the greatest experience, that a large proportion of the unfortunate results depend upon improper instruments, and especially upon the use of such as are deficient in power." The observations which on this point we have already quoted from Dr. Barnes, apply here with peculiar force. Power and control are co-relative factors toward the attainment of the result which we desire, and if there is a deficiency in the former, we can have but little confidence in the issue of the case.

With this forceps we pull directly in the axis of the brim. One cannot grasp the handles of the ordinary forceps with comfort with both hands and still make any great axis-traction. Most physicians say that the hands become cramped and lose all their muscular power after pulling for a short time.

In cases attended with some difficulty, who has not seen physicians with their feet placed against the side of the bed or the buttocks of the patient, hanging on to the handles of the forceps and pulling away with all their strength, while bathed in a profuse perspiration. These violent exertions are entirely wrong and unnecessary, as the arms alone should be used, and the body placed in a position where the traction can be easily arrested if there is any slipping of the blades. It is the improper use of the wrong kind of forceps that makes it such fatiguing and dangerous work.

Dr. E. A. Tucker said that axis-traction meant nothing more than pulling in the axis of the parturient canal, and without it he could not understand how delivery could be effected. He believed that he could get as good axis-traction without complicated mechanism as with. He had used the Tarnier instrument many times, but had since utterly discarded it, and his feelings were about the same with regard to all such instruments. The obstetrician was apt to trust too much to the instrument, and not to his own sense of the proper direction in which to pull. One should be able to deliver with traction exerted by one hand, if at all. The mistake was commonly made of hurrying things after applying the forceps, instead of giving the head time to mould. He had given even as long as fifty minutes after applying the forceps, thirty of which were consumed in moulding the head before any advance was made.

Dr. Marx thought well of axis-traction instruments, which he believed were being used more instead of less in this country.

Dr. Collver and others also made some remarks.

Chloroform Bottle.—Dr. E. A. Tucker exhibited a chloroform bottle which he had found in use among firms who handled acids, the glass stopper being so formed as to permit of escape of the fluid by drops or in a stream, as might be desired. He said it was cheaper and better than the bottle he had devised and shown to the Section some months ago.

Nymphfebulation. — Dr. Herman L. Collver exhibited photographs of a case of nymphfebulation, or locking of the nymphæ, practised on the young woman by her husband during his periods of absence. She had come from Germany, was twenty-eight years of age, had been married ten years. She had known her husband before marriage in the old country, and when she came to meet him here he resorted to this method of keeping her out of mischief while he was away. He first perforated the labia minora, and after the pain and swelling had diminished he introduced a small padlock, which he would remove on his return. He had practised this five years. Dr. Collyer said he had known of cases where buckles had been fastened over the labia, but this was the only one known to him of perforating and locking them together.

Entanglements and Shortening of the Umbilical Cord.—Dr. T. J. McGillicuddy read the paper. Probably in twenty-five per cent. of all labors the cord was either around the neck or in some other abnormal position which it assumed during the movements of the fœtus. It might cut off the blood supply and thus cause death of the fœtus; where the cord was unusually long it might be found wrapped two or more times around the neck, or around the neck, shoulders, and body. The author related two cases of death in the early months from constriction of the cord, in one the cord being found wound around the neck three times, in the other encircling the shoulder and body as well. A third pregnancy had gone to about term before the strangulation had taken place, due to the cord drawn tightly around the neck once. In the fourth case the woman had been in labor thirty-four hours. On extracting the child it was found in a state of decomposition, the cord around the neck and shoulder. A fifth case of death of the fœtus was related, then a sixth case in which the shortening of the cord produced by being wound around the neck, had resulted in acute inversion of the uterus fourteen hours before he saw the patient. Some other cases were referred to in literature, and then attention was called to the medico-legal interest of such cases, for the mother might be charged with strangling her newly-born, when in reality the strangulation had taken place in utero from winding of the cord about the neck. He also thought it was a cause of hemorrhage by traction on the cord thus shortened. He had seen an infant with the cord wound four times around its neck. In every labor he felt for it as a possible complication. Excessive pulling upon the cord sometimes caused flexion of the head upon the sternum and prevented the occiput from presenting. The abnormal position of the cord also favored exhaustion of the mother from delayed delivery. Labor was easier in the sitting or squatting posture, and it tended to relieve the cord to a certain extent.

A Pathetic Case.—Dr. A. Palmer Dudley had seen a few cases in which the cord was wound around the neck of the child one or twice. In one the woman had been infected by syphilis from her husband, had had several abortions in consequence before he saw her and discovered the syphilitic history and gave iodide of potassium. He succeeded in carrying her along to near term, when one night she was suddenly awakened by a rat gnawing at her face. In her fright she jumped completely over in bed, and from that time ceased to feel fœtal movements. Dr. Dudley instituted labor, but the child was born dead, having the cord wrapped twice around its neck, where it had left a blue line. They feared for the mother's reason, and she died suddenly some days later, exact cause unknown.

Spontaneous Rupture of the Cord.—Dr. Simon Marx said there were only two cases of spontaneous rupture of the cord known to him. One, mentioned by Dr. McGillicuddy, having come under his own observation, and undoubtedly due to the presence of a gumma in the cord. The woman was syphilitic. Entanglement of the cord was quite common. If around the neck at labor, the propriety of tearing or cutting it and extracting rapidly arose; otherwise strangulation might occur from tension.

Dr. E. A. Tucker thought the diagnosis of shortening of the cord or threatened strangulation could be made by careful study of the case. Umbilical souffle, rapid beating of the fœtal heart, and tumultuous movements were an aid. Where possible, he slipped the cord over the head when wound around the neck, but failing in this, he extracted quickly, and had not lost a child.

The Chairman spoke of interference with natural rotation where the cord was wound around the neck or shoulders. In this way many cases of obstinate posterior positions could be accounted for. The remedy was to unwind the child in the opposite direction, turning it completely around.

Surgical Treatment of Anteflexion of the Uterus.—Dr. Charles Bell White read the paper. A sharp bend in the axis of the uterus, which could not be straightened by the finger or by bimanual palpation, was accompanied in some cases by retroposition, in others by descent of the uterus. In both forms the cervix was apt to be elongated and the case likely to be mistaken for ordinary retroversion. He thought the condition began with menstruation, the heavy uterus, lacking in tone and support, becoming bent forward and gradually becoming fixed in that position. Dysmenorrhœa was attributed to interference with circulation, not to obstruction of the outflow from the uterus. The ordinary forms of surgical treatment comprised divulsion, curettement, amputation of the cervix, salpingo oophorectomy. He did not know that anyone had advocated lifting the uterus and fixing it in the new position. He had so treated one case. The girl had suffered greatly, and as other means had failed, he resorted to laparotomy, expecting to find the utero-sacral ligaments taut and the cause of the retroposition of the anteflexed uterus, but was surprised to find them relaxed. Lifting the uterus, he noticed that it straightened the bend, and therefore he fastened the fundus to the anterior wall. The result had been complete relief. Alexander's operation of shortening the round ligaments would not lift the uterus and straighten it. He would advise anterior fixation only in severe cases.

Dr. W. E. Porter would treat anteflexion and the dysmenorrhœa accompanying it by such measures as divulsion, Wylie's stem drain, tampon, boro-glyceride.

Dr. Collver did not think so severe an operation as laparotomy justifiable; that cases could be relieved by other measures. He would not introduce a stem, but would rely upon gauze for drainage.

Dr. Jarman had seen the case reported by Dr. White, and approved of the treatment where other measures failed to give relief from severe symptoms. Ventral fixation was preferable to taking a reef in the round ligaments within the abdomen, as suggested in the remarks of Dr. Porter, for the reason that these ligaments might stretch sufficiently to let a knuckle of gut fall between the uterus and abdominal walls, and become strangulated.

Dr. A. P. Dudley explained the dysmenorrhœa on the basis of interrupted circulation, which also was a causative factor of the original condition. The difficulty with Dr. White's operation was to obtain consent to its performance from the patient.

Dr. White closed the discussion.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICO-CHIRURGICAL SOCIETY — ACTINOMYCOSIS — PATHOLOGICAL SOCIETY—MALIGNANT DISEASE OF LARYNX—ACUTE SEPTIC EPIPHYSITIS—MALIGNANT DISEASE OF GROIN AND SECONDARY DEPOSITS—EPITHELIOMATOUS CYSTS—WOLFFIAN ADENOMA OF KIDNEY.

London, November 28, 1894.

The Societies are making heavy demands on our time and attention just now, though it often happens that some of the most interesting are ill adapted for a brief report.

At the last meeting of the Medico-Chirurgical there was a discussion on actinomycosis, which interested especially the dermatologists but which cannot be profitably reduced to a paragraph, and the paper on which it was founded was hardly worth summarizing.

At the Pathological Society there was an interesting exhibition of a number of specimens, and the reports of the cases gave rise to some valuable remarks. Thus Mr. Stephen Paget showed one of malignant disease of the larynx of a man aged sixty-four. A question arose as to whether it could be a sarcoma or carcinoma, and it was referred to the Committee on Morbid Growths.

Mr. Stephen Paget also showed a specimen of acute septic epiphysitis from a boy aged thirteen. A member questioned the correctness of the name, and suggested it was a case of acute pyæmia from the first, the wound being probably inoculated with a streptococcus.

Mr. C. A. Morton showed a malignant growth in the glands of the groin following the subsidence of a painful enlargement of the glands, with secondary growths in the skin at a distance from the primary tumor. The glands of both groins were enlarged and very painful, and then, on the subsidence of this condition, malignant growth appeared in those of one side. The patient was a man, aged forty one. Many months later a similar growth appeared in the glands of the other groin, and secondary growths in the skin and subcutaneous tissue of the abdominal wall, and in the lungs. The spleen was not affected. There was no source of primary infection. The histology of the growth was that of sarcoma rather than lymphadenoma; but the clinical history suggested that the disease was not simply primary sarcoma of the glands.

Mr. Bowlby showed an epitheliomatous cyst of the neck from a man, aged fifty-eight; the tumor had been noticed about two months before death. A similar specimen was shown by Mr. F. C. Wallis. The patient was sixty years of age, and noticed the swelling six weeks before he went to the hospital, in January last, when the swelling was the size of an orange. The growth eventually fungated, and the man died. A section showed typical squamous-celled carcinoma.

Mr. Bland Sutton said these cases were of great clinical importance on account of the rapidity with which they proved fatal. They had been described by German writers as "branchiogenous carcinoma," and by English pathologists as "malignant cysts." If these tumors arose in the bronchial clefts they would probably appear in infancy or youth, and not after mid life. He regarded the cervical lesion as secondary, the primary lesion being some small neoplasm hidden away, perhaps in a pharyngeal recess, and easily overlooked. One he had seen had this origin.

Mr. Shattock doubted if the epithelioma in a bronchial cyst was usually squamous. He had recently investigated a case and found that the epithelium was columnar and ciliated.

Mr. Shattock also exhibited microscopic sections of large adenoma of the kidney of a child, and discussed the reasons for thinking that such growths arose in the Wolffian body; he did not himself see that any proof had yet been adduced.

"ORIGIN OF THE TERM ANÆSTHETIC."

To the Editor of the Medical Record.

Sir: I notice, in your issue of December 8th, an account of a conversation upon this point, between Mr. Edgar Willett and Dr. Oliver Wendell Holmes, when the latter was in England, in 1886.

It is quite possible that Dr. Holmes had forgotten that he had written to Dr. Morton a letter elaborately analyzing the varied appropriateness of several names, and I take pleasure in sending to you from among my father's correspondence a copy of Dr. Holmes's original letter, exactly corroborative of the conversation above referred to. Dr. Holmes's letter reads as follows:

"Boston, November 21, 1846.

"My Dear Sir: Everybody wants to have a hand in a great discovery. All I want to do is to give you a hint or two, as to names, or the name, to be applied to the state produced and the agent.

"The state should, I think, be called 'anæsthesia.' This signifies insensibility, more particularly (as used by Linnæus and Cullen) to objects of touch (see 'Good-Nosology,' p. 259). The adjective will be 'anæsthetic.'

"Thus we might say the state of anæsthesia, or the anæsthetic state. The means employed would be properly called the anti æsthetic agent. Perhaps it might be allowable to say anæsthetic agent, but this admits of question.

"The words anti-neuric, aneuric, neuro-leptic, neurolepsia, neuro etasis, etc., seem to be anatomical; whereas the change is a physiological one. I throw them out for consideration.

"I would have a name pretty soon, and consult some accomplished scholar, such as President Everett or Dr. Bigelow, Sr., before fixing upon the terms, which *will be repeated by the tongues of every civilized race of mankind.*

"You could mention these words which I suggest for their consideration; but there may be others more appropriate and agreeable. Yours respectfully,

"O. W. Holmes.

"Dr. Morton."

When the young child now known as anæsthesia had been born into the world by the public demonstration of a painless capital operation at the Massachusetts General Hospital, October 16, 1849, it had no name, and none could be immediately found for it, since the language of the day had not as yet been called upon to express the act or the state produced by the act. It was necessary to christen it. Accordingly, a meeting was held at the house of Dr. A. A. Gould, at which were present Dr. Henry J. Bigelow, Dr. O. W. Holmes, and Dr. Morton, and Dr. Gould read aloud a list of names which he had prepared. On hearing the word "Letheon," Dr. Morton exclaimed, "That is the name the discovery shall be christened." Dr. Gould and the others also favored this name, derived from the mythological river

Lethe. But after a subsequent consultation with Dr. Holmes and a consideration of the terms suggested by him in the above letter, Dr. Morton adopted the terms anæsthesia, anæsthetics, and "etherization," the terms now in common use.

While upon this subject it may interest your readers to read another letter of Dr. Holmes's, written forty seven years later on—in fact, only a few months before his death—wherein no failure of his vigor or felicity of expression is wanting. This letter, now in the possession of the writer, has been published only in part, in the August number of the *Century Magazine* of the present year, in an article entitled "Dr. Morton's Discovery of Anæsthesia." It reads as follows:

"Boston, April 2, 1893.

"My Dear Sir: Few persons have or had better reason than myself to assert the claim of Dr. Morton to the introduction of artificial anæsthesia into surgical practice. The discovery was formally introduced to the scientific world in a paper read before the American Academy of Arts and Sciences by Dr. Henry J. Bigelow, one of the first, if not the first, of American surgeons.

"On the evening before the reading of the paper containing the announcement of the discovery, Dr. Bigelow called at my office to read the paper to me. He prefaced it with a few words which could never be forgotten.

"He told me that a great discovery had been made, and its genuineness demonstrated at the Massachusetts General Hospital, of which he was one of the surgeons. This was the production of insensibility to pain during surgical operations by the inhalation of a certain vapor (the same afterward shown to be that of sulphuric ether). In a very short time, he said, this discovery would be all over Europe. He had taken a great interest in the alleged discovery, had been present at the first capital operation performed under its influence, and was from the first the adviser and supporter of Dr. W. T. G. Morton, who had induced the surgeons of the hospital to make trial of the means by which he proposed to work this new miracle. The discovery went all over the world like a conflagration.

"The only question was whether Morton got advice from Dr. Charles T. Jackson, the chemist, which entitled that gentleman to a share, greater or less, in the merit of the discovery.

"Later it was questioned whether he did not owe his first hint to Dr. Horace Wells, of Hartford, which need not be disputed. Both these gentlemen deserve 'honorable mention' in connection with the discovery, but I have never a moment hesitated in awarding the essential credit of the great achievement to Dr. Morton. This priceless gift to humanity went forth from the operating theatre of the Massachusetts General Hospital, and the man to whom the world owes it is Dr. William Thomas Green Morton.

"Experiments have been made with other substances besides sulphuric ether, for the production of anæsthesia. Among them, by far the most important, is chloroform, the use of which was introduced by Sir James Y. Simpson. For this and for the employment of anæsthetics in midwifery he should have all due credit, but his attempt to appropriate the glory of making the great and immortal discovery, as revealed in his contribution to the eighth edition of the 'Encyclopædia Britannica,' is unworthy of a man of his highly respectable position. In the ninth edition of the same work his article 'Chloroform' is omitted and a fair enough account of the discovery is given under the title 'Anæsthesia.'

"Yours very truly, O. W. Holmes."

I am, yours very truly,

William J. Morton.

New York City, December 9, 1894.

Female Apothecaries.—Paris has only one apothecary shop controlled by a woman, while Brussels has five. London had 1,340 female apothecaries in 1891.

LOCALIZATION OF VISUAL CEREBRAL CENTRE.

To the Editor of the Medical Record.

Sir: In the Medical Record for December 1st, there appears an article entitled "A Contribution to the Study of the Location and Physiology of the Visual Cerebral Centre," which is so misleading in its conclusions, that it seems justifiable to call your attention and that of your readers to its errors. Since the appearance of Nothnagel's classical work on Cerebral Localization, it has been agreed that the only facts upon which reliance can be placed in determining the location of function in the brain are to be derived from cases of small lesion of long standing with accurate autopsy.

The entire tendency of recent investigation upon the visual area of the brain, as shown in Henschen's great works, "Pathologie des Gehirns" (1893) and Vialet, "Les Centres Cérébraux de la Vision" (1893), and Noyes, "Diseases of the Eye" (1894), is to prove that the primary cortical visual centres lie about the calcarine fissure in the occipital lobe, that the angular gyrus has nothing whatever to do with vision, and that there is no lesion behind the optic chiasm, either in thalamus or visual radiation or cortex anywhere which will produce a blindness in one eye alone. All lesions posterior to the chiasm produce homonymous hemianopsia. The entire consensus of opinion is opposed to the view first advanced by Ferrier and the English school, that blindness in one eye can be produced by a cortical lesion, and the only case with autopsy, cited by Gowers, is unsatisfactory and inconclusive, because of an imperfect clinical examination of the visual field.

In the article which I beg leave to criticise, the author has failed to recognize this consensus of opinion, citing only the English case. He reports a case without autopsy, which is manifestly inconclusive, and which an ordinary observer would easily recognize as a case of hysterical blindness, regarding the nature of which theories abound but knowledge is wanting; the recovery alone being sufficient to prove that no serious localizable cerebral lesion was present.

Fearing that the readers of your journal might be misled by this article, I have taken the liberty to point out its fallacies.

Yours very respectfully,

M. Allen Starr.

22 West Forty-eighth Street, December 4, 1894.

Medical Items.

A Fight for a Tooth.—A peculiar case occurred lately in Gera, and has not yet been definitely decided. A gentleman who had suffered for some time from toothache consulted a dentist, and on his advice consented to have the offending molar extracted. This was skilfully effected, not without some trouble, for the tooth proved to be a perfect monster in size, with roots measuring as much as two centimetres. The dentist was naturally desirous of preserving such a trophy, and, although the patient claimed the tooth as his property, refused to part with it. An action was accordingly commenced on the charge of defraudation, the defendant claiming he acted by the right of a time-honored custom, and that the tooth on being removed was a *res nullius*, and belonged to the first who took possession. I am afraid this will prove quite a difficult quibble to settle.—Berlin Correspondent *Occidental Medical Times*.

A Thirty-Pound Man.—Abner Astrop, a dwarf, died recently at his home in Johnson County, Ky., at the age of fifty-two years. His weight was but thirty pounds, and he was two inches less than three feet tall. His parents established him in a small cross-roads store when he was twenty years of age, and he spent his life in it, refusing to exhibit himself in museums.

IS IT THE BEGINNING OF THE END?

BY JAMES WEIR, JR., M.D.,
OWENSBORO', KY.

WHEN we come to examine the history of the world we find evidence that certain nations have, at times, reached a high state of prosperity, and have then degenerated to such a degree that they have either passed entirely out of existence, or have lapsed into a state of semi-barbarity. This has generally been brought about by conquest, but the races conquered had first become enfeebled by their habitudes of thought and manner of living. It is a well-established fact that luxury brings debauchery, and that debauchery occasions degeneration. All nations that have, heretofore, reached the zenith of their prosperity, have been engulfed, at some time or other, in the maelstrom of luxurious habits, and have fallen under the lethal influence of a degeneration occasioned solely by debauchery; for the luxury and debauchery of one class brought increased poverty on, as well as excess in, other classes, and poverty and excess are prominent factors in the production of degeneration, as we shall see further on in this paper. Says the brilliant author of "Psychopathia Sexualis," Krafft-Ebing: "Periods of moral decadence in the life of a people are always contemporaneous with times of effeminacy, sensuality, and luxury. These conditions can only be conceived as occurring with increased demands upon the nervous system, which must meet these requirements. As a result of increase of nervousness, there is increase of sensuality, and, since this leads to excesses among the masses, it undermines the foundations of society—the morality and purity of family life. When this is destroyed by excesses, unfaithfulness, and luxury, then the destruction of the state is inevitably compassed in material, moral, and political ruin."

Such was the condition of the Latin race when the fierce and hardy Vandals overran the Roman peninsula; such was the condition of the Assyrians when Babylon fell beneath the onslaughts of the great Macedonian; such was the condition of the Egyptians when the northern myriads swept down upon the fertile valley of the Nile and destroyed forever the once powerful and all conquering kingdom of the Pharaohs; and such, too, was the condition of the French nation in 1794, when Anarchy unfurled its red banner at the head of the most gigantic social revolution the world has ever known. At the present time, community of interests, as well as higher civilization, would utterly forbid the total subjugation of one civilized nation by another, such as occurred in the olden times; hence no nation need fear annihilation from such a source. The danger comes from another point and consists in the almost certain uprising, at some time in the future, of degenerate individuals in open warfare and rebellion against society.

The question whether the world is growing better or worse is often debated, and can be answered affirmatively on both sides. Better, because superstition, bigotry, and dogmatism have given way, to a great extent, to the tolerance and freedom of higher civilization and purer ethics in normal, healthy man; worse, because crime (and I mean by crime *all* antisocial acts) has greatly increased on account of the pernicious influence of degeneration. That superstition, bigotry, and dogmatism are on the wane, and that they will, sooner or later, be entombed in that depository of obsolete savage mental habitudes—absolute and utter oblivion—a glance at the success that science has achieved in the warfare waged against it by the Church, will at once declare. (Throughout this article I use the word Church to express priests of any and every denomination, whether Jew, Gentile, or Pagan, Protestant or Catholic.) A short incursion into this subject, *i.e.*, the Church's warfare on science, is absolutely necessary, for the triumph of science over its enemies—superstition, bigotry, and dogmatism, coincidently, ignorance and illiterateness—shows that the civilized world, at the present time, is markedly different in some respects from the world of ancient, mediæval, and even comparatively recent times; and, in summing up, this changed condition will be a weighty factor in making up an answer to the question which heads this paper.

When Olympus first faded away from the enlightened eyesight of the Greeks, and changed into space besprinkled with stars; when Zeus no longer held his divine court on its mystic summit; when oracles became mute and the fabled wonders of the "Odyssey" either vanished or resolved themselves into prosaic commonplaces under the investigations of the sceptic or the accidental discoverer, the Church made a most strenuous protest against the destruction of its traditions. Some of these early seekers after truth were killed and their goods confiscated. The Church issued its edict against heresy (and any doctrine that taught a belief antagonistic to the accepted tenets of pagan mythology and theogony was heresy), and hurled its anathemas against the heretic. Olympus, in the eyes of the Church, still existed, and Zeus, the man-god, still quaffed the sacred ambrosia in its shady groves. The Sirens still sang their entrancing songs, while Scylla and Charybdis were ever stretching out eager arms toward unwary mariners. Gigantic one-eyed Cyclops, with Polyphemus as their leader, still patrolled the shores of Sicily and kept their "ever-watchful eyes" turned toward the open sea. The hardy Greek sailor landed on the Cyclopean island, and discovered that Polyphemus, and Arges, and Brontes, and Steropes, and all the other one eyed monsters were nothing but sea-wrack, bowlders, and weeds. He sailed farther, past Scylla and Charybdis, and discovered no greater dangers than sharp rocks and whirlpools. Yet farther he sailed out into the mysterious sea, and the only Siren's song he heard was the whistling of the wind through the cordage of his vessel. In vain the Church thundered against the daring investigator. Neither fire, nor sword, nor imprisonment, nor death itself, could check the march of truth. Mythology and pagan theogony had received their death-blows; superstition, bigotry, and dogmatism were elbowed aside and gave place to dawning science. The Church held that that which had been believed by pious men for untold ages must necessarily be true. Science, in the garb of philosophy, with cold, dispassionate criticism proved that these hitherto accepted truths were arrant fallacies. The poets and writers then took up the subject, and finally the people fell into line, so superstitious, bigoted, dogmatic mythology died, intellectuality took its place, and higher civilization took a step forward.

With every new discovery, with every victory over superstition, bigotry, and dogmatism, civilization took a

step upward until it stands to day as far above the civilization of those old days as do the giant stems of the mighty red-woods above the chaparal and undergrowth of the California forests. In its battle with superstition civilization has grown strong, hardy, and, above all, vigilant. This last quality it will need most of all in its coming battle with the combined hosts of antisocial degenerates. In its battle against the Church civilization has gained the right to think for itself. It has demanded, and is now receiving, to some extent, the right of education, of erudition; and education is, and will be, a most potent warrior against degeneration.

That a luxurious manner of living eventually leads to debauchery, and that debauchery is a prime factor in creating degeneration, no physiologist of the present day will for one instant deny. I wish to show, in this paper, that luxury is hurrying us toward a social cataclysm, beside which the downfall of the Roman Empire, the destruction of ancient Egyptian and Babylonian civilizations, and the bloody days of the French Revolution, will sink into utter insignificance.

A brief *résumé* of certain historical epochs will be necessary in order to furnish a parallel from which I wish to draw several indisputable and incontrovertible conclusions.

The Roman people, under the leadership of its ancient heroes, was a nation of hardy warriors and husbandmen. That pre-eminent military genius, Julius Cæsar, had carefully fostered this warlike spirit in the bosoms of his compatriots, and by a series of brilliant campaigns had made the Roman nation the most powerful on the face of the globe. The Roman legions were not only victorious on land, extending their conquests into Iberia, farther Gaul, and still farther Britain, but the Roman triremes also swept the Mediterranean, from the Pillars of Hercules to the shores of Syria and Egypt. Wealth poured into the country from all sides and the people revelled in a boundless prosperity. Luxury had already begun to enervate the hardy soldiery at the time of Cæsar's assassination, yet not enough to show degeneration and demoralization. The empire under the first emperors steadily grew richer and more powerful, and the luxury of the rich more unlimited and licentious. At length a change can be noticed. The Roman legions, hitherto victorious over every foe, are now frequently vanquished; conquered tribes uprear the standard of revolt and refuse to pay tribute; the territorial boundaries of the empire materially shrink, and its once-conquered provinces pass out of its dominion forever. The gradual degeneration of this nation is faithfully mirrored in the characters of the emperors who governed it. Nero, Caligula, Tiberius, Caracalla, and Messalina, the depraved wife of Claudius and daughter of Domitia Lepida, herself a licentious and libidinous woman, were but accentuated types of the luxurious and debauched nobility. Not only did the nobility become victims of degeneration, but the poorer classes also lost their virility, until at last we find the stability of the nation preserved through the instrumentality of foreign mercenaries. The greatness of this once wide-spread empire dwindled away, the freedom of its institutions contracting along with its shrinking boundaries, until we find it lapsed into a state of barbarian despotism under the son of Aurelius; and, had it not been for outside influences, it would have eventually fallen into a state of utter and complete savagery.

Now, let us turn to a much older civilization. When the first conquerors of Egypt, about whom history can tell us so little, first occupied the fertile valley of the Nile, the country, in all probability, was inhabited by negroes. This conquering race drove out or enslaved the native population and founded the ancient kingdom of Egypt. This kingdom waxed strong and mighty until at the time of Rameses the Great, three thousand two hundred years ago, it was the most powerful monarchy in the whole world. This mighty son of Ra, Meiamoun Ra, or Rameses, as he is most generally styled, was a warrior and a statesman. He led his victorious troops north, east, and west, conquering nations as he went, until he dominated and brought into a state of vassalage over two-thirds of the then known world. Wealth flowed into his kingdom from all the surrounding countries, consequently luxury, with its never-failing associate, debauchery, made their appearance and the decadence of this mighty kingdom set in. It is true that many Pharaohs reigned after Rameses, and that the monarchy maintained its greatness for a long period of time; but luxury had taken hold on the people at the time of their greatest prosperity and had sown the seeds of degeneration, which flourished and grew apace, until the emasculated and effeminate people yielded up their independence to the conquerors, and passed out of existence as a nation forever.

Now, let us turn to a recent civilization. At the time of Louis XVI. the French nation was thoroughly under the influence of degeneration consequent to a luxury and licentiousness that had had a cumulative action for several hundred years. The peasantry and the inhabitants of the faubourgs, owing to their extreme poverty, itself a powerful factor in the production of degeneration, had lapsed into a psychical state closely akin to that of their savage ancestors. The nobility were weak and effeminate, the majority of them either sexual perverts, or monsters of sensuality and lechery. The middle class, then as ever the true conservators of society, seeing this miserable state of affairs, attempted to remedy it. Not fully understanding the dangers of such a procedure, they allowed the degenerate element to share in their deliberations. Their moderate and sensible counsels were quickly overruled by their savage associates, who brought about a Reign of Terror (with such psychical atavists as Marat, Danton, and Robespierre at its head), the like of which the world had never seen before nor has ever experienced since. I have demonstrated, in the three instances of history cited above, that degeneration has invariably followed luxury, and that a social and political revolution has been, invariably, the result of this degeneration; therefore, as we ourselves are entering upon an epoch closely akin to the three several epochs just mentioned, it will be well for us to study the phenomena that bring about such revolutions.

It is conceded by everyone that man completed his cycle of physical evolution many thousands of years ago. Since his evolution from his pithecoid ancestor the forces of nature have been at work evolving man's psychical being. Now, man's psychical being is intimately connected with, and dependent on, his physical being, therefore it follows that degeneration of his physical organism will necessarily engender psychical degeneration. Hence, if I can prove that man, by leading a life of luxury or one of poverty and want, produces physical degeneration, it will naturally follow that psychical degeneration will also accrue; and, as one of the invariable results of degeneration is atavism or reversion, both physical and psychical, the phenomenon of a social revolution characterized by pronounced savagery and barbarity, in which society is overthrown and anarchy instituted in its stead, will no longer appear strange and unnatural.

Neurasthenia, or the loss of nervous tonicity, is a prime factor in the production of degeneration. The offspring of neurasthenic parents always show degeneration in some form or other. That luxury produces neurasthenia can be demonstrated beyond the shadow of a doubt. Nine-tenths of the clientèle of the gynecologist is derived from the wealthy, luxurious, and fashionable class. The same may be said of the neurologist and alienist. Paresis and kindred forms of insanity are, almost exclusively, forms of degeneration affecting wealthy people, while the proportion of sexual perverts among the rich is remarkably high.

Let us see if we cannot discover some of the factors in the causation of such wide-spread and abundant neuroses among those fashionable and luxurious individuals who arrogate to themselves the title of "Society." Man is, naturally, a diurnal animal, but the fashionable

world has reversed the natural order of things and has made him a nocturnal animal. Now, the long continued influence of artificial light exerts a very deleterious effect on the nervous system; hence it is not to be wondered at that so many men and women of society are neurasthenic. Not only are those individuals who, voluntarily and preferably, spend the greater portions of their lives in artificial light, rendered nervously irritable, but those also who are driven by force of circumstances to turn night into day are likewise afflicted. Several years ago I met a distinguished editor at Waukesha, who was suffering greatly from nervous exhaustion. He told me that he was so situated that he did all of his work at night, often writing until three o'clock in the morning. I advised him to quit this and to do his editorial work during daylight. Not long after he wrote me that he had followed my advice, and that he was a new man in point of health. The loss of nervous vitality makes itself evident by a feeling either of exhaustion or irritability. The fashionable devotee, in order to counteract this, either stimulates the system with alcohol, or exorcises the "fidgets" by the use of sedatives, such as chloral or morphia. The baneful effects of such medication are not at once appreciable, but if continued for any length of time they will eventually result in a total demoralization of the nervous system. Time and again have I seen fashionable men and women, at the close of the season, veritable nervous wrecks. What necessarily would be the effect of physical and psychical lesions like these on a child begotten by such parents? The inevitable result would be degeneration in some form or other. Again, many men and women stand the drain of a fashionable season on their nervous systems without attempting to recoup through the agency of drugs, and at the end find themselves physically and psychically exhausted. They go to the seaside or some other resort, and, in a measure, recover their nervous vitality, only to lose it again during the next season. This continues for season after season, the nervous system all the time becoming weaker, until some day there is a collapse ending in hysteria, paresis, or some other of the hundred forms of neurotic disorder. What will be the effect on the progeny resulting from the union of such individuals? Again the answer must necessarily be—degeneration. Artificial light is not the only cause of this nervous irritability. The long and continued intercourse of the sexes in the ball-room, where the women are dressed so *decolleté* that they excite sensuality in the men, very frequently without the men being conscious of the fact, must necessarily exert a deleterious effect on the nervous system. Contact of the sexes in the dance is only pleasurable because of that contact. I am fully aware of the fact that this idea is scouted and denied by those who indulge in the waltz and kindred dances. They claim that no thought of carnality ever enters into their feelings. I know from personal experience that they are honest in this declaration, yet from a psychical standpoint they are wofully in error. Æstheticism and carnality are by no means as dissociate as the æsthete would have us believe. All pleasurable emotions that have their inception in the senses are fundamentally of carnal origin. The waltz is æsthetic, yet all of its pleasure is based on an emotion closely akin to sensuality. Men derive no pleasure from waltzing with one another, nor do women under like circumstances.

Nature demands in the interest of health a certain amount of exercise. The luxurious society man or woman utterly disregards this demand of nature, consequently indigestion, with all of its associated ills steps in, and becomes an additional factor in the production of nervous exhaustion. To tempt the appetite, highly seasoned foods, many of which are deleterious and injurious, are prepared and taken into the torpid and crippled stomach. Finally, nature rebels and the unfortunate dyspeptic is forced to go through life on a diet of oatmeal, or, weakened by lack of healthy sustenance, the brain gives way and the victim passes the remainder of his or her life in a lunatic asylum. Children begotten by miserable invalids like these, beyond a peradventure, must necessarily be degenerate. Indigestion is not the only ill that nature inflicts for any disregards of her laws. She is a rough nurse but a safe one, consequently she forbids the rearing of her hardiest creation, man, in hot houses, as though he were a tender exotic. The luxurious individual pampers his body, following the dictates of his own selfish desires and utterly disregarding the laws of nature, and, before he reaches middle age, discovers that he has become an old, old man, weak in body, but still weaker in mind. The children resulting from the union of the various neurasthenics described above are necessarily degenerate. As they grow up they show this degeneration by engaging in all kinds of licentious debauchery, and unnatural and perverted indulgences of appetite. In nine cases out of ten they will spend the fortunes inherited from their parents in riotous debauchery, and will eventually sink, if death does not overtake them, to the level of their fellow-degenerates—those who have been brought into existence by poverty and debauchery, and who await them at the foot of the social ladder. Among such degenerate beings the doctrines of socialism, of communism, of nihilism, and of anarchy have their origin.

Now, let us turn our attention to the evidences of luxury and debauchery, and the consequent evidences of degeneration which obtrude themselves on all sides. The reckless extravagance of the nobility of the Old World is well known. Vice and licentiousness even penetrate to the royal households, and princes of the blood pose as roués and debauchees. As I have demonstrated elsewhere, degeneration in the wealthy classes of society generally makes itself evident by the appearance of psychosexual disorders. The horrible abominations of the English nobility, as portrayed in the revelations of Mr. Stead, are well known. Charcot, Segalas, Féré, and Bouvier give clear and succinct accounts of the vast amount of sexual perversion existing among the French, while Krafft-Ebing informs us that the German empire is cursed by the presence of thousands of these unfortunates. When we come to examine this phase of degeneration in our own country, we find that it is very prevalent. This is especially noticeable in the larger cities, though we find examples of it scattered broadcast throughout the land. The editor of one of our leading magazines, in a remarkable series of letters, has shown that the wealthy New Yorkers revel in a luxuriousness that is absolutely startling in its license. Thousands are expanded on a single banquet, while the flower bills for a single year of some of these modern Luculli would support a family of five people for three or four years. Bachanalian orgies that dim even those of the depraved, corrupt, and degenerate Nero are of nightly occurrence. Drunkenness, lechery, and gambling are the sports and pastimes of these ultra rich men, and it is even whispered that milady is not much behind milord in the pursuit of forbidden pleasures.

Psycho-sexual disorders are not the only evidences of degeneration in the wealthy, by any means. Many a congenital criminal is born in the purple, who shows his moral imbecility in many ways. Sometimes he sinks at once to the level of a common thief, but generally his education keeps him within the pale of the law. Always, however, his sensuality is unbounded, and he will hesitate at nothing in order to gratify his desires. This unbridled license has already had its effect elsewhere. We see that it has even corrupted the guardians and conservators of the public peace. The recent investigation of the police board of New York shows a degree of corruption that is simply overwhelming, and that the same state of affairs exists in Chicago, New Orleans, St. Louis, and other large cities, I have every reason to believe. There are yet other evidences of degeneration; witness the eroticism that is to be found in our literature. Unless a book appeals to the degenerate tastes of its readers it might just as well never have been published. This is not cynicism; it is plain, unvarnished truth—witness

the success of "His Private Character," of "Is This Your Son, My Lord?" of hundreds of other works of the same character. Again, turn to the stage and we find the same thing. The tragedies and comedies of Shakespeare are shelved, while society plays and "living pictures" hold the boards. Salacity, with only sufficient covering to barely hide downright lewdness, is everywhere apparent. Now, what is the result of all this? There can be but one answer, and that is degeneration. That which happened centuries ago will happen again, for man is governed by the same laws of nature now as he was then.

Statistics show that insanity is markedly on the increase. This is not to be wondered at when we take into consideration the fact that debauchery is the rule, and not the exception, among certain classes of people. Syphilis, one of the most productive causes of degeneration, is exceedingly active throughout the whole civilized world. Blashko states that one out of every nine or ten men in the city of Berlin is tainted with syphilis. This is wholly attributable to the unbounded sensuality of the people. Crime of every description is rearing its hydra-head and clasping in its embrace an alarming proportion of human beings. I have shown elsewhere[1] that the congenital criminal is the result of degeneration, and that he comes from all classes of society. He is, however, most frequently the product of the lower class, and lives and dies among his congeners. I have shown also[2] that the anarchist, the nihilist, and the socialist belong to the same category of degenerate beings. Poverty, brought on by the luxury of the rich, by war, and by high taxation, has, during the last millenary period, been very fertile in the production of degenerates in the Old World. Lack of food and sanitation, the usual adjuncts of poverty, are powerful factors in the production of degenerate individuals. The Old World has gotten rid of these people as rapidly as possible by unloading them on our shores. Year after year, practically without restriction, thousands of these antisocial men and women have swarmed into our country, until we, comparatively speaking a nation just born, contain as many of these undesirable citizens as any of the older nations. They still continue to enter our gates, and we are adding to their number, as I have shown, by our own production. Some day—and I greatly fear that day is not very far distant—some professional anarchist (for there are professional anarchists as well as professional thieves) will consider that the time is ripe for rebellion, and, raising the fraudulent cry of "Labor against Capital," instead of his legitimate cry, which is "Rapine, Murder, Booty!" will lead this army of degenerates, composed of anarchists, socialists, nihilists, sexual perverts, and congenital criminals, against society. And who will bear the brunt of this savage onslaught? The ultra-rich? By no means. The great middle class—the true conservators of society and civilization, will fight this battle. It will be a strife between civilization and degeneration, and civilization will carry the day. There would have been no French Revolution had the middle class been as wise then as it is to day. They were taken by surprise at that savage, bloody time, but as soon as they recovered how quickly they brought order out of chaos! Education is the bulwark of civilization, and the great middle class, freed of dogmatism, bigotry, and superstition, is welcoming education with open arms. It is gaining recruits, and is strengthening its defences, so that when the end comes its enemies may find it fully prepared. When this fight takes place, millions of dollars' worth of property will be burned, and thousands of lives will be sacrificed, but when the smoke of battle clears away civilization will be declared the victor. And the ultra rich, what of them? They will simply open their purses, like they did in ancient Rome, and pay for the privilege of being protected. The sober middle class is a business people, and they will demand and obtain assistance from their wealthy brethren. From the signs of the times and the evidence before me, I have no hesitation in declaring that I believe that the beginning of the end is at hand. This social cataclysm may not occur for many years, yet the agencies through which it will finally be evolved are even now at work, and are bringing the culmination of their labors ever nearer and nearer as time passes.

"WAVELAND."

EDUCATION A FACTOR IN THE PROPHYLAXIS OF DISEASES OF WOMEN.[1]

BY FRANCES STORRS, A.B., M.D.,

TOPEKA, KAN.

FIFTY-ONE years ago Dr. Oliver Wendell Holmes, whose loss we mourn to-day, published a paper upon the contagiousness of puerperal fever, and struck the first blow for prophylaxis in the diseases peculiar to women. The clear argument of that famous classic won its way in the face of bitter opposition and learned opinion—this, too, without the aid either of microbe or microscope. To-day the spirit of that paper is recognized as the spirit of medical progress in the last half-century. Prophylaxis has revolutionized the practice of medicine, and wrought a firm foundation for the splendid superstructures of our systems of State medicine and boards of public health. Parallel with the development of the prophylactic management of disease, even dependent upon that management for success, has been the growth and perfection of modern surgery. Hand in hand they have entered hospital and infirmary, wards for children and lying-in women, and the results have been good to hear.

It is a curious fact that to-day, in the department of gynecology, the so-called diseases of women, prophylaxis has been so nearly lost sight of, while surgery has usurped the field. I need not remind you of the multiplicity of the surgical articles upon gynecological subjects in medical literature during the past ten years, their name is legion, and many are already relegated to the dark ages; but the indices to our recognized authorities upon gynecology are worth considering for a moment, and will illustrate my point. In the "Cyclopædia of American Gynecology," published in 1888, we look in vain for any article relating directly to the etiology of the prevalence of disease among women. Indirectly, several of the authors speak of the causes of certain conditions, but only in brief. Dr. George T. Harrison, in writing upon uterine displacements, in the second volume, makes the pertinent statement: "Prophylaxis is usually left out of the question by systematic writers."

In the "Cyclopædia of Gynecology," brought out by William Wood & Co., in 1887, chiefly the work of German writers, the eight volumes contain no reference to prophylaxis, and only very casual reference is made to etiology.

Pozzi deals only with pathological details and treatment.

Garrigues, in a work of 660 pages, devotes less than six to the discussion of "Etiology in General." Prophylaxis is spoken of here and there, but at no great length.

Thomas, fifteen years ago, and the recent Thomas and Mundé, devote one chapter to the etiology of uterine disease, and throughout these books, especially the later work, appear constant hints as to the prevention of certain conditions. Tait has no chapter on etiology, but he never fails to make his opinions upon the causes of specific conditions clear.

There is little difference of expression in these scant comments upon etiology. Briefly, the causes of these so common pathological conditions in women are of two varieties:

1. Etiological factors for which the woman is chiefly

[1] Read before the Eastern Kansas Medical Society, at Kansas City, Kan., October 9, 1894.

responsible. 2. Etiological factors for which someone else is chiefly responsible.

Under the first head belongs the list which Thomas gives: "Neglect of outdoor exercise; excessive development of the nervous system; improprieties of dress; imprudence during menstruation; imprudence after parturition; prevention of conception and induction of abortion; marriage with existing uterine disease;" and I add from Garrigues, "over-education, particularly in music." These the woman might prevent.

Under the second head: Child-bearing and its consequences, many evil results of which the doctor might prevent; and infection by the gonococcus, which in ordinary cases the husband might prevent.

Here are eighty-five per cent. of the diseases of women. To the remaining fifteen per cent. belong the neoplasms and malformations, which we shall turn over to the surgeon without protest or comment.

Concerning the last-mentioned etiological factor, the gonococcus: If the infection of the utero-tubal tract by the germs of gonorrhœa meant inevitable, sudden death to the woman thus infected, some means would be found potent enough to reduce such fatalities to the minimum. But since it means only a life of such misery that death is a longed-for release, wives and mothers continue to be exposed to that infection; and too often, alas! the protection of the physician is given the offender rather than the innocent offended. And the modern gynecologist, secure in his new found ability to diagnose pus tubes, views with complacency the seed-sowing that is everywhere before his eyes, and smiles a little as he contemplates the harvest of long rows of ticketed jars.

Concerning child-bearing as a cause of uterine disease, too much has been written to warrant even a passing remark from me. Yet something must be radically wrong somewhere, that so many neglected cases of lacerated cervix and perineum, with the accompanying subinvoluted uteri and long train of nervous symptoms, come into the specialist's hands.

It is with the first variety of etiological factors, however, that this paper has principally to deal. There seems to be a tendency in all these works to accept the present condition of woman as an inevitable one, even implying that they prefer to be ill, and choose a life of pernicious dressing and reckless imprudence, especially to exaggerate nervous phenomena and induce uterine affections. What wonder that the art of extirpation has supplanted the science of prevention in treating such irrational beings, and that the very latest and most approved method of dealing with diseased pelvic organs is to preserve them entire in alcohol, as being too complicated a mechanism for the ordinary woman to be entrusted with!

It is far from my purpose to decry the results of surgical gynecology. No one realizes more keenly than I the utter futility of "treating" a tube distended with pus, and that we need no further demonstration of the fact that most pathological processes of long standing in the pelvis are only aggravated by much of the so-called conservative treatment.

But to return to the list of the causes of disease above quoted as being those for which woman herself is largely responsible. One of them is hardly worth a discussion.

Woman's dress bears the brunt of masculine denunciation whenever her ill health is mentioned; yet I venture to assert, as a matter I have been at no small pains to investigate, that nine tenths of the women in the ordinary walks of life dress comfortably, and of the women who have learned to think for themselves, the other tenth is busy inventing some advanced and enlightened costume.

For all the rest of the imprudence, carelessness, and the like in that list enumerated, there is but one excuse, which is no more an excuse in dealing with physiological law than in the violation of the voice of civil authority, but which is too often pleaded as an excuse in both cases; that is ignorance, and an ignorance which is density itself.

Two great necessities, contingent upon mere physical existence, confront every woman; by conformity to their laws she must lose or win, live or die. Nature insists upon self-preservation and preservation of the species. Moreover, she scorns to perpetuate a deteriorating type. How little the ordinary wife and mother, even in these boasted *fin de-siècle* days, knows of the real significance of life, or those mighty forces that know no deviation; and how little she is prepared for the part she must needs play, whether she will or no, in this fierce struggle for mere survival. If it takes three years of constant study and clinical observation to fit a man to wait upon a woman in confinement, and to faithfully discharge the few small duties nature has left undone at that time, how much longer ought it to take to fit that woman for her part in the preceding nine months, and for the responsibility which becomes hers at that time?

Tait alone, of the authors whom I have mentioned, speaks of the ignorance of women in regard to the vital processes of their nature, as largely responsible for the prevalence of uterine disease. He condemns such ignorance as unnecessary and inexcusable, and suggests that it may be removed by the study of the analogous sciences; that the laws of reproduction are the same wherever manifested; and to the observer of plant life who has witnessed the development and understands the structural significance of anther, oviduct, and ovary, the ordinary processes of sexual life present no mysterious difficulty of comprehension. I may be pardoned for differing with so great an authority, but in my school-days, when fitting for college, with a head full of Latin, Greek, and pure mathematics, a very nice little work, written upon the analogous botany idea, was put into my hands as a safe and proper thing for me to read. I don't think it did me any harm, but it left a very confused idea of the semi-physiological, semi-sentimental aspect of the subject so distasteful that I never cared to investigate the subject further.

What all women need as a preparation for their highest function in life, is a thorough training in anatomy and physiology. That training should begin at an early age in preparation for the advent of menstruation, the physiological import of which process should be made as clear as our best authorities can make it. From fourteen to eighteen or twenty, the aim of the young woman's training and education, in school and out, should be toward physical perfection. Systematic exercise in the gymnasium and out of doors should be a daily certainty, and the full process of gestation and parturition, with the development of the embryo, and the growth and needs of the infant, should be unfolded in continuous instruction.

Any interference in the natural order of development in the young girl should be taken in its very incipiency. Interference in nutrition, which is often succeeded by pathological conditions only amenable to the surgeon's knife, may be easily handled in their early stages. When women turn their attention to acquiring physical fitness for motherhood, there will be less demand for the professional laparotomists.

In all seriousness, this is no Arcadian dream. There is not a mother alive but would spare her daughter the suffering she has undergone in acquiring the "Wisdom of Experience." The difficulty is, she does not know how, but she does feel her ignorance. Over and over again they say to me, "If I had only known."

More than that, there is a growing dissatisfaction with the results of our present system of higher education for woman. The women who go out from our colleges to fulfil the law of their destiny by becoming the mothers of families, feel that some very essential subjects are left out of our college curricula, and they would be glad enough to exchange a few books of Homer, or even the enjoyment of Dante in the original, for some sound facts about life and health.

Garrigue says that our girls are over educated, and especially in music. Not over-educated, but educated in books too soon. Physical education must come first, and

there will be plenty of time afterward for culture and art.

It doubtless has occurred to some of you that this paper would better have been read before some enthusiastic body of organized women, who might forthwith form themselves into a club for the collection of bones and the exchanging of specimens.

Not at all. Clubs are well enough in their place, but this is a question involving the great modern principle of prophylaxis in medicine.

If the diseases of women are many of them preventable, then should the medical profession have a care that they are prevented. If women are reasonable beings—and who would deny that they are—then they can be taught, and it is the medical profession who must decide what they are to be taught.

Dr. Holmes has given a priceless example to the profession of America, and he lived to see the second and third generations rise up and call him blessed. No greater tribute can be paid his life and works than by the perpetuation of the spirit in which his work was done, the enthusiasm for the science of prophylaxis wherever disease is found.

EMERGENCY CASES OF SKIN DISEASES.

By FRED. J. LEVISEUR, M.D.,

DERMATOLOGIST TO RANDALL'S ISLAND HOSPITALS.

When the surgeon is called in cases of emergency, he certainly will be pleased to find a wound already cleanly covered with a temporary dressing, or a fractured limb in an improvised splint. Wrong or delayed action in these cases is frequently followed by very serious consequences. The first help in some skin diseases is not of such great importance, it is true, but it is a fact that mistakes are made continually which it takes a good deal of time or trouble to correct afterward. In his paper, read at Rome, and entitled "Non Nocere,"[1] Dr. A. Jacobi has collected a treasure of advices and warnings. It is to be regretted that time and space limited his remarks to certain affections occurring in infancy. Harm is done quite frequently in the treatment of skin diseases, and especially in emergency cases, *i. e.*, cases in which the presence of alarming symptoms or the apprehension of the development of such, prompts the patient to seek immediate medical help.

Make a Correct Diagnosis.—A correct diagnosis forming the basis for our therapeutical action is essential in the first place. Acute eczema, for instance, is sometimes mistaken for erysipelas, even by the better-versed physician. I am referring to that special form of eczema which makes its appearance in the face near the ears, nose, or eyes, and consists of a patch with round, distinct border line. Its color is brownish red. Its surface is covered entirely or in part by a thin layer of brown crust. In the very beginning close inspection will reveal the presence of millet-sized vesicles. In the majority of cases, however, the appearance will already have been changed by the application of some irritating lotion or salve, applied under the impression that the affection is erysipelas. The itching is now aggravated until it becomes almost unbearable. The patient's general condition suffers considerably from sleepless nights or from the weakening effects of morphine or chloral; and if—as happens not infrequently—the patient becomes somewhat feverish, the phantom of erysipelas is complete. One should carefully bear in mind the characteristic symptoms of erysipelas. Typical cases begin with a chill and vomiting, followed, after twelve to twenty four hours, by an eruption, which at first consists of a spot of about the size of a silver dollar, irregular in outline and painful on pressure. Its border is somewhat raised, and it progresses rapidly, not unlike a miniature wave. At a later stage the entire face may become swollen, the eyes closed, the ears thickened, and possibly the affected area studded here and there with bullæ or crusts. The fever is usually high, and the patient makes at once the impression of being seriously sick. To return to eczema, there is generally a history of nasal catarrh, a chronic affection of the middle ear, or a conjunctivitis. We are justified, I believe, in assuming that the pathological cause of this particular form of eczema is a micro-organism, not yet known, but differing essentially from Fehleisen's coccus of erysipelas and Rosenbach's of erysipeloid. E. Fridenberg[1] and a few others before him report that they have observed this eczema to occur after the instillation of mydriatics. I have no objection to the name dermatitis periocularis medicamentosa, but I believe it better not to call it pseudo erysipelas. Elliot[2] defines erysipeloid as an inflammation of the skin which develops in a wound as the result of its infection with certain special micro-organisms found in dead or decomposed animal matter. It manifests itself primarily in the form of a sharply defined, slightly elevated, dark, violaceous, almost livid red zone, which appears around the point at which the infection has taken place. The area of redness extends peripherally, and at the same time involution and fading of the portion first attacked takes place. During the entire course of the process itching and burning exist, being oftentimes exceedingly annoying. There is no desquamation or scaling of the epidermis at any stage, and no systemic disturbance.

Again, erysipeloid should not be confounded with pseudo-erysipelas. This latter affection is usually ushered in—according to Kaposi[3]—by a chill and fever, and consists of a tense, painful swelling, of vivid red color. It is found, as a rule, to affect the extremities. After two or three days the tissues break down and suppuration sets in, often followed by an enormous destruction of the subcutaneous tissue, fasciæ, muscles, bones, and joints.

The eruptions caused by the internal use of drugs often simulate other diseases. Caspary[4] remarks correctly, that the physician who is called upon to treat an acute eruption, the diagnosis of which is not beyond doubt, should think of the possibility of having to deal with a drug eruption, and try to find out by inquiring of the patient or those around him. Morrow[5] says that the scarlatiniform rash of belladonna, quinine, chloral, morphia, etc., may be distinguished from scarlatina by its sudden onset, without prodromic symptoms, and the absence of fever and high temperature. The rubeolaform eruption of antipyrine, copaiba, etc., may be differentiated from measles by the same negative evidence. The pustular eruption of bromine and iodine may closely simulate small pox. There are some popular patent medicines in the market which contain some iodine and are liable to produce lesions, the umbilicated character of which may suggest small-pox.

The difficulty to discriminate between varicella, varioloid, and variola,[6] is a subject which has been discussed so often that I hardly need enlarge upon it. Varicella, as is well known, is a disease occurring mostly in children from six months to ten years old. It has very slight prodromic symptoms, and consists of the appearance of successive separate crops of superficially seated vesicles. Severe constitutional symptoms are absent.

The hemorrhagic affections of the skin may furnish emergency cases which are difficult of diagnosis. Purpura hæmorrhagica may be confused with scurvy, or the hemorrhages of hæmophilia, leucocythæmia, and pernicious anæmia. Fortunately, the treatment of these hemorrhagic affections is so similar that, by mistaking one for the other at first, no serious consequences will follow.

If I were not prevented by the limitation of space from

going into details, I could extend the list of possible mistakes much further by mentioning rarer cases; for instance, erythema scarlatiniforme,[1] precocious malignant syphilis, pemphigus vulgaris and foliaceus, dermatitis exfoliativa neonatorum, pityriasis rubra, scleroderma, etc. It may suffice to quote in this connection Dr H. R. Crocker's advice, which is, to make the diagnosis in a given case by settling the following questions in the order named: "How long has the patient had the disease? What was its cause? What symptoms, especially as regards itching, fever, etc., attend or preceded the eruption? What is its cause?"

Ohmann Dumesnil[2] says that diagnostic skill of the highest character will frequently prove of little or no avail in cases of eruptions due to the artifices of malingerers. The ingenuity and tact of the physician are called into requisition, and it is more the motive of the patient than the actual condition which will lead to any suspicion.

Look Out for Possible Complications.—It is not sufficient to merely make a correct diagnosis, but it is also necessary to be on the lookout for complications. The case of a patient in one of the city hospitals is still fresh in the minds of many. A man who suffered from alcoholism and at the same time had a tuberculo pustular syphilide, contracted small-pox. The symptoms of the latter disease were so much obscured by the other two affections that the failure to make a correct diagnosis was perfectly pardonable. The patient died, and the true nature of the disease which caused his death was revealed upon the dissecting table.

The following complication came under my personal observation: M. H——, a boy, nine months old, had an infantile eczema on both cheeks for which the family physician prescribed tinctura rusci to be painted on the affected parts every day. At first there was some improvement, but suddenly a very acute pustular dermatitis spread over the face. On opening the lids of the left eye, which was closed by considerable swelling, I found a small pustule in the centre of the cornea. Dr. Gruening, who was consulted at once, predicted (and such was the result), that a central opacity of the cornea causing strabismus would remain.

I also had occasion to observe a peculiar complication in a severe attack of urticaria:

O. S——, a boy nine years of age, who was subject to outbreaks of urticaria after eating fish, one evening, at a children's party, partook of the forbidden food and immediately developed alarming symptoms. He was taken home almost unconscious, unable to breathe, his lips and tongue were bluish red and swollen, and the body covered with large wheals. I was informed that he was suffering at the time from adenoid vegetations in the vault of the pharynx, for which he was under treatment. Six years later, after taking a teaspoonful of white vaseline, which was recommended to him as an effective laxative, by a friend, he had again an attack of urticaria with extremely severe dyspnœa, etc. Examination showed that the adenoid vegetations had returned in spite of repeated operations which had been performed in the meantime. The treatment in both attacks consisted of putting the patient into a bath tub and sponging him with cold water until breathing was somewhat easier. On account of the pharyngeal swelling it was not deemed safe to give him an emetic, and a tablespoonful of castor oil was administered.

Dr. Mendel has reported a case which in some respects closely resembles the above. An exanthema caused by copaiva was complicated by the presence of adenoid vegetations. There was a great deal of swelling, pain in the pharynx, and severe dyspnœa.[3]

Be Careful in the Use of Antipruritic Remedies.—It is a fact well known but deserving to be emphasized again, that our best antipruritic remedies, tar and its chief derivative, carbolic acid, do more harm than good in cases of general pruritus. They may afford some temporary relief, but the skin is liable to get irritated, furunculi may form everywhere, and the patient is apt to fall from the Scylla of itching into the Charybdis of general dermatitis or furunculosis. Besides, a peculiar intolerance of the integument against all local treatment is frequently established. If a new attack occurs it may be so severe as to drive the patient almost crazy and to the verge of committing suicide. In such cases a hypodermic injection of morphine, chloral internally, or even chloroform anæsthesia, must be resorted to. A cold douche or bath containing sulphur, carbonate of soda, alum, or sublimate may be given a trial. There is no doubt that mental depression is one of the most important factors in the etiology of this distressing affection. The physician called in such an emergency case should therefore carry out his treatment with energy and tact.

The old error of treating the most prominent symptoms instead of the disease is frequently committed in prescribing antipruritic remedies for acute general eczema, drug eruptions, or similar acute inflammatory conditions of the skin. The following case may serve as an illustration of the truth of this statement:

Mrs. A. P——, forty six years of age, had had for years a slight chronic eczema on the fingers of both hands. During a sickness of a member of her family she happened to come in frequent contact with preparations of carbolic acid, and thus developed an acute eczema on the hands, forearms, and face. In order to relieve the intense itching, her family physician gave her a wash containing some carbolic acid. Soon after the first application a most acute eczema spread over the entire body, and when I was called to see the patient, I found her in a deplorable condition. She had to be swathed in bandages saturated with zinc-calamine solution for several hours, after which her body was covered with Lassar's paste spread on strips of linen. Wherever possible these strips were bound down with bandages. This treatment not only relieved her itching but was also the first step to a final cure.

The Use of Antiseptic Remedies.—Antisepsis in the treatment of skin diseases differs in a great many respects from surgical antisepsis. A healing by first intention, of most lesions, is not to be expected; certainly not if the corium has been destroyed; but even if it is only impaired, denuded of the epidermis, or if bullæ have been formed, the process of reparation can solely be accomplished by catarrhal (epithelial) suppuration, the product of which is the "dry scab" under which healing takes place easily and undisturbed. This is nature's own antiseptic routine, which we should try to imitate as far as possible by using remedies which, although inert as it were, are capable of absorbing moisture and forming a coating that furnishes protection against air and against infection from the outside. In this sense these remedies are better antiseptics than those which have earned their reputation in the realm of surgery as being destroyers or antagonists of micro-organisms.

In emergency cases of dermatitis ambustionis of the second degree, *i.e.*, burns and scalds, the old-fashioned carron oil or corn starch, with the addition of boric acid, oxide of zinc, salicylic acid, bismuth, dermatol, etc., is far more effective and reliable than iodoform. Or, if lotions or the continuous bath are used, solutions of boric acid or liquor aluminii acetici (ten per cent.) are preferable to solutions of carbolic acid, sublimate, etc. In herpes zoster simple cornstarch, dusted on freely and bound down carefully by the aid of a thick layer of absorbent cotton, is by far the best treatment. In two cases of this disease I have seen the lesions break down and an extensive dermatitis develop under a dressing of iodoform gauze. In a case of intertrigo between the legs of a female infant, a dressing with carbolic acid gave rise to deep ulceration. In short, it has been my experience in such emergency cases that I was more often

concerned in the removal of antiseptics previously applied and their bad effects, than in advising their use.

I present this epitome in the hope of creating an increased interest in this class of cases of skin diseases which are apt to confront the practitioner at any moment and should not find him unprepared, but able to meet all requirements.

"Hoffman Arms," 640 Madison Avenue.

THE CARD INDEX OR CARD CATALOGUE AS ADAPTED TO HISTORY-TAKING IN PRIVATE PRACTICE.

By ROBERT L. DICKINSON, M.D.,

Lecturer on obstetrics, and assistant obstetrician, long island college hospital; obstetrician to kings county hospital.

Synopsis.—This method of keeping records consists in using one or more cards (measuring about 6 × 6⅔ inches) for each case, the cards being ranged under an alphabet index and stacked on edge in a drawer or box, and folded down the middle for carrying in the pocket.

Such a system (the card size being immaterial) is the only portable, elastic, simple, orderly and self indexing way of keeping records and is as readily used at the bedside or operating table as in the office.

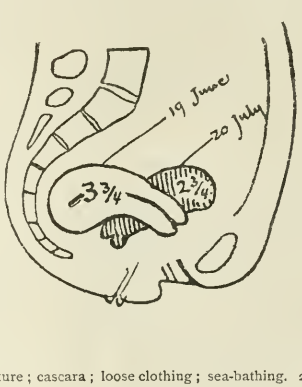
Disadvantages of Books.—Books are inelastic. If the case runs to the foot of one page, where shall it be continued? One can rarely guess at the space required in beginning a history. The next page is occupied; one must skip to the first blank page, or borrow part of a page near by, with the result that a long record will be in scraps through one or more case-books and scattered so that the parts of the history cannot be assembled. A separate index, in a separate book, is required after a while, in order to avoid searching the index of each book. Books are not portable. Notes taken at the house or hospital must be copied or pasted in. Books grow worn and shabby from much handling, if large, and if thin many are required. After all the other cases are closed up, one may have still to use an old book for a single case. He cannot keep its history with his recent cases.

Disadvantages of Sheets.—Sheets of stiff paper may be kept in alphabetical order in a letter file or binder, but they inevitably become frowsy at the corners, they do not stack on edge, they are not readily run through the fingers like the leaves of a book when a bunch of them under a certain letter is picked up, as cards are, and they are generally too large for carrying in the pocket. The method is only suited to hospital conditions. Dr. Richmond Lennox and I have used both sheets and cards and find we save much time and discomfort with the cards.

Advantages of Cards.—*Portability.*—For office use cards will be found to be handier than a book, and the specialist, above all men, will find them convenient. For bedside notes this is the only handy method. For immediate record of consultation work and for operative

Smith, Mrs. John, 32. Father tuberc. Pneumon. 6 years ago. Slender, overworking, worrier. *Headaches* every 2-3 dys; good eyes; good dig., but costive. Piles, rarely bleeding; chest, right; clothes tight; corset springs 3 inches; urine: 60 oz., 1023; no alb. or casts.

G. Mar. 6 yrs; 2 children; oldest, 4; ygst, 1; 0 Misc.
Labors severe, forceps. Puerperiums fever.
Menses, formerly not *painful, irregular.*
Now pain, none slight, *Severe cramps front R. L. iliac reg.*
Backache, before, *during,* after, *between,* constant.
In bed 1½ *dys.* Much dragging.
Flow free, scanty. *Clots,* membrane.
Irregular every 20-30 *days,* weeks, *lasting* 6 *dys. Last men.* 7 Je.
Vag. discharge constant, profuse, slight mucus, *purul,* foul.
Urination frequent, not painful. *Dyschezia, dyspar.*
Walking, working, not *painful.* *Dates trouble from* last labor.



Retroversion.
Subinvolution.
Induration right brd. lig.
Ext. *hæmorrhoids.*
Uterus mobile.
Ovaries moderately displaced, not tender.

Partial reposition ich. tamp. iac to cervix. Basham's mixture; cascara; loose clothing; sea-bathing. 23 Je, same. 29 Je, backache and leuc, less do. 5 July, s. r., Smith pessary. 10, easier period; impr. position; ℞ Aloin Strych., bellad. 20, hard r. pess.; much better; 2⅝ cavity, and so forth.

Fig. 1.—Card for taking case histories. Actual size. The rubber stamp that is used to print part of the history, if desired, and the stamp of an outline for graphic notes, are also shown.

and obstetric cases, it is exactly adapted, while for medico-legal cases notes made on the spot are the only ones the medical man may consult in the witness chair. In reporting a single case or a group of cases at a society meeting, or in getting together case histories in writing a paper, the cards required are picked out and sorted as desired. One carries in the pocket the cards of patients ill at home, selecting those needed as one leaves the office, and dropping the convalescents.

Elasticity.—Whether there be twenty cases, or two thousand or twenty thousand, the whole history of each patient is assembled and whatever the number of histories they are always in order, yet there is always room for more.

Self-indexing.—The cards are ranged under an alphabet printed on buff bristol cards (guides) that stand taller than the history cards. This index can be in twenty-six letters or carried to two, three, or four letters, as in the Burr index, *i.e.*, Bradley might come under B in the simple way, Br for the two-letter method, Bra for the three-letter index. Beyond two thousand, however,

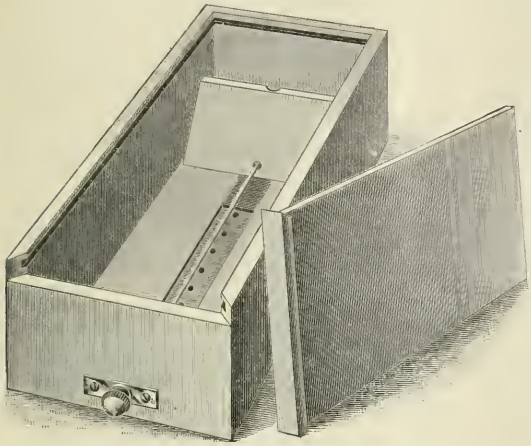


FIG. 2.—Box to hold the cards, where a drawer is not available. The guard rod here shown at the bottom of the box is used in library work to prevent removal of the cards, but is unnecessary in private practice. One of the blocks that slant the cards at the proper angle is seen, with the holes that steady the catch of the rear block to adjust it for any number of cards.

we use the "directory" method by entering every twenty-fifth name on a guide, as I have done in the identification-and-rating-card-index to the thousands of men examined for the civil service commission. Practically, however, after a while we keep a small working list under an alphabet in the front of the drawer, and under a separate alphabet behind stand the histories which we are not liable to need again.

Details.—The cards I am using are 6 × 6⅜ inches, thin, blue-ruled, with red line for headline, standing on edge in a drawer where I look down on them at my side. When Mrs. Bradley arrives I pick up the bunch of B's and run them through as quickly as one does the index of a book. For long cases cards can be fastened together very solidly and conveniently by a Middleton Clip at the upper right-hand corner. It is small and thin and does not have to be punched through the paper. Sketches or loose notes are readily pasted on the cards or can be kept in envelopes of the exact size of the cards provided for this purpose, at a small additional cost. Instead of a drawer—and in any deep drawer a partition can be fastened—a box with lid and lock can be had, but a drawer is most convenient.

For the beginner it is especially important to start with a system that cannot be outgrown, that is elastic, and that will train him to orderly methods.

Reasons for this Size, Ruling, Grade of Paper, etc.—The card is the largest that will go into the pocket-book or wallet of average size, with one fold. This fold must be upright, so that cards will stack and turn easily when replaced in the drawer. Paper stock cuts economically to this size. The material is the thinnest that will stand on edge without sagging. The ruling is a standard adopted by librarians as suiting the average handwriting; and all these things, and other important details, are based on the long study and elaborate experience of the Library Bureau, makers of standard supplies for our great Libraries. Satisfaction will be wanting from the hands of an ordinary printer; a perfect edge, absolute exactness of size, and an even distance of ruled top-line from the top, so that the names appear in exactly the same spot, are all essential to speed and comfort in running over a bunch of cards. The Library Bureau (of 146 Franklin Street, Boston, and Stewart Building, Broadway, New York) do very handsome and satisfactory work at reasonable rates.

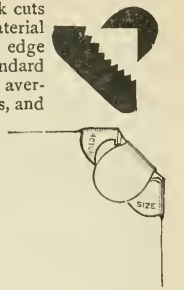

FIG. 3.—Clip to hold cards when one or more is used on the same case, shown from the rear before and after fastening. It works best on the right upper corner. Middleton paper fastener.

The proportions and details of this arrangement have been the outcome of much study, and all the fittings are kept in stock. Variations in size of card will cost more in money and delay, but variations in details, such as a printed form, any ruling or none, or any kind of card as to thickness, color, or variety of tints of edge for different kinds of cases, are easily adapted. For some specialists, as ophthalmologists, whose notes are brief and who write small, the standard postal size, nearly 3 x 5 inches, works very well and is much cheaper One who writes large may desire a wider ruling than three sixteenths of an inch, but it is to be clearly understood that my plan will not suit men who take copious notes in a large handwriting.

Practically it is found that two-hundred to three hundred cards make a working list for a busy man. The consultation cases, and the patients gone or moved away, can go under a separate alphabet in the back of the drawer when the lists grow bulky. Another alphabet may serve to index diseases, or interesting cases, or the subjects on which one is gathering data, but at first all cards may stand under the single alphabet, if desired.

In libraries the cards are made fast in place by a guard-rod running through a hole in the bottom of each card. A turn of the drawer knob unlocks the rod, and as it is slipped out the card is freed. This can be applied to our cards, but it is unnecessary.

The full outfit consists of,

1,000 cards, weight No. 7506, ruled with double red line at top, 29 blue lines $\frac{3}{16}$ inch apart, not punched, costing.	$4.00
1 alphabet index (A–Z guides) buff bristol board, costing...	.95
2 blocks, the rear sliding in slot with catch, so as to set the case for any number of cards, in a drawer 6¾ by 14¼ inches, or longer, oak, mahogany or walnut, with handle and label holder.....	4.50
Or box, oak, mahogany or walnut, with lock.....	3.50
The whole outfit costing, with box.....	8.00
with drawer.....	9.00

One may start with fewer cards, but it is best to get two A–Z indexes. The Middleton paper fasteners can be ordered also, or procured at a stationer's. In ordering, specify carefully: Box with or without lock; or drawer; kind of wood desired; two blocks, one with catch; label-holder; number of cards, ruled or plain, unpunched; and number of alphabet guides.

NOTE.—I have found that this method is in use in the Johns Hopkins Dispensary, but many details have been bettered in these plans, as experience shows. Many business houses employ the large cards extensively.

145 CLINTON STREET, BROOKLYN, N. Y.

PUERPERAL FEVER.[1]

By THERESA BANNAN, M.D.,

SYRACUSE, N. Y.

PUERPERAL fever is defined as a septicæmia developed from the absorption of foul material through wounds due to parturition, the most common source of such material being the uncleanliness of the attendants. Hence in these days of asepsis and antisepsis the physician who reports a case of puerperal fever almost challenges the charge of gross negligence.

It will be unnecessary for me to touch on the literature of this subject, since it is the foundation of modern obstetrics. In a city the size of this, where there is no large maternity hospital, the infectious character of lying-in fever is rarely brought to the notice of the profession. The following cases occurred in the Maternity Department of one of our hospitals, being the first cases of the kind in the history of the institution.

An outline of the care given during the puerperium will not be out of place. The patient is prepared for labor by a bath, a bichloride vaginal douche, and an enema. Care is taken that the bladder is emptied. A short night-dress is supplemented by a folded sheet tied around the hips. Cotton stockings reaching half-way up the thigh complete the toilet. Everything about the patient and her bed is clean. The nurses wear their regular uniform, and the physician is dressed in a cotton gown. The diagnosis of the presentation is first attempted by external palpation, the internal examination being made when labor is undoubtedly present. The hands are prepared for this examination by being thoroughly scrubbed with soap and water—and then bathed in a 1 to 3,000 bichloride solution. The examining finger is protected from any contact until it enters the vagina. Unnecessary examinations are avoided, although the perineum is generally stretched to diminish the chances of laceration. As soon as the head has cleared the vulva one hand grasps the fundus of the uterus while the other assists the delivery of the body. The placenta is expressed within five or ten minutes, ergot given in routine, and a vaginal douche. A sterilized pad and abdominal binder are applied, and the woman is removed to the ward. Vaginal douches are given twice a day for one week, not because it is considered necessary, but because it seems best in a hospital. Such is the routine of the Maternity Department, and such was the care of the two following cases:

CASE I.—L. E——, aged eighteen, unmarried, primipara, had been in the hospital two or three months. She had always been in good health and continued so during pregnancy. Urine normal. Labor began about midnight of July 9, 1894, and she was delivered about 7 A.M. Vertex presentation, first position. Perineum was stretched, and laceration of first degree occurred and was not repaired. Placenta and membranes expelled entire. Everything normal until the morning of the second day, when, at 7.30 A.M., the temperature was found 100.8° F. Four hours later the patient had a severe chill, accompanied by pains in the abdomen, and a temperature of 103.2° F.; pulse, 100; respiration, 30. Ergot was given, and two drachms of sulphate of magnesium and quinine, grains two, *t.i.d.*, was begun. Free perspiration followed the chill and the bowels moved freely, but at 10 P.M. temperature had reached 104.8° F.; pulse, 147; respiration, 56. Phenacetine, five grains, and another dose of salts were given, hoping to produce a fall of temperature by natural channels of radiation. But the next morning, at 7.30, temperature was 104.4° F.; pulse, 120; respiration, 40. At 10 A.M. the uterus was irrigated with sterilized water. This was done not because it was indicated, the lochia being normal, the uterus hard and not sensitive, but because I wished to protect myself from censure, knowing well that the majority of physicians would condemn such an omission. No shreds or clots were washed out, and no odor was perceptible in the return flow. The double tube was used. Two hours after irrigation the patient had a severe chill, and the temperature went up to 105° F. Once again the uterus was irrigated, this time with the single glass tube and a 1 to 8,000 bichloride solution. Nothing was washed out except a little fresh blood produced by the tube. Completely satisfied that if the source of infection was within the uterus, irrigation was not the indicated treatment, no other irrigation was made. The abdominal uneasiness disappeared, however, after the second irrigation, whether because of it or of the antipyrine, five grains, which was given twice, while the two grains of quinine were increased to five. Salines were also continued.

About this time the search for the focus of infection disclosed three abrasions on the inner sides of the labia minora. These were covered with a grayish exudate, forming the so-called diphtheritic patches. Vaginal douches of bichloride were ordered three times a day, and the parts to be separated by iodoform gauze. Under the two doses of antipyrine the temperature fell to 100.6° F.; pulse, 70, and remained so during the night.

To make an impression on the fever calomel and bicarbonate of soda, ten grains each, with fifteen grains of quinine, were administered at one dose, but three hours later, 11.30 A.M., she had another severe chill and temperature, 102.4° F.; pulse, 90. This being the third chill, and occurring at the same time each day, a malarial element seemed, in the absence of other factors, to be a cause of the high temperature. Quinine was given in large doses until cinchonism was produced. There was no splenic tenderness nor mammary disturbance. Feeling that the lacerated perineum might have some causal influence, although it had not been covered with the grayish patch, it was now, on the fifth day, gently scraped and repaired. Peroxide of hydrogen was now applied to the gray patches every three hours, and was continued until they disappeared. At 9 P.M. the temperature reached the highest point of the day, 103° F. During the night it remained at 102° F., and at noon of the following day, when a chill was expected, there was only a sensation of chilliness with temperature 101.4° F. This seemed favorable; but three hours later the thermometer recorded 104° F. Antipyrine was employed to reduce the temperature, and small doses of calomel and the salines were given to keep the bowels loose.

Next day at 9 A.M. temperature was 100.4° F., and at noon 105° F.; pulse, 100, without a chill. In spite of antipyrine it continued 104° F.; pulse, 110, all the afternoon until 9 P.M. Quinine in full doses and phenacetine were used, but temperature was 103° F. all night, and during the following morning continued to rise. With a feeling akin to desperation all medication was ordered stopped except salol and phenacetine, two and one-half grains each, which were given every two hours, alternating with phenacetine, five grains. Regular diet was given instead of liquid. Such a step was decided upon because of the inefficiency of the treatment, which, whether local or systemic, appeared to produce no effect on the course of the disease. Moreover, the patient was very comfortable, even during the highest fever. Only during the chill did she complain of discomfort, and so incredible did the presence of so much fever seem that she was watched while the temperature was being taken to exclude trickery.

Under the salol and phenacetine, begun on the eighth day after labor, temperature continued to fall until it was 99° F., and remained down for one day. On the next day, the tenth, at 9 A.M., temperature was 103° F.; pulse, 98, and at noon 103.4° F.; pulse, 116. Fowler's solution was now begun, for its tonic and anti-malarial effect, quinine having been abandoned. The temperature remained at 102.4° F. all the afternoon, and in spite of the antipyretics, reached 103° F. in the early morning. It varied from 101° to 102° F. for the next two days and the antipyretics were stopped. Without again reaching 100° F. it returned to normal, and the patient went on to recovery, much the worse physically for her experience.

[1] Read before the Syracuse Academy of Medicine, October 23, 1894.

Five days after the delivery of Case I., another woman was delivered in the same room, under identical conditions, and placed in the same ward with her. Though her labor had been long and tedious, necessitating manual dilatation of the os and constant attention to free the anterior lip from the occiput, she passed a perfectly normal puerperium.

Case II.—A. H.——, forty years of age, primipara, unmarried, was delivered under the same conditions as Case I. on August 30, 1894. She had slight pains all day, and at 7 P. M. they became vigorous, and she was delivered about 11.30 P.M., being a short labor for one of her age. Everything was normal until the head cleared the vulva, when the cord was found so tightly around the neck that the least traction imperilled its continuity. The head had become so elongated from pressure that the cord could not be slipped over it, so was tied and cut and the child extracted. There was no laceration of the perineum.

Next day the temperature was 99.4° F.; but thirty six hours after delivery reached 102.8° F., rising to 103.2° F. in the evening. At 3 P.M. of the following day temperature was 104.6° F.; pulse, 120. Ten grains of quinine and salines were given, and the next morning temperature was 101.4° F., and in the afternoon 103.2° F. The following day, the fifth day after delivery, temperature was 103.6° in morning, and 105.2° F., with pulse 128, in the afternoon. During this day the abdomen had become very much distended with gas in the intestines. Pressure discovered not the least pain in any part, and except for the difficulty of respiration, due to the distention, the patient felt very comfortable. In the evening Dr. Allen saw the case with me, and discovered a slight bogginess in the left broad ligament. Diphtheritic patches were sought, but not found until the following morning.

The treatment decided upon was to give an intra-uterine douche and note the effect, and to support the patient's strength by strychnia, whiskey, and peptonized food. The lochial discharge was normal. Next morning a uterine irrigation of 1 to 3,000 bichloride was made, which washed out two or three small inoffensive clots. The abdominal distention had, in the meantime, increased and was treated by turpentine enemata and stupes, and also by turpentine per mouth. The rectal tube was inserted also, and the tincture of nux vomica substituted for strychnia, nevertheless the temperature remained stationary at 104.2° F.; pulse, 120; respiration, 28 to 44. On the following day improvement by the lessened distention was noted; the pulse did not rise above 120, but the temperature was 103.4° F. in the morning, 104.8° in the evening. The diphtheritic patches had been treated as in Case I., but nothing seemed to control the fever, and as the temperature was 104° F. the following morning, the phenacetine and salol were given twice and temperature fell to 101°, ascending to 103.6° F. at 9 P.M. One ounce of sulphate of magnesium was then given, smaller doses having little effect. The temperature remained at 104.4° F. all the following morning, yielding somewhat to the antipyretics in the afternoon. The salts having little effect one ounce of castor-oil was given, and the salol and phenacetine administered every two hours. Still the temperature fluctuated between 103° to 104.8° F., with pulse 120. The oil was repeated, and next morning, the eleventh after delivery, temperature 99.2° F. at 9 A.M. and 104.2° F. at noon. This was the last rise, and patient went on to recovery. At the first rise of temperature the patient had been removed to the medical ward.

The Maternity Ward was thoroughly fumigated and the labor-room furniture washed with bichloride. Within a week two women were confined, one of whom entered in labor. She developed two diphtheritic patches, but had not the slightest disturbance of temperature or pulse. The only change in care was the omission of douches after labor.

The above cases are similar in having, as far as could be discovered, the same cause—diphtheric patches on the abrasions due to parturition. The fever was unusually high in both cases, while the discomfort produced was slight. They differ in that one case severe chills occurred, while the pulse rarely corresponded with the temperature; in the other case great abdominal distention and much cardiac disturbance were present. Both women had emotional paroxysms, which, no doubt, somewhat disturbed the nervous poise. The treatment, though far from satisfactory, was in accordance with my best judgment. To repeatedly irrigate the parturient canal when not clearly indicated seemed meddlesome. Antipyretics were not used early lest they should obscure the condition without affecting the cause. When all other treatment failed to reduce the temperature, and the evils of its constant elevation were feared, antipyretics then used confessed failure along more scientific lines of treatment. The preservative power of Mother Nature was not forgotten. Both patients received excellent care, day and night, from the nurses in charge, and, whatever the cause of their illness, it would seem far removed from neglect.

503 Warren Street.

CASES OF MONSTROSITIES, WITH SPECIAL REFERENCE TO THE THEORY OF MATERNAL IMPRESSIONS.[1]

By JOHN H. BARRY, M.S., M.D.,

Long Island City, N. Y.

Medical genius and scientific investigation have done much to make the physician of to-day feel envious of the proud advantage he holds over the minds of long ago.

But the self-same scepticism, the same disinclination to attempt a translation of the wonderful and the monstrous, actuates us as actuated our forefathers, and we pause spell-bound at the diverse manifestations of the workings of an Infinite Being, just as they acknowledged their inability to cope with the miraculous and mysterious.

Thus it is that the etiology of monstrosities is as vague as ever, and medical pride bows in abject submission when confronted with the task of averting the misfortune, or even comforting the pangs of sorrow and distress incident upon a monstrous conception. It is with no likelihood, then, of diverting from the well-beaten path, but rather to furnish my quota of evidence, that the record of the appended cases has been undertaken for your interest and possible instruction.

Case I. *Anencephalus.*—Mrs. A——, twenty-four years of age, primipara, was delivered on October 18, 1893, of an anencephalic infant, presumably full term, and bearing the following gross characteristics: No frontal bone developed above supra orbital ridges, latter marking summit of skull; collapsed membraneous covering over frontal area of calvaria; three segments of dense tissue, resembling placental tissue, arising from a common stem in the region of foramen magnum, each segment being about the size of an almond. Bulging eyes, frog-faced countenance; ovoid contour to chest and trunk plainly observable while babe lies prone. Six fingers on either hand; six toes on either foot. Tendency to apposition of plantar surfaces of feet when brought in contiguity. Spinal column intact; no spina bifida: notable tumefaction of abdomen. Lived about three minutes. No autopsy allowed.

Case II. *Hernia Cerebri* (*Occipital Meningocele; Breech Presentation*).—On August 29, 1894, same mother as in Case I., delivered spontaneously what was presumably an eight months'-foetus, bearing the following characteristics: Frontal bone present; marked cleft antero-posteriorly extending from nasal process of frontal bone to anterior fontanelle. Superior angles of either half of frontal bone marked by delayed osseous development, the same condition obtaining in anterior and

[1] Read before Queens County Medical Society, October 30, 1894.

posterior superior angles of parietals and anterior superior angles of occipital bone, so that each semilunar segment going to form anterior and posterior fontanelles contrived to form unduly large ones, into which the tip of finger could be readily inserted. Skull development, notwithstanding, more perfect than in Case I. Countenance nearer normal, more or less ovoid contour to chest and trunk. Spinal column seemingly intact; marked luxation of hip-joint in flexed position; double genu recurvatum; plantar surfaces of feet clearly apposed (talipes varus); six toes on either foot; six fingers on left hand; five on right hand. A hernia the size of a goose egg, and analogous in its nature to the sense of feeling imparted by squeezing a loop of intestine, was situated over region of foramen magnum. A smaller hernia, the size of a hen's egg, situated over region of upper cervical vertebræ. On attempting reduction of larger hernia, smaller one enlarged, and *vice versa*. There was also to be found a circular cleft of hard palate, about midway between alveolar process of superior maxilla, and vault of pharynx, of about the calibre of a thermometer case. Marked abdominal tumefaction. In left hypochondriac region could be felt large, irregular, resisting tumor, possibly a misplaced viscus. Lived about fifteen minutes. No autopsy allowed, but photographs obtained.

Case III. *Birth-mark on Neck.*—Mrs. C——, aged twenty-nine, primipara, about seven months pregnant; consulted me on April 24, 1894, for diffuse cervical phlegmon, at that time unilateral. Palliative measures were resorted to in the hope of checking suppuration, but to no purpose. With considerable diffidence regarding patient's delicate condition, chloroform was administered on April 26th, and an incision made in right cervical region, but without reaching pus of any account. Wound was packed with iodoform gauze, and immediate effect of operation was to diminish tension and swelling of tumor. On morning of April 28th, tension and swelling were much exaggerated over original condition, and diffuse, deep seated adenitis of left side of neck was clearly observable. Symptoms of septicæmia appeared and rapidly progressed; fœtal heart-sound was looked for with negative result. Radical operation was suggested and refused, and a grave prognosis given. On morning of April 29th labor pains came on, and the patient was delivered, within a few hours, of a premature fœtus, presumably dead about forty-eight hours, with a denuded, swollen, circular area about one and one-half inch in diameter in left cervical region and corresponding to the site of the mother's latter formed phlegmon.

Patient went on with a temperature of 105° F., and pulse of 160, and died at 10 P.M. of same day.

Case IV. *Supernumerary Digit.*—Mrs. B——, forty-two years of age, multipara, was delivered on October 4, 1894 of a female child, with last phalanx of a little finger hanging by a slender thread from middle of fifth finger of left hand. Specimen snipped off and here presented. No history of maternal impressions could be elicited.

In reviewing the literature of the subject of maternal impressions, we find recorded, in turn, all phases of monstrosities, some of which will bear recital in an abbreviated form:

1. Anencephalus attributed to maternal impressions: Mother saw while pregnant the body of a man, the top of whose head had been cut off in a railway accident (*University Medical Journal*, Philadelphia).

2. E. Giraud, in the *International Journal of Surgery*, New York, reports a case of anencephalus which lived twelve days, moaning constantly.

3. Same author, and Armstrong, in *London Lancet*, report cases of anencephalus with spina bifida (latter's case, whole length of spinal column), in which mothers were scared by just such sights while two months pregnant.

4. E. T. Shelley, in *New York Medical Journal*, reports anencephalus, born at seven months. Brain was represented by dark mass on child's neck and back; spinal canal open for some distance down back.

5. In *Annual of Universal Medical Sciences*, 1894, is reported a case of occipital meningocele which lived several days without cerebral symptoms.

6. Venables (Halifax) delivered female fœtus, well developed except head. Face depressed, ears not fully developed; calvaria entirely absent; skin covered reddish, pulpy mass, having slight resemblance to brain. Frontal bone rudimentary.

7. Clarke (*British Medical Journal*) also showed monster of this kind, with double genu recurvatum, talipes, and proptosis of one eye.

8. M. M. Brown (*Medical World*, Philadelphia) reports complete spina bifida; absence of occipital, parietal, and frontal bones.

9. J. B. Elkins (*Massachusetts Medical Journal*, Boston) reports case of diaphragmatic hernia; lived one hour. At autopsy, coils of intestine in left pleural cavity, as were also spleen, pancreas, stomach, and entire intestinal tract, with the exception of a small loop of duodenum, ascending colon, and rectum. Left lung collapsed; liver had fallen downward and occupied nearly whole of abdominal cavity.

10. Joseph Collins, in Medical Record, reports a case of complete transposition of viscera in a fœtus, and the same is reported of a girl fourteen years of age.

11. Croon, in *Edinburgh Medical Journal*, reports a case of blind intestine; no viscera; abdomen filled with loose, fibrous tissue.

12. Theresa Bannon in Medical Record, June 23, 1894, reports a case of anencephalus in which spinal cord and nerves as far as eighth dorsal were exposed, all bone development having been arrested in posterior spinal arches; all joints rigid; defective muscular development at umbilicus two inches in diameter.

13. Any number of cases are reported of polydactylism and syndactylism.

I shall endeavor to treat of the several aspects suggested by these cases; of their etiology, in the abstract; of interesting points of diagnosis, with especial reference to Case I.; of their bearing, *pro* and *con*, upon the theory of maternal impressions; of observations regarding said theory; and lastly, as to the duty of the physician toward impressionable, nervous, pregnant women.

And first as to etiology. Psychic impressions, anxiety, grief, fear, have long been looked upon as the sheet-anchor in our translation of the cause of monstrosities. Further, we know that any cause tending to produce separation of the fecundated ovum from uterine mucous membrane, *e.g.*, endometritis, attempts at abortion, etc., to be operative in producing monstrosities. Syphilis is set down as a cause, and hydramnios as, at least, a frequent concomitant. Regarding etiology in the abstract, we learn that even before the ovum reaches the uterus the mucous membrane becomes thickened and vascular, so that its opposing surfaces entirely fill the uterine cavity.

Those changes differ in degree, but not in kind, to those taking place at each menstrual epoch. As a result, a distinct membrane is formed which affords the ovum a safe anchorage and protection until its connections with the uterus are more fully developed. Is it not possible that in such cases as result in monstrosities this change in the mucous membrane is not perfected, and, as a result, we have a barren soil for the development of the ovum? Or again, the decidua serotina, that part of the decidua vera on which the ovum rests, and which, normally, is characterized by its extreme vascularity and serves the purpose of supplying nutriment to the fœtus may be imperfectly developed, and, as a result, an imperfect or anomalous fœtus developed? The fact that psychic impressions are more operative in the first three months of pregnancy, during which time adhesion of decidua vera and reflexa has not taken place, would seem to be corroborative of this view. The division of blastodermic membrane into epiblast and hypoblast, and, later, into mesoblast, being imperfect or irregular from any cause, may operate to the end of an imperfectly developed fœtus, as we learn that these layers have each its

special province in the formation of the fœtus. The epiblastic membrane, going to form just those parts of the fœtus which are more frequently undeveloped in monstrosities must, as a matter of course, be most frequently impaired.

As to the cases in point: Mrs. A——, mentioned in Cases I. and II. had distinct predilection for lower animal tastes. She was much devoted during her first pregnancy to the care of a dog and a pet rabbit, the latter of which was to be frequently seen nestled in her lap or poised on her shoulders. Her friends repeatedly discouraged these attentions on her part, but to no purpose. Regarding her second pregnancy, she studiously eschewed these attentions, and her statement warrants the belief that if impressions were potent, or operative to the end of a monstrous conception, they could only be found in the fact that she was constantly upbraided with her misfortune, and most agreeably informed that she could beget nothing better than a dog.

With regard to Case III. I can only say that patient had considerable misgivings regarding what effect any operation might have upon her as yet unborn child, and that, sick as she was, she apprehended disfigurement of her baby, and inquired immediately upon its birth as to whether it bore any birth marks.

Regarding Case IV., as already stated, no history of maternal impressions could be elicited, save the far-fetched one of an injury to the ankle of one of her other children early in her last pregnancy, about which she was considerably exercised.

Case I. proved a very interesting one in the matter of diagnosis. Upon examination the presenting part, on the one hand, lacked the symmetry and density of the normal globular head; on the other hand, manifested many points of difference from a presenting breech. The jut of tissue arising from the region of the foramen magnum, and referred to in the history of the case, was a very confusing feature. It felt not unlike a prolapsed cord, and feeling more satisfied, at best, that it was a head rather than a breech, and being able to trace and feel its insertion, the thought occurred whether, though never having heard or read of it, a funis could arise from any other situation than that of the umbilicus. The application of the forceps lent only some vague information, for while their easy and perfect fitting made it more certain that a head was engaging, the supposed prolapsed cord, with its point of insertion, came better into the range of the examining finger, and was more confusing and embarrassing than ever. Finally, in despair, I acknowledged my inability to diagnose the condition, and declared to the attendants that the case must be a freak, which in truth, and I take no credit for saying it, proved to be a most admirable diagnosis.

Case II. was immediately diagnosed upon the beginning of labor as a breech presentation. It was born spontaneously and unexpectedly after but a few pains. When born, this fœtus appeared to have considerably more vitality than one reported as Case I.

As to the theory of maternal impressions, there seems to be a general opinion among writers on the subject that a psychic impression is more apt to produce an effect, if of considerable duration; that feelings of anxiety, grief, and fear stand in closer etiological relation to the impression theory than those of joy and delight; that impressions occurring during early pregnancy are more potent in respect to defects of development, while impressions occurring late in pregnancy are more apt to be attended by scars or marks upon the fœtus. Further, the fact of a mother anticipating a defective child, and the statement on the part of a mother made prior to birth of a child, respecting reasons why she might expect a deformed or monstrous fœtus are each given its respective weight in arguments *pro* and *con* upon the plausibility of the maternal-impression theory.

In a table of ninety most remarkable cases, published by Professor W. C. Dabney, of Virginia, in Keating's "Encyclopædia of Diseases of Children," it is observable that a very large majority of cases are referred to the early period of pregnancy.

Regarding cases in aforesaid table which can be deemed in any way correlated to those mentioned in this paper, we find that Case IX. is that of a mother frightened by a rabbit—child born with hare-lip; two subsequent children normal.

Case LXXXV., mother frightened by a pet squirrel attempting to bite her. Child born with compact mass of hair extending from eyebrows over head and back, and closely resembling a squirrel. Also two well developed incisor teeth. Case XC., wherein child was born dead, with large, fresh-looking blebs corresponding in site to extensive burns mother had received thirty six hours prior to birth of child, shows considerable parallelism to Case III. of this paper, both as regards necessary brevity of impression and the fact of scar or mark rather than defect of development.

Regarding Anticipation on the part of Mother.—In Cases I., II., and IV. mothers did not expect defect. In Case III. mother did apprehend birth mark.

Regarding Duration of Impression.—In Cases I. and II. probably long. In Case III. not longer than seventy-two hours.

Regarding Circular Cleft of Palate.—Embryologists say that superior maxillary processes of first branchial arches come together during the first eight or ten weeks of fœtal life, and at the ninth week, or soon afterward, the hard palate is closed, and on it rests the septum of the nose. So that if Case II. is to be explained on the theory of maternal impressions, such impression must have taken possession of patient early in pregnancy in order to account for circular cleft of palate.

Dr. W. T. Taylor, of Philadelphia, has reported the case of a lady who gave birth to five children in succession, each of whom had cleft palate. In the first instance defect was attributed to maternal impression. And as defect was slighter in each successive child, it is supposed impression was gradually effaced. And right here is a point regarding Cases I. and II. Case II. being doubtless nearer normal than Case I., can we find the reason for it in the fact of a less intense causative principle in the latter pregnancy, of a less impressionable nervous organization on the part of the patient?

The theory of maternal impressions, from the literature of the subject, may be summarized or epitomized, without any claim to original observation, as follows:

Maternal Impressions.—*A.* (1) Are responsible for fœtal defects, or (2) are not responsible. *B.* (1) If responsible, then it must be shown that impression was made at a period of pregnancy, antedating developmental period of deformed part. (2) If not responsible, then all deformities are due to errors of development. *C.* Judgment dictates latter premise untenable, as many marks doubtless occurred late in pregnancy, when development was practically complete. *D.* Long impressions more apt to influence fœtus. Short impressions less apt to influence fœtus.

Fœtal Defects.—*A.* Mental: Due to emotional disturbances; as to how caused, we know absolutely nothing. As to frequency, only six out of four hundred and forty-three cases made out in a certain statistics. *B.* Bodily: Vascular, supposedly most frequent, doubtless very frequent, but often overlooked.

In conclusion, what can be the practical import of these, or any other observations upon the subject at issue?

It seems to be the concensus of opinion that one cannot go far wrong by assuming it to be his duty to discourage morbid reflection, worriment, or apprehension of defective progeny in the minds of nervous, impressionable, pregnant women. If the minds of our pregnant patients are schooled in the aversion of voluntary, catastrophal sightseeing, are taught that it is rather the prolonged impression that is more operative for harm, it is just possible that monstrous conceptions might be a less frequent misfortune.

126 Ninth Street, Long Island City.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 29, 1894.

AN ATTACK ON THE DIPHTHERIA ANTITOXIN.

A PAPER of the greatest interest and importance was read at a recent meeting of the Berlin Medical Society, by Dr. Hansemann. The paper carries especial weight because the author is announced as an assistant of Professor Virchow's, and his work and conclusions are presumably endorsed by the dean of modern pathology.

Dr. Hansemann comes out in flat contradiction of the alleged properties and powers of the Behring immunizing serum. He asserts that in Bretonneau's diphtheria the Loeffler bacillus is not always present, and is not its sole cause. This view will appeal to some clinicians and bacteriologists at least, for it is admitted that the Loeffler bacillus is present in some very mild cases of diphtheria as well as in apparently healthy throats, while, on the other hand, it is also known that a streptococcus diphtheria (or sore throat) is sometimes extremely severe and dangerous.

Dr. Hansemann asserts that Loeffler's bacillus is found constantly in rhinitis fibrosa, without producing diphtheria, and that these alleged pathogenic microbes may multiply in the throat without modifying the course of the diphtheria. All this, we believe, will have to be admitted by pathologists who have without bias studied the disease. Dr. Hansemann asserted further that in the case of animals an injection of a Loeffler bacillus culture caused not diphtheria, but a disease *sui generis*, the Loeffler bacillus disease; that epidemic diphtheria had never been observed in animals; that guinea-pigs, in contact with diphtheria patients, had never taken diphtheria; but that a case is known where a cat, with which a child suffering from diphtheria had played, had developed all diphtheria symptoms, without, however, any Loeffler bacilli being discoverable.

He then proceeded to describe the three qualities claimed for the antitoxin—namely, its therapeutic action, its harmlessness, and its immunizing power. He said that the present statistics give an erroneous impression (as already shown by Gottstein in his recently published pamphlet), as many children suffering from lighter forms of throat complaints are now sent to the hospitals to be treated with serum, thus swelling the proportion of cured cases, which would, he said, otherwise not be higher than the usual average. He said that the serum injections could by no means be considered harmless, as affections of the kidneys had frequently followed—in one case more severe in type than had ever yet been observed after diphtheria. He said that it was clear, from Behring's new directions to increase the immunizing dose from sixty to one hundred and fifty unities, that no results have yet been achieved as far as immunizing goes.

The final criterium of the efficacy of the antitoxin treatment is clinical experience. Even if Hansemann's pathology is correct, therefore, it will make no difference provided the diphtheria patients get well.

The difficulties in estimating exactly the value of a new therapeutic procedure which comes loudly heralded and solidly endorsed are very great. Unusual attention is paid to every patient, greater watchfulness, more thorough supervision, and earlier diagnosis and treatment are always found. These factors must all be considered in estimating the results of the serum treatment.

It would be not only a disappointment to all well-wishers of humanity, but would be a serious blow to the rising prestige of medical science, if, after all, the serum treatment should fall short of its high expectations.

EVERY MAN HIS OWN EDITOR.

IT is a well-known fact that many large business firms publish a special journal to advertise their particular line of industry. These journals are all printed by the same house and contain the same articles, but differ in the title-page, being in one city *Brown & Co.'s Monthly*, in another *Smith & Co.'s Magazine*, etc.

According to the *Medical News*, an attempt to foist this ingenious product of modern journalism upon the medical profession is being made. A circular containing the propositions made gives these interesting details:

"First, we will get out a journal in every way as good as the one you have in hand each month, in size, quality, etc. We will allow you one page to be filled with your own items of interest relating to your own doings, those of your patients, friends, and institution, or whatever you may choose. We will carefully eliminate the word ——— from the journal. Instead of it being called the —— *Medical Journal*, as now, you may give it any name you choose, as the *Grand View Sanitarian*, or *The Lewiston Medical Reporter*, or whatever seems appropriate to you for your location and institution. In the space now used for our motto, 'A magazine for the doctor and his family,' we will print your name as local editor, publisher, or whatever you wish.

"We shall be glad to have at any time short articles of practical value and general interest from yourself or colleagues for publication in the body of the journal, which we will insert as we find opportunity.

"In return it is hoped you will take at least one hundred copies of the journal each month at $6 a hundred, additional copies to be furnished you at the rate of 5 cents each. In no case can less than 100 copies be sent. The pay in each instance must accompany the order, and also copy for your local news page, and be received at the home office by the 15th of each month. The price we have made you is cost. (No publishing house in the country could get you up exclusively 100 such journals as ours for less than $225.) We are able to make this price to you only on account of the great

number we issue. Our pay comes through our advertising columns, which are valuable and appreciated.

"The gain to be derived by you taking hold of this enterprise is great, we believe, beyond all proportion of the cost. In the first place, it binds you to nothing. You are at liberty to stop whenever you choose. You may secure subscribers to your journal in your own town and county. It will be worth more than the regular price and make it pay for itself in dollars and cents. You can send other copies to desirable parties with your compliments and attention, which will win and hold their regard. Other copies left with your druggist for judicious distribution will be like bread cast upon the waters. But undoubtedly the greatest benefit of all will be the prestige that your connection with such a journal will give you and your institution wherever it goes.

"In short, there is no end to the usefulness to which doctors may and do put their journals. Please give this matter the careful attention its importance merits.

"Very truly yours,

"The ——— Medical Journal Co.,

"———, *Manager.*

"P. S.—In case you do not care to furnish copy for local page at any time, a notice with cut of your institution can occupy the space very effectively."

This plan, as will be seen, enables every doctor to have his own journal if he wishes.

We do not think, however, that it will succeed, and hence spare our readers any elaborate comments. The trouble will lie in the fact that all medical journals appeal to the same class of readers, and the appearance of syndicate journals will soon be detected and exposed.

MOUTH HYGIENE.

The care of the patient's teeth is a matter too often neglected by the medical adviser, principally, no doubt, because of the important position the dentist now occupies in relation to every well-to-do family. The vast majority, however, of those seeking medical advice never go near a dentist unless for the purpose of having a root extracted. School children, the inmates of homes, asylums, prisons, and even hospitals are shamefully neglected in this particular. In most public institutions not only is the tooth-brush unknown, but it is almost an impossibility to secure proper cleansing of the teeth even in those taking mercury, for instance, where the danger of salivation is much increased by this neglect. Many institutions have gentlemen of the dental profession connected with their boards, but the teeth are much more apt to be overlooked than any other portion of the economy, and their every-day toilet slighted. It is, indeed, not an uncommon experience to find those who in health never omit the morning brush, go for days and weeks together without proper mouth-cleansing when they are sick—the time above all others when the brush is most required. Of course, if the patient is too ill an antiseptic mouth-wash may replace it in a measure. A little volume of popular essays on the care of the teeth and mouth has just been published by Victor C. Bell, A.B., D.D.S., and we mention it here, not because of any new ideas or theories it embodies, nor because of its literary merit or beauty of illustration, for many things are more attractive than casts of irregular teeth and pictures of false sets. Such information as it contains, however, is most important for all to know, and if the advice given were followed many a pain would be spared and many a tooth saved.

The proper care of the teeth of school children is receiving more attention in England than it formerly did, and no little credit is due to Dr. Cunningham, of Cambridge University, for his efforts in behalf of school-children's teeth and his contributions on this subject to the Seventh International Congress of Hygiene and Demography, and his essay on oral hygiene, for which he was awarded the gold medal prize at the International Dental Congress held in Chicago during the World's Fair.

This gentleman says that parents and schoolmasters pay so much more attention to the quality of the child's food than they do to an efficient dental mechanism for its mastication, because of their ignorance of its importance and of the advantages, both economic and educational, to be derived from adequate attention to the teeth.

In speaking of tooth powders he says, "The principal action should be mechanical rather than medicinal. The powder should be very finely grained and should contain no cuttle-fish powder, no powdered oyster-shells, no pumice powder. It should consist of alkaline substances and contain no acid ingredients, nor such as are capable of changing to acid in the mouth. All fermentable substances such as carbo-hydrates are contra-indicated." He agrees with Miller, that precipitated chalk should form the basis of a powder, and also recommends a dash of neutral or slightly alkaline soap. He also considers a tooth-soap preferable to tooth-powder.

The physician needs not to be told how great is the necessity to the economy of sound teeth, nor need we enumerate the pathological conditions traceable to their decay; but all must admit and regret the shocking lack of general information upon this important subject, and the need for instruction, especially in the schools. We commend therefore the diffusion of knowledge concerning teeth, and if the woodcuts of artificial upper dentures, interdental splints, cleft palates, obturators, and drills contained in Dr. Bell's book will have the effect of frightening people into an early visit to a dentist, and if infants will gaze upon irregular dentition as depicted upon page 61, and never after suck their thumbs, much will have been gained for the cause of mouth beauty as well as mouth purity.

HOSPITAL STAFFS AND MANAGING BOARDS.

The recurrent irritation between medical boards of hospitals and the trustees shows, if nothing else, that there is something wrong in the system as it usually exists. We do not say that medical boards are always right and lay trustees always wrong, but we do assert that a method of management that provokes constant quarrelling and outbreaks of ill-feeling is seriously at fault.

In our opinion the fault lies chiefly in the fact that the medical staffs are not allowed sufficient share in the management. In some hospitals their advice is asked only as a matter of form, and the rules absolutely forbid any physician being a member of the managing board. The capacity of physicians to manage their executive and or-

ganizing skill, have been, we are sure, much underrated. Few men who attain that large success which gives to them hospital positions, do not possess considerable business capacity. When this is combined with technical knowledge, it makes the physician a person whose counsel is eminently valuable in directing the management of a great hospital.

If this fact were better known and more wisely appreciated, we should not have a hospital scandal every year, to fret the soul and disturb the serenity of academic discussions.

We refer to this now because Philadelphia has just been much disturbed by hospital controversies. The *Medical News* of December 8th describes a "flagrant instance of the outrageous impertinence of laymen, in their office of hospital trustees, in disposing of the services of physicians in a dictatorial and unjust manner."

The protest of the *News* had little effect, for in its issue of December 22d it says: "We little expected that a more striking illustration of the same spirit would so soon be shown, as happened the next week in Philadelphia. A member of the visiting staff of a great hospital was displaced ignominiously and without warning, without an official charge being made against him, or an official opportunity being offered him for replying to possible charges. Not even an official notice was sent him of his summary dismissal. From newspaper reports one learns that the reasons for this remarkable proceeding were that the physician thus contemptuously treated, in order that he might obtain blood from the patient's finger for purposes of diagnosis and investigation, had not given quinine to a patient so soon as he might have done."

ONLY IMPORTED ANTITOXIN EFFECTIVE.

By resolution of the New York City Board of Health, Drs. T. Mitchell Prudden, and Herman M. Biggs, were requested to "prepare and submit some plan for the determination of the strength and purity of the various preparations of antitoxin which are now, or may be hereafter, offered for sale in the city of New York, so that the public may have some guarantee that only genuine preparations of antitoxin of proper strength are furnished for sale."

In response to this request a report was made to the Board of Health, in which it was stated essentially that no trustworthy antitoxin is as yet manufactured in this country.

They assert that it is of the utmost importance to those who use this remedy that there should be some reliable guarantee, for every preparation placed upon the market, that it has been prepared by competent persons, and that in every case it possesses the requisite purity and power. The preparations now occasionally furnished in this country, in small quantity, by the German pharmaceutical houses, Schering and the Farbwerke (Hochst-am-Main). have specific guarantees as to strength and purity by bacteriologists of universally recognized skill and experience. Unless some such security is afforded, it would be quite easy for unscrupulous persons willing to commit such a crime, to place on the market small bottles of yellowish fluid labelled "antitoxin," containing an inefficient amount of the healing agent, or even none at all, and for a time at least profit by the extraordinary demand for it, perhaps at the cost of life and at the risk of discrediting a most potent and beneficent remedy.

That this is not a merely fancied and only possible menace to the welfare of those stricken with this dreaded disease, and so often the wards of the Department of Health, is shown by the fact that already in the city of New York several different preparations of alleged diphtheria antitoxin, said to have been prepared in this country, and wholly, so far as we can learn, without proper guarantee of efficiency, have been furnished and used for the treatment of diphtheria. One of these preparations has been already subjected to the necessary crucial tests by the Department, and found wholly inefficient and inert.

It is not stated whether tests were made of the imported articles.

DR. CONAN DOYLE IN CHICAGO.

No visitor to this country has received warmer hospitality or treatment more fully commensurate with his reputation than Dr. Conan Doyle. We trust that he is not responsible therefore for circulating stories reflecting on the intelligence and even vanity of his hosts. The *British Medical Journal* publishes the following somewhat weird tales of the doctor's Chicago experiences:

"He was," says the *Journal*, "introduced to the leading literary club of Pigstickopolis as 'Canon' Doyle. This led to his being mistaken for an ecclesiastical dignitary, and at a breakfast given in his honor the creator of 'Sherlock Holmes' was considerably taken aback by being invited to 'ask a blessing.' He is also said to have been overwhelmed with requests to preach in half the churches of Chicago. He was deluged with letters addressed to the 'Rev. Dr. Doyle,' 'Rev. Canon Doyle,' 'Very Rev. Canon Doyle,' and, finally, by swift promotion, 'Right Rev. Dr. Doyle.' To add to the tribulations of the distinguished writer whom we are still proud to claim as a professional brother, though he has definitively exchanged the lancet for the pen, he has been mistaken for the creature of his own imagination, and it is said was actually invited by the Mayor of Chicago to enter the service of the municipality as Chief of the Detective Police. Such are some of the penalties of fame."

The Philadelphia Board of Charities and Correction has appointed Dr. Hobart A. Hare a member of the staff of physicians at the Philadelphia Hospital, in place of Dr. Judson Daland, who has been dropped. The reason given for this action on the part of the board is, that Dr. Daland is alleged to have allowed certain patients suffering from malaria to go untreated for a certain length of time in order that he might study the development of the peculiar organism which produces malaria. To a board capable of such action for such reasons it probably makes very little difference what criticisms may be made upon its action, but we think it likely that the medical profession and the medical press will not rest content without knowing more and saying something about such a policy.—*Boston Medical and Surgical Journal.*

News of the Week.

The Death of Dr. George A. Peters.—The following resolutions were passed December 7, 1894, by the Medical Board of St. Luke's Hospital. "After many years of faithful and distinguished service as Attending and Consulting Surgeon of St. Luke's Hospital, the career of our honored colleague, Dr. George A. Peters, has come to its inevitable close. His career has been more intimately, and for a longer period, identified with the history of this hospital than that of any surgeon ever connected with its staff. Dr. Peters was appointed an attending surgeon on the organization of the first medical staff of the hospital in March, 1859. He retired from active service in December, 1863. He was consulting surgeon until January, 1872, when he was reappointed on the attending staff and again retired from it in December, 1887. From that time until his death he was consulting surgeon, and President of this Board. During the entire period of the existence of this Hospital, therefore, Dr. Peters gave to it his best energies and his loyal service. For twenty years he performed active service in the wards, and for fifteen years he gave to his colleagues the benefit of the ripe judgment which was the fruit of his large experience. In his personal and professional relations to his associates and subordinates, Dr. Peters always commanded confidence and respect. Toward his patients his conduct was marked by a cheerful and sympathetic spirit, and by a quaint and characteristic humor which often dispelled gloom and inspired courage. His work as a physician and surgeon, both in public and private practice, was distinguished by a singularly keen perception and alert intelligence, by remarkable readiness in resources, by practical common sense, and above all, by an earnest purpose, at any sacrifice of time and strength, to help those who sought his skill and counsel. The long and intimate association of Dr. Peters with the administration of St. Luke's Hospital will endear his memory to the managers, and to his colleagues of the Medical Board. In the history of this institution, no one has earned more truly the commendation and the reward promised to 'the good and faithful servant.'

"Signed, W. H. Draper, M.D.,
"Robert Weir, M.D.,
"*Committee.*"

Dr. Thomas R. Norris died suddenly on Friday, December 21st, at his home, 106 Pennsylvania Avenue, Brooklyn, in his sixty-third year. He came to this country from Ireland when he was a boy. He became prominent in the Democratic organization in Brooklyn, and served as Coroner, Commissioner of Charities, and Superintendent of the Poor.

An Outbreak of Rabies.—Sixteen persons were bitten by a mad dog in Salem, N. J., recently. Six of them have been put under treatment at the New York Pasteur Institute. Of ten bitten persons three were found to be uninjured owing to the protection afforded by clothing.

Bacteria in Railway Cars.—Investigation of the atmosphere of English railway coaches shows that there are sixteen thousand microbes to the cubic inch in the first class, thirty-four thousand in the second class, and seventy-eight thousand in the third-class compartments. There is a suspicion that the railroad managers have prompted these statistics in order to check the waning popularity of the expensive classes.

Physicians Strike.—The physicians of the city of Newburgh, forty in number, and of the town of Cornwall, recently met and passed resolutions which they presented to the Orange County Board of Supervisors, in session at Goshen, in which they demand that the scale of prices fixed by the Board for attendance of physicians at coroners' inquests be increased from $5 to $10 for post mortems and for autopsies from $15 to $30. Drs. Wooley and Jova, a committee representing the physicians, appeared before the Board of Supervisors yesterday and stated that under no circumstances would the physicians act unless the prices demanded be paid. The Board refused to raise the rates, claiming that the price established is good pay, and that it would be unfair to the physicians of other parts of the county to pay more to those from Newburgh and Cornwall. The Newburgh Coroner will be compelled to employ a doctor from one of the county towns not in the combine at future inquests. An effort was made to get all the physicians in the county to organize in the strike, but it did not succeed. Coroners' inquests are very expensive in Orange County, and cost the tax-payers from $5,000 to $7,000 a year, while the State of Massachusetts, under a different system, is taxed but little over three times as much per year for inquests as this county. Yesterday the Supervisors passed a resolution requesting Senator Lexow and the two Orange County Assemblymen to advocate the abolition of the office of Coroner by the Legislature, as provided by the amended Constitution, and to adopt a more modern and economical system.

Antitoxin Legislation in France.—The Paris correspondent of the *Medical Press* writes (November 28th), that, in view of the danger to the public likely to arise from the uncontrolled manufacture and sale of curative serums and antitoxin, the French Government is invited to incorporate in the bill Regulating the Practice of Pharmacy, a section specially dealing with this class of remedies. In order to ensure that the horses employed in the preparation of serum are perfectly healthy, and generally to provide for the requisite skill and care being brought to bear, the following clauses are proposed: That attenuated virus, therapeutical serum, modified toxines, and similar products intended to be used in the prophylaxis or treatment of contagious diseases, can neither be sold nor distributed gratuitously without a personal permit to be accorded by the Government on the advice of the Council of Public Health and the Academy of Medicine, such permit to be temporary, and its maintenance to be subject to the result of periodical inspections by a special commission. The products in question are to be sold exclusively by duly qualified pharmacists, and each phial is to bear the source and date of the preparation. Provided always (as the lawyers say) that these regulations will not be held to apply to Jennerian vaccine, whether human or animal.

The Value of Pancreas Extract in Diabetes.—Dr. P. Watson Williams, of Bristol, England, reports three cases of diabetes treated with extract of pancreas, and he thinks that practically nothing can be accomplished by this mode of treatment as at present employed.

Therapeutics at the International Medical Congress, 48.
Therapy, cellular, 165.
Thermogen, the, 242.
Thermogenesis, cutaneous application of certain alkaloids as regulators of, 113.
Theses, some ancient medical, in Paris, 192.
Thioform, 462.
Thirst following abdominal section, cause of, 444.
Thomas, John Davies, notice of book by, 277.
Thompson, J. H., a source of infection in corneal abscess, 463.
Thorne, Dr. Thorne, public health services of, 477.
Thorner, E., notice of book by, 276.
Thornton, James B., congenital deformity, 346.
Thornton, John, notice of book by, 502.
Throat, malignant tumors of the, importance of early diagnosis of, 62; neurasthenic, 62; sewer gas as a cause of disease of the, 257.
Thrombosis, extract of leeches in the prevention of, 137; primary, of the pulmonary artery, 311.
Thyroid extract, dangers of, 306; new method of giving, 439.
Thyroid feeding, for Basedow's disease, 640, 671; in myxœdema, 724; in psoriasis and other skin diseases, 427; toxic effects of, 692.
Thyroidism, relation of, to exophthalmic goitre and hysteria, 704.
Tobacco and fatigue, 480.
Todd, Dr. John M., death of, 210.
Toe-nail, ingrowing, 635.
Tolstoi on vaccination, 736.
Tongue, extirpation of the, for cancer, 634; sarcoma of the, 154; tractions on the, for asphyxia, 141, 454; traction on the, in hysteria, 378.
Tonsil, concretions in the, sore throat due to, 761; mycosis of the, 62; pharyngeal, cyst of the, 137; rheumatic affections due to disease of the, 63; sarcoma of the, 61.
Tonsillitis, treatment of, 111, 242.
Tooth, fight for a, 800.
Toxins, antidiphtheritic, see *Diphtheria;* intestinal, 384.
Trachoma, shady side of surgical treatmeat of, 231.
Transfusion, claim for damages by one giving blood for, 95
Trent, J. H., cyanide or ferrocyanide of potassium, 256.
Trephine, a new aseptic, 313.
Trephining for traumatic clot, 344.
Trichinosis, 542.
Trismus neonatorum, 313.
Tri-State Medical Society, Jacksonville, meeting of the, 617.
Trusses, glycerin pads for, 736.
Tuberculin, diagnostic use of, in cows, 74.
Tuberculosis, and erysipelas, antagonism of, 308; articular, 152; asses' serum for, 466; bovine, 150, 186; bovine, diagnostic use of tuberculin in, 74; contagiousness of, 310; channels of infection in, 624; Colorado as a climate for sufferers from, 27; creasote, guaiacol, and benzoyl of guaiacol in, 121; etiology of, 644, 721; general, 93, 663; goat serum in, 637; hydronaphthol in, 72; immune serum of the goat in, 702; in butter, 437; in children, 374; in domestic pets, 124, 559; infection of, in a laboratory, 658; of the adrenals without bronzing, 552; of the bladder and kidneys, 186; of the bladder, lactate of cocaine in, 224; of the frontal sinus, 553; of the larynx and pharynx, 411; of the seminal vesicles, extirpation for, 163; ozone in, 124; osseous, excited by railway injuries, 759; perineal, injections of glycerin and sulphur for, 765; peritoneal, recovery from, after operation, 445; prophylaxis of, 27, 309, 721; pulmonary, climatic segregation of persons affected with, 474; climatic treatment of, 120; pulmonary, contagiousness of, 464, 736; pulmonary, marriage of persons affected with, 474; pulmonary, roughing it *vs.* coddling, 481; pulmonary, treatment of, 654; pulmonary, treatment of the fever of, 591; rarity of, in the highlands of Pennsylvania and New York, 181; relationship between bovine and human, 412; renal, surgical interference in, 118; restriction and prevention of, 473; sanitarium treatment of, 120; social causes of, 405; State prevention of, 122; strychnine in, 27; the serum treatment, 496; unequal dilatation of the pupils in, 320; value of third blood-corpuscle in, 41.
Tuberculous lymphangitis of the arm, 573.
Tumors, malignant, toxines of erysipelas in, 82.
Turpin, Dr. Virginius A., death of, 534.
Twin gestation, anomalous fœtal nutrition in, 74, 141.
Twins, double pay for, 286.
Typhoid fever, 310; a bed-bath apparatus for use in, 253; abortion of, 760; and malaria, mixed infection of, 23; combined carbolic acid and chloroform in, 512; diseases of the heart in, 384; easy method of bathing in, 43; in children, treatment of, 435; in infancy, 1; in Montclair, N. J., 651; in the District of Columbia, 785; lactophenin in, 302; nature and prevention of, 507; nephritis of, 493; no class distinction in, 755; or typhus fever, a doubtful case, 155; origin of, 274; recent epidemic of, at Windsor, Vt., 647; relation of the bacillus coli communis to, 527; relation of, to drinking-water, 447; susceptibility to vaccination after, 310; the oyster as a carrier of, 656, 657, 743; treatment of, 782; treatment of, twenty-five years ago, 51; with an unusual history, 663; with extensive ulcerations, 155.
Typhoid infection, putrefactive gases as predisposing agents in, 492.
Typhoid spine, the, 109, 479.
Typhus fever, in Paris, 405; or typhoid fever, a doubtful case, 155.
Tyrrell, R. Shawe, the affinity of gout and rheumatism, 401.

U

Ulcers, varicose, treated by a painless method, 655.
Ulna and radius, fracture of the, 537.
Umbilical cord, compression of, during forceps delivery, 174; entanglements and shortening of the, 798; spontaneous rupture of the, 798.
Underhill, Mr. W. L., death of, 125.
United States, observations on medicine in the, 335.
Universities, Professor Jebb on the, 315.
Ureter, impacted stone in the, 703.
Uretero-ute ine fistula, hysterectomy for, 671.
Ureters, inflammation of the, 81.
Urethra, electrolysis in stricture of the, 470; relief of deep stricture of, without external urethrotomy, 117; stricture of the, 24; stricture of, cause of, 583; treatment of stricture of the, 153.
Urethritis, nervous symptoms of patients with chronic, 684.
Urethrotomy, internal, for stricture, 170.
Urinalysis, importance of, in diagnosis, 760.
Urine, ammoniacal, a new salt in, 479; correction of the odor of, 563; incontinence of, cured by circumcision, 173; leakage and stricture formation, 116.
